Pinus Pinaster needles dried naturally with a moisture content of about 10% are used in this work. The vegetation is weighed and spread out on a square table of $0.8 \times 0.8\ m^2$ size that is placed on a digital balance A&D HW-100KGL with a resolution of $10\ g$ and a recording frequency of $1\ Hz$. The weight is recorded on a computer through a data acquisition software RSKey v.1.40 see Fig.1. To follow the variation of the height of the flame an optical video camera Sony FDR-AX53 and an infrared camera SC660 from FLIR were placed on the front of the table while a second optical video camera Sony HXR-NX30E was placed laterally to the table. The resulting videos were converted into images, and the flame height was manually measured against a vertical scale placed close to the sample.

Figure 1: The experimental setup at the Fire Laboratory of ADAI (Coimbra).

The samples are ignited at one side, and the variation with time of the front position was recorded to estimate the ROS. The fuel bed packing ratio $\boldsymbol{\varphi}$ is varied by varying its mass ($\boldsymbol{m}$) and height ($\boldsymbol{e_b}$) according to the following equation:

$$\boldsymbol{\varphi} = \frac{\boldsymbol{m}}{\boldsymbol{S.e_b.\rho}} \qquad (1)$$

where $\boldsymbol{\rho}$ is the fuel particles density. The porosity measures the proportion of air in the fuel bed $\mathbf{1} - \boldsymbol{\varphi}$.

3. Results and discussion

The influence of compactness on rate of spread of the above described *Pinus Pinaster* is compared in Fig.2a to *excelsior* and ¼ inch *cribs* fuels (Rothermel, 1972) and laser-cut cardboards (He et al, 2021). The ROS behavior shows at least an optimum ratio for all presented fuels for $\varphi < 10$ %. An optimum ratio is observed for *Pinus Pinaster* (PP) needles around 5.5% close to that found by Rothermel for *cribs* fuels, but the ROS of PP needles increases again for smaller ratios as if they have another optimum packing ratio. Two optimum ratios have been observed also for excelsior fuels (Rothermel, 1972) and cardboards (He et al, 2021), and have been attributed to thermochemical effects. However, heat transfer has been found to be the main cause of non-monotonic ignition time (Boutchiche et al, submitted). As the ROS corresponds to the ignition time of the nearest fuels of the flame, absorption heat transfer might be also the cause of the optimum ratios observed for the rate of spread. Ignition and combustion are influenced also by surface-to-volume ratio SVR. The optical length of radiation heat transfer is related to these quantities by

$$\boldsymbol{\delta} = \frac{\mathbf{4}}{\boldsymbol{\varphi \times SVR}} \qquad (2)$$

In Fig.2b, the ROS is presented as a function of the optical length. The absorption probability decreases exponentially with with the fuel thickness ($e^{-e/\delta}$) (Boutchiche et al, submitted). As the optical length at the optimum ratio of PP needles is around $12\ mm$, much smaller than the fuel bed thickness which varies from $e = 40$ to $e = 70\ mm$, the maximum ROS is characterized by a surface absorption of the heat flux similar to that of the *excelsior* fuel bed (around $20\ mm$) (Rothermel, 1972). As mentioned above, the ROS seems to increase again for larger lengths which corresponds to the existence of a second optimum ratio. This optimum ratio seems to corresponds to an optical length much larger than the fuel bed thickness, which means that the heat flux is absorbed by the whole fuel bed. A similar absorption behaviour occurs for *cribs* (Rothermel, 1972) and cardboards (He et al, 2021).

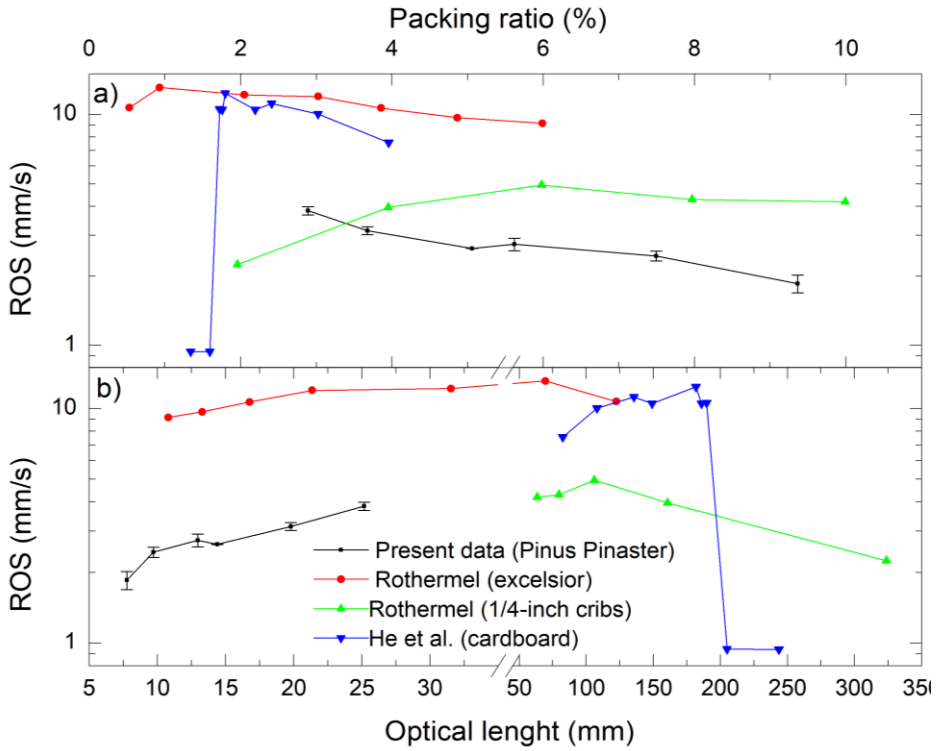

Figure 2: Rate of spread as a function of a) packing ratio, b) Optical length

Now let us examine the thermochemical effects through the mass-loss rate of the fuelbed during spread, which is proportional to the potential reaction velocity according to equation (35) of (Rothermel, 1972). Since internal combustion is involved during spread, the mass-loss rate corresponds to the emitted flammable gas, and is thus expected to vary with porosity. In Fig.3a the mass-loss rate evolution during fire spread is presented for an example configuration of fuel bed. Here, the contribution of glowing embers that remain in the burned area, and the pre-heating contribution of the foreward area are neglected compared to that of the burning area. After ignition, the burning rate seems to increase linearly with time during spread, and decreases when the forward front reaches the end of table. The increase of the burning rate may be explained by the increase of the burning area of the fuel as fire spreads. Indeed, at ignition, the front is a straight line, but becomes curved as the front advances due to the edge effects (see Fig.3b). At the edges, fire spreads slowly compared to the center because of the lack of nearest burning fuels contribution. Assuming the burning rate homogeneous, the increase of the curvature of the front during spread corresponds to an increase of the burning area, and thus to the increase of the total mass-loss rate. Therefore, the slope in Fig.3a may depend on the rate of spread. It is thus burning rate is the minimum for the initial line front,

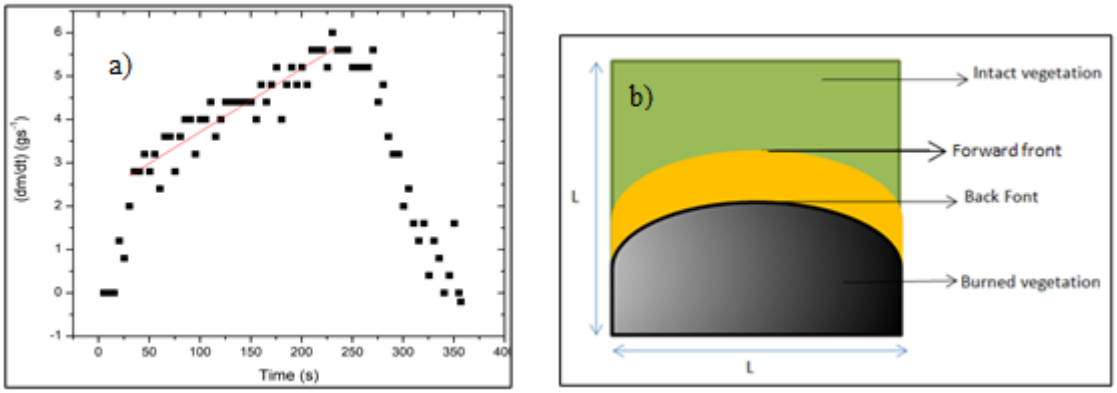

Figure 3: a) The mass-loss rate as a function of time of selected sample $m = 1.2\ kg$; $e = 5.5\ cm$ b) schematic view of the front during spread.

To examine the influence of the optimum packing ratio on potential reaction velocity, it is convenient to consider the minimum mass loss rate corresponding to the initial fire line. This avoids the contribution of the rate of spread on the burning rate. In Fig.4 the minimum mass-loss rate seems to be independent of the packing ratio within errors in the range of φ up to 10 %. Therefore, the optimum ratio observed for *Pinus Pinaster* in Fig.2 seems to not be caused by the burning rate (or reaction velocity (Rothermel, 1972)). The heat transfer mechanism may be the main cause of this non-monotonic behavior as found for ignition (Boutchiche et al, submitted).

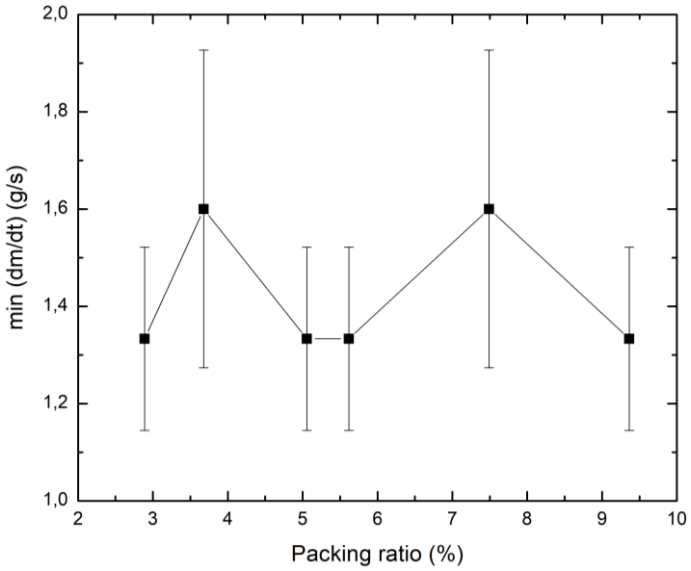

Figure 3: The mass-loss rate as a function of the packing ratio.

The flame height seems to follow the same trend as ignition time by varying the packing ratio. The flame heigh is not shown to avoid clutter.

4. Conclusion:

The effect of the packing ratio and optical length on the rate of spread of *Pinus Pinaster* fuels is examined and compared to those of other fuels in litterature. An optimum packing ratio corresponding to a maximum rate of spread is found for a ratio of 5.5 %, and the trend indicates the existence of another maximum rate of spread for a much smaller packing ratio. By using the optical length, the maximum rate of spread occurs at an optical length of about 12 *mm* much smaller than the fuel bed thickness, which corresponds to a maximum surface absorption. While the other maximum rate of spread is expected to occur at an optical length much larger than the fuel bed thickness, which means a bulk absorption of heat flux. Although an internal combustion occurs during spread, the mass loss rate seems to be independent of the packing ratio in the range of ratios considered.

Abstract

The main objective of this study was to analyse the effect of recurrence and burn severity on ecosystem multifunctionality in Pinus pinaster forests. We selected a large wildfire that occurred in the Sierra del Teleno in 2012 (NW Spain), where we differentiated two recurrences and two burn severity situations. As a result, four scenarios were identified: low recurrence plus low severity, low recurrence plus high severity, high recurrence plus low severity, high recurrence plus high severity. In each one, a number of 1 m x 1 m plots proportional to the burned area were established. Three years after the wildfire we evaluated in each plot: (1) percentage of covered soil, (2) total percentage cover of herbaceous species, (3) percentage cover of each woody species, (4) total plant species richness. Also, a composite soil sample was collected from each plot. Chemical (total organic carbon, total nitrogen and available phosphorus) and microbiological (microbial biomass carbon) properties were analysed in each soil sample. The following variables were used as indicators of ecosystem functions: percentage of covered soil, total cover of herbaceous species, Pinus pinaster cover, total plant richness, total organic carbon, total soil nitrogen, available phosphorus and microbial biomass carbon. Another indicator of ecosystem functions was calculated: floral colours of shrub species diversity using the Shannon index. The values of each ecosystem function indicator were standardized. The indicators/functions of regulating ecosystem services were: Climate regulation (indicator: total % of organic soil carbon) and Erosion protection (indicator: covered soil %). The functions/ indicators of supporting ecosystem services were: soil fertility (indicator: total nitrogen and available phosphorous) and soil quality (indicator: microbial biomass C). The indicators/functions of cultural ecosystem services were: species diversity (indicator: plant species richness) and aesthetic value (indicator: the Shannon index of floral colours). The functions/indicators of provisioning ecosystem services were: grass for livestock (indicator: % cover of herbaceous species) and timber production (indicator: % cover of Pinus pinaster). The results indicated that all scenarios apart from low recurrence plus low severity negatively affected the multifunctionality of the ecosystems.

1. Introduction

In the Mediterranean Basin dramatic shifts in fire regime have been detected during recent decades, driving an increase in large and severe wildfires, with significant consequences on ecosystems and societies at different scales (Singleton et al., 2019). Impacts include loss of lives and infrastructures, alterations in functional processes (e.g. erosion, vegetation dynamics or carbon cycle) and reduction in ecosystem service provision (e.g. food, timber or fresh water stocks) (Taboada et al., 2021). In general, these alteration of the ecosystem services are related not only to fire severity but also to fire recurrence that modify ecosystem resilience, due to damage to vegetation and soil characteristics.

In recent decades, rural depopulation and agricultural land abandonment have favoured the expansion of shrublands and forests to the detriment of open areas such as pasturelands and croplands. Consequently, fuel amount and its connectedness increase, leading to a simplification of the landscape mosaic associated with an increase in the risk of extreme wildfires that are more dangerous to people and ecosystems. In this context,

increase in drought periods and thermal anomalies associated with climate change are favouring fuel ignition (Stephens et al., 2014). Indeed, according to global change predictions, Spain will be included in a primary climate change hotspot, where warming will be above the global average. Both changes in climatic conditions and land use contribute to the increase in new wildfire regimes, with more frequent catastrophic fires causing abrupt changes in the functioning of ecosystems and in the delivery of ecosystem services to society. In general, ecosystem functioning is inherently multidimensional and so, multifunctionality measures can summarise the ability of an ecosystem to deliver multiple functions or services simultaneously (Manning et al., 2018).

Mediterranean ecosystems largely affected by megafires are those dominated by *Pinus pinaster*, which provide relevant provisioning, regulating, cultural and supporting ecosystem services. A new and innovative approach to evaluate the status of the forest ecosystem and interruption of multifunctionality by fire is currently being implemented. This approach of studying the modifications in biotic and abiotic processes that determine the provision of ecosystem services in *Pine* forest, represent an integrated analysis of the footprints of large recurrent and severe wildfires. Thus, the knowledge acquired in this integrated analysis would help in the implementation of novel solutions to promote landscapes and socio-ecological contexts less susceptible and more resilient to recurrent high burn severity wildfires (Moreira et al., 2020).

The main objective of this work was to analyse the effect of recurrence and burn severity on ecosystem multifunctionality in *Pinus pinaster* forests in Northwest Spain.

2. Material and methods

The study area (Figure 1) is located in Sierra del Teleno (NW Spain), within the perimeter of a megafire (11,600 ha) that occurred in August 2012, affecting a forest dominated by *Pinus pinaster*, with the understorey community dominated by *Pterospartum tridentatum* (L.) Willk., *Halimium lasianthum* (Lam.) Spach and *Erica australis* L. (Calvo et al., 2008). The climate in this region is temperate with dry warm summers. The orography is heterogeneous, ranging from flat to mountainous areas. Soils are developed over siliceous lithologies.

Prior to the fire in 2012, the area had suffered another large fire in 1998 of around 3000 ha. Therefore, within the perimeter of the 2012 fire, we defined two recurrent scenarios: low recurrence (a single fire in the last 15 years) and high recurrence (two fires in the last 15 years). Additionally, based on a dNBR (differenced Normalized Burn Ratio) index derived from Landsat pre-fire and post-fire images (September 20th, 2011 - September 6th, 2012) and CBI (Composite Burn Index) field measured values (Key and Benson, 2006), we established two severity scenarios within the perimeter of the 2012 fire: low severity (dNBR between 220-550) and high severity (dNBR between 550-1400). Overlaying the recurrence and severity classes, we identified four scenarios (low recurrence-low severity (LR-LS), low recurrence-high severity (LR-HS), high recurrence-low severity (HR-LS) and high recurrence-high severity (HR-HS). Within the fire perimeter, we selected a 3000 ha study framework where the four scenarios of recurrence and severity were represented (Figure 1) to collect field data. A total of 88 1 m x 1 m plots were established: 20 in LR-LS, 20 in LR-HS, 20 in HR-LS and 28 in HR-HS. Three years post-fire, we evaluated in each plot the visual percentage cover of each plant species and the bare soil. In addition, a composite soil sample (consisting of 4 subsamples) was collected from each plot. Chemical (total organic C, total N and available P) and microbiological (microbial biomass carbon) properties were analysed in each soil sample.

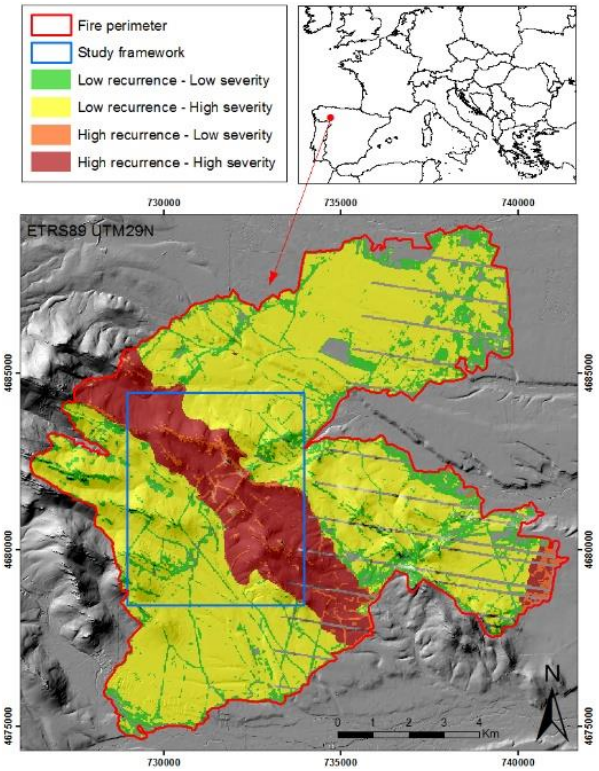

Figure 1- Study framework within the perimeter of the Sierra del Teleno megafire which occurred in 2012, and the considered recurrence-severity scenarios

Soil organic C was obtained by Walkley-Black dichromate oxidation (Nelson and Sommers, 1982). Total N was determined by the Kjeldahl method (Bremner and Mulvaney, 1982) and available P was analysed following the Olsen *et al.* (1954) procedure. Microbial biomass C was determined by the fumigation-extraction method (Vance *et al.*, 1987).

The variables used as indicators of ecosystem functions were (Table 1): percentage of covered soil, total cover of herbaceous species, *Pinus pinaster* cover, total plant richness, total organic carbon, total soil nitrogen, available phosphorus, microbial biomass carbon and % of floral colours of shrub species diversity using the Shannon index (Shannon, 1948). The values of each ecosystem function indicator were standardised according to the following procedure: Standardized value = (Unstandardized value – Minimum value) / (Maximum value – Minimum value).

Minimum and maximum values correspond to the lowest and highest unstandardized values of each indicator, respectively. Consequently, a set of standardized data was obtained for each indicator, ranging from 0 (minimum value) to 1 (maximum value).

The indicators of regulating ecosystem services were: climate regulation (indicator: total % of organic soil carbon) and erosion protection (indicator: covered soil %). The indicators of supporting ecosystem services were: soil fertility (indicator: total N and available P) and soil quality (indicator: microbial biomass C). The indicators of cultural ecosystem services were: species diversity (indicator: plant species richness) and aesthetic value (indicator: Shannon index of floral colours). The indicators of provisioning ecosystem services were: grass for livestock (indicator: % cover of herbaceous species) and timber production (indicator: *Pinus pinaster* percentage cover).

In the soil fertility function, in which we used more than one indicator, the average value of these indicators was calculated. In the same way, ecosystem multifunctionality was calculated by averaging the values of regulating, supporting, cultural and provisioning ecosystem services.

Generalized linear models (GLMs), with a quasi-Poisson error distribution (log link function) to account for overdispersion, were applied to evaluate the effects of recurrence and burn severity on ecosystem functions, services, and multifunctionality. Data analyses were carried out with R (R Core Team, 2021).

Table 1. List of functions for regulating, supporting, cultural, and provisioning ecosystem services, and indicators used to define these functions.

Ecosystem functions		Function indicators
Regulating ecosystem service		
Climate regulation	Carbon sequestration	Total organic soil C (%)
Erosion protection		Covered soil (%)
Supporting ecosystem service		
Soil fertility	Soil nutrient storage capacity	Total N (mg kg-1) Available P (mg kg-1)
Soil quality		Microbial biomass C (µg C g^{-1} dw soil)
Cultural ecosystem service		
Species diversity		Plant species richness
Aesthetic value		Shannon index of floral colours of shrub species
Provisioning ecosystem service		
Grass for livestock		Total cover of herbaceous species (%)
Timber production		Total cover of *Pinus pinaster* (%)

3. Results and discussion

The significant negative effects of recurrence and burn severity in the regulation of ecosystem services, even three years after wildfire (Figure 2), are a consequence of the impact on climate regulation and erosion protection functions. Recurrent and severe fires are characterized by the elimination of vegetation cover and therefore, the soil is non-protected, and could be affected by erosion processes after rain events. However, in low recurrent plus low severe fire scenarios, a higher level of survival of vegetation, which facilitates the protection of the soil, is observed. Another ecosystem service negatively affected by burn severity is provisioning (Figure 2), as grass for livestock and timber production functions had higher values in low recurrent and severe scenarios, decreasing with increased severity or recurrence. González-De Vega et al. (2018) also observed a lower presence of herbaceous species with increasing burn severity. In the same way, high recurrence and severity affect reducing the probability of regeneration of *Pinus pinaster* (Fernández-García et al., 2019).

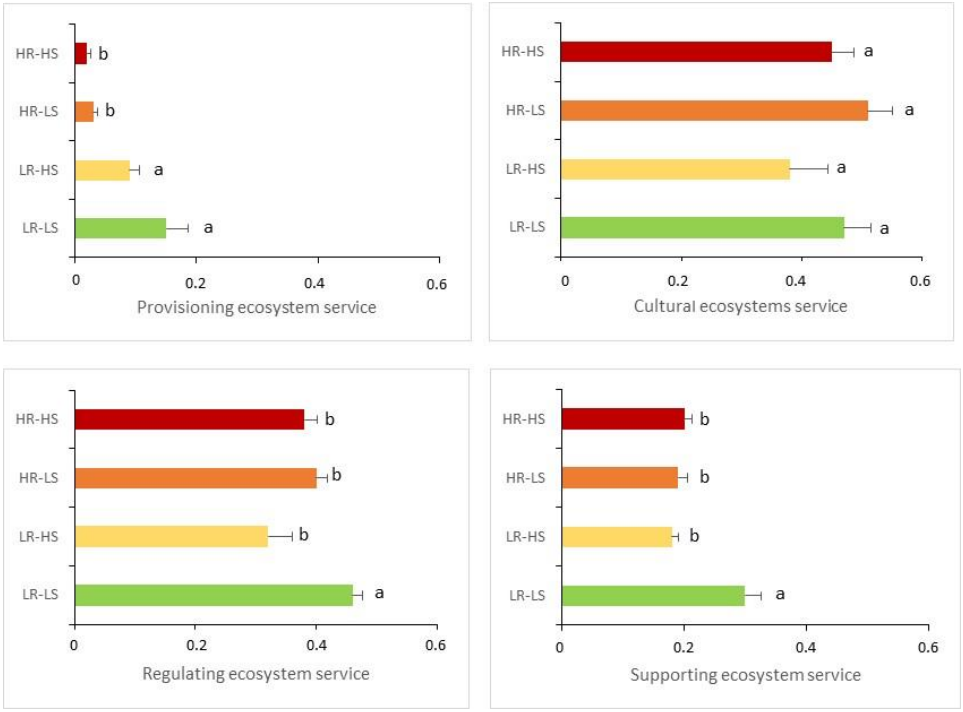

Figure 2. Average value and standard error of provisioning, cultural, regulating and supporting ecosystem services for each scenario: Low recurrence and low severity (LR-LS), low recurrence and high severity (LR-HS), high recurrence and low severity (HR-LS) and high recurrence and high severity (HR-HS). Different letters indicate significant differences ($p < 0.05$) between scenarios.

High recurrence and/or high severity negatively modify nutrient availability due to the reduction in soil organic matter content (Hedo et al., 2015). These patterns determine the reduction in supporting ecosystem services observed in these scenarios of high recurrence plus low and high severity (Figure 2).

Three years after fire, we only detected a significant decrease in plant richness after high recurrence and burn severity. However, the recovery of woody species with different flower colours showed an opposite pattern, as the elimination of the dominant tree species favoured colonization by other understory shrub species. These two opposing patterns mean that the cultural ecosystem services do not show significant effects among recurrence and burn severity scenarios.

As a result of the effects of fire recurrence and severity on plant community and soil properties, which act as indicators of functions, and modulate post-fire ecosystem multifunctionality (Lucas-Borja et al., 2021), showed a clear reduction in those scenarios different to low recurrence plus low severity (Figure 3).

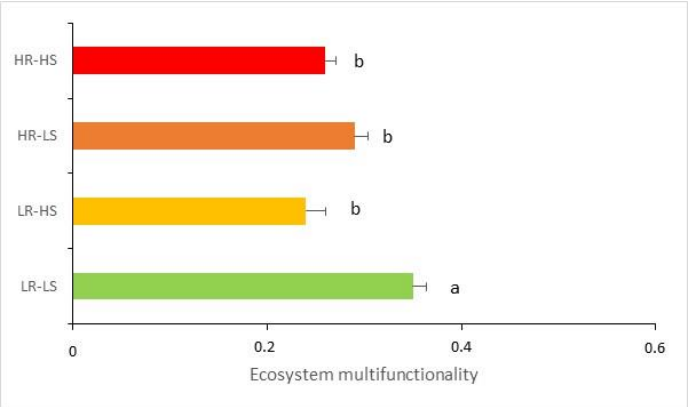

Figure 3. Average value and standard error of ecosystem multifunctionality for each scenario (Low recurrence and low severity (LR-LS), low recurrence and high severity (LR-HS), high recurrence and low severity (HR-LS) and high recurrence and high severity (HR-HS). Different letters show the presence of significant differences (p < 0.05) between burn severity categories.

4. Conclusions

The footprint of a megafire, three years after, is very evident through the reduction of ecosystem multifunctionality under those scenarios of high recurrence plus low or high burn severity. This integrated approach to the study of the effects of large wildfires on the functioning and provisioning of ecosystem services in fire prone ecosystems represents an outstanding advance in the design of adequate post-fire recovery strategies to minimise the impact and accelerate the recovery of the vegetation and soil.

Wildfires, Fuel moisture content, fire danger, FWI, prediction

Abstract

Fuel moisture content is one of the fundamental parameters in forest fire research and management given its implications for many aspects of fire danger systems. In Portugal, such as in many other countries, to classify the days with more favourable conditions for wildfires it is common to use the Canadian Forest Fire Weather Index System (CFFWIS) which is based on the estimation of moisture content of several fuel components. The mathematical structure of CFFWIS requires as input the daily meteorological parameters which are used to estimate the moisture content of the soil for different layers that are the primary outputs of the system – the fire moisture codes. The final output parameter of the system is the Fire Weather Index (FWI) which represents a measure of the fire danger due to meteorological conditions.

The temporal scale of the study is from 2018 and 2021 and the study area is in Lousã, a central region of Portugal. In this work, in addition to the meteorological data, we will use as input the direct measurements of dead fuels in the CFFWIS and analyse its influence on the FWI. The fuel moisture content (m_f) is determined through the sample collection of dead pine needles in Lousã. For this temporal scale, m_f by sampling is significantly lower than the modelled m_f using meteorological parameters. An advantage of using the m_f measurements is to increase the range of FWI variation, giving a higher sensitivity to the index to more easily discriminate the days with high fire danger and large burned areas. Two methods are addressed: "FWI a" which represents the traditionally FWI determined only by meteorological parameters, and the "FWI b" which is determined with fuel moisture content measurements and with meteorological data for the days that we did not have measurements.

The original FWI, based only meteorological parameters, is compared with the FWI determined using m_f measurements. The different methods will be related with the number of fires and burned area to analyse their performance. The results show a good fit between m_f and FWI for days with extreme weather conditions (m_f<5%).

1. Introduction

Fuel moisture content is determinant in the extension of the burned area (Lopes, 2013; Viegas et al., 2017) being a fundamental parameter in wildfire research and management given its implications for many aspects of fire danger. Recent work found that high values of the Fine Fuel Moisture Code (FFMC) may determine when large fires can occur, supporting close relationships between moisture thresholds and fire behaviour (Carmo et al., 2021). The assessment of fuel moisture content reveals to be crucial for the characterization of extreme fire events allowing the improvement of early warning systems over extreme weather conditions.

Traditional fire danger systems rely on meteorological indices, based on variables that are routinely measured on weather stations (Chuvieco et al., 2010). To estimate the fire danger in Portugal, as in Europe (Viegas et al. 1999), it is common to use the Canadian Forest Fire Weather Index System (CFFWIS) developed by Van Wagner (1987). The CFFWIS produces the Fire Weather Index (FWI) which is a composite index that represents the meteorological conditions and gives an indication of the expected fire intensity (Van Wagner 1987). The structure of CFFWIS is presented in Figure 1.

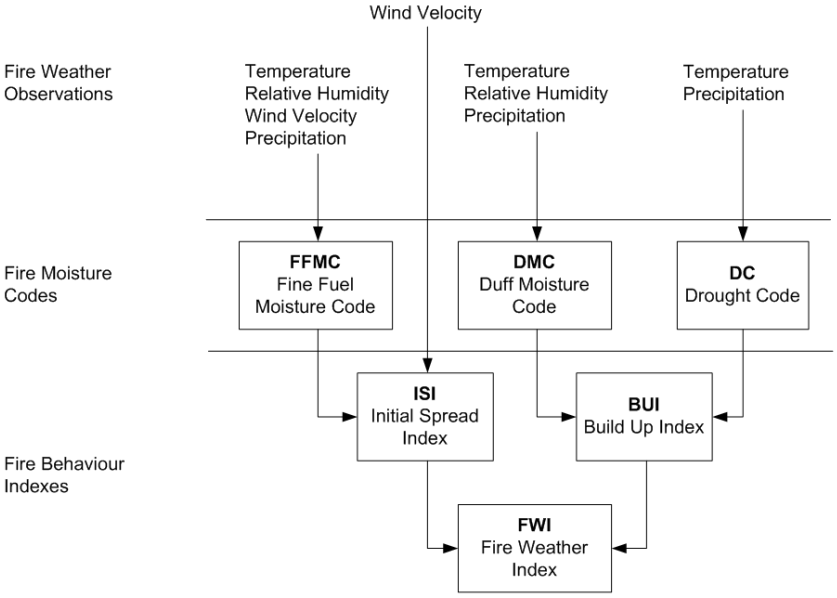

Figure 1 - Structure of CFFWIS by Van Wagner 1987.

The basis of this system is the prediction of dead fuel moisture content based on a set of physical equations calculated through meteorological data that are the input parameters (see Figure 1). The intermediate outputs are respective to fire moisture codes: Fine Fuel Moisture Code (FFMC) is associated to the surface litter, the Duff Moisture Code (DMC) is associated to the duff layers about 7cm deep, and the Drought Code (DC) is associated to the soil layers about 18cm deep and is well correlated with live moisture content (Viegas et al., 2001). The intermediate outputs of the system are the fire behaviour indices: Initial Spread Index (ISI) and Build-Up Index (BUI) giving a relative indication of the initial fire spread after the ignition and of the availability of the fuel to participate in fire propagation, respectively. These indices are combined to provide the final output parameter of the system – the Fire Weather Index (FWI), which represents the expected intensity of a spreading fire. The indices are cumulative as they take into consideration the effect of weather conditions in the previous days. The increase in each of these components corresponds to an increase of fire danger. These meteorological indices have some limitations when applied to other regions than that led to its formulation, namely they do not provide a real quantitative assessment of fuel moisture content value and therefore need to be validated with local data.

Based on the model used to calculate the CFFWIS, an approach to analyse the role of fuel moisture content on large wildfire occurrences will be addressed. We intend to analyse how FFMC changes when it is determined through direct measurements of fuel moisture content (m_f) and, consequently, how FWI changes.

The study is based on m_f measured in Lousã, a central region of Portugal. The analysis focuses exclusively on dead fine fuels, leaving aside the dynamics of live fuel with fire. In this paper the time period from 2018 to 2021 (4 years) is considered.

2. Methodology

2.1. Determination of the m_f

The fuel moisture content is determined by sample collection of several species in a field plot located in Lousã near the Forest Fire Research Laboratory (LEIF) – Figure 2.

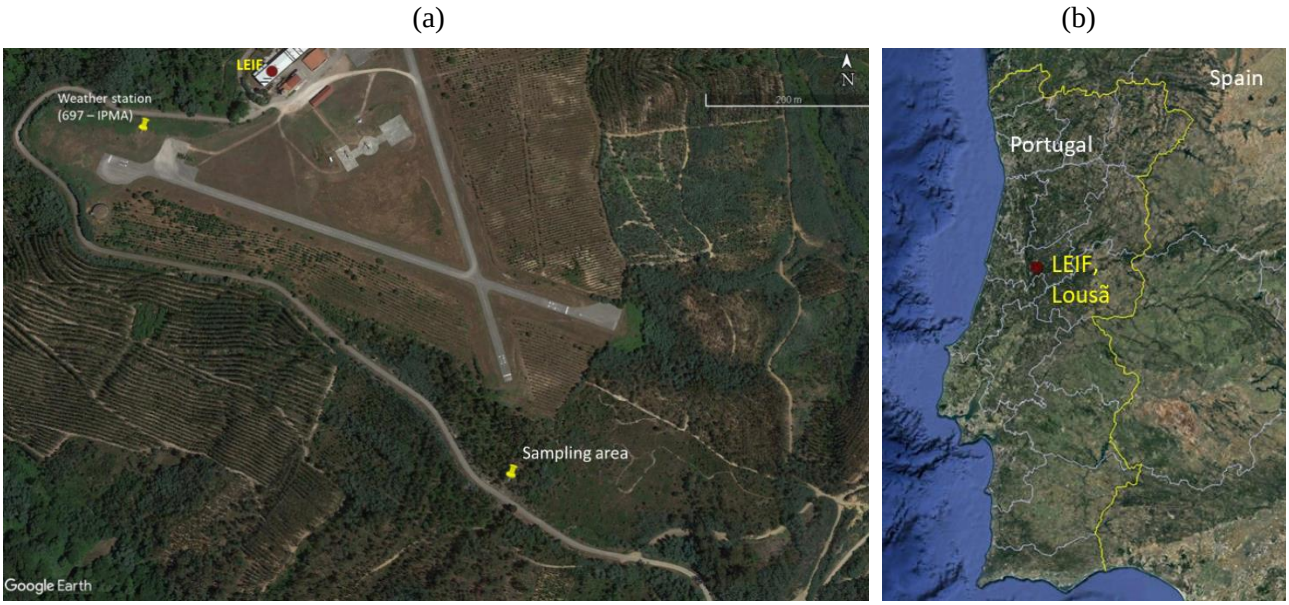

Figure 2 – (a) Local of the sampling area, Forest Fire Research Laboratory (LEIF), weather station and (b) their position in the Portuguese territory.

In LEIF, the samples are weighed with 5g each (initial mass: m_i), they are dried in an oven (24h and 105ºC) and their dry mass: m_d is determined. Fuel moisture content, $m_{f_{sampling}}$, in a dry basis is determined by Equation 1.

$$m_{f_{sampling}} = \frac{m_i - m_d}{m_d} \quad (1)$$

For this analysis, the m_f measurements of pine needles of *Pinus Pinaster* are used.

Figure 3a presents the relation of the m_f modelled in the CFFWIS ($m_{f_{meteo}}$) and the m_f observed ($m_{f_{sampling}}$) for all data (450 days). Figure 3b) presents the distribution of both m_f (modelled and observed) among the study period.

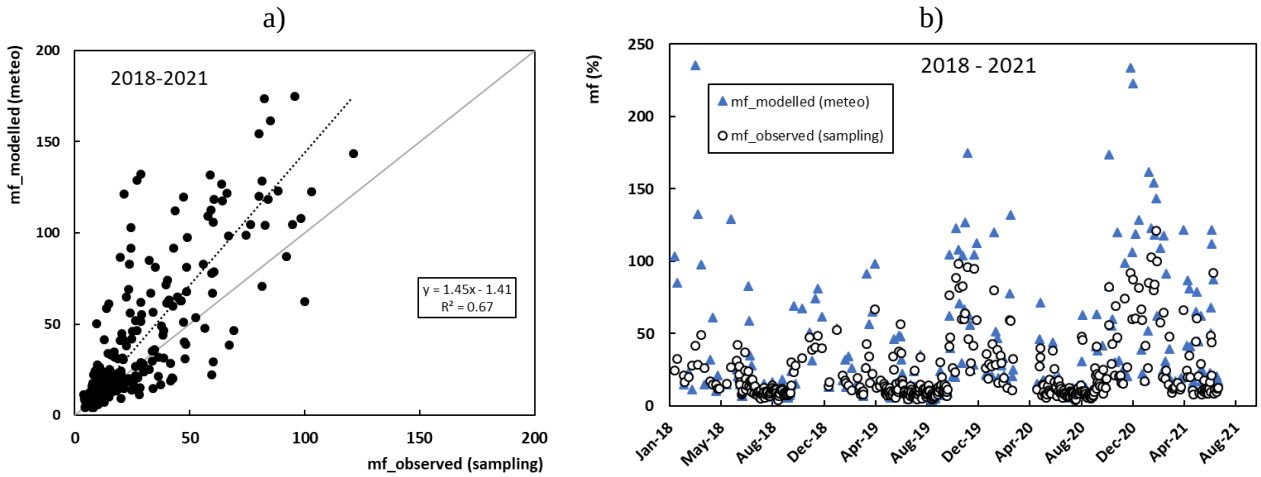

Figure 3 – a) Relation of the $m_{f_{meteo}}$ proposed by Van Wagner (1987) with the observed $m_{f_{sampling}}$ in Lousã; b) Distribution of the $m_{f_{meteo}}$ and the o $m_{f_{sampling}}$ per day.

Both figures show that the range of values for observed m_f is lower than the range values for modelled m_f.

Between 2018 and 2021 and considering all data (n=450), the sample mean for $m_{f_{sampling}}$ and $m_{f_{meteo}}$ was 20.47% and 28.36%, respectively. A "T-test for Equality of Means" was done using the statistical software

SPPS (28) to verify if the $m_{f\ sampling}$ is significantly lower than the $m_{f\ meteo}$. The following test hypothesis were done:

- H0: $m_{f\ sampling}$ mean = $m_{f\ meteo}$ mean;
- H1: $m_{f\ sampling}$ mean < $m_{f\ meteo}$ mean.

Output of the test is presented in Figure 4.

Independent Samples Test

		t-test for Equality of Means							
				Significance				95% Confidence Interval of the Difference	
		t	df	One-Sided p	Two-Sided p	Mean Difference	Std. Error Difference	Lower	Upper
mf	Equal variances not assumed	4,09	708,88	<,001	<,001	7,88	1,93	4,10	11,67

Figure 4 – Output of the "T-test for Equality of Means" between two independent variables: $m_{f\ sampling}$ and $m_{f\ meteo}$.

The test has a p-value <0.001, so for any usual significance level ($0.01 < \alpha < 0.1$) we reject the null hypothesis (H0) and we keep the one-sided alternative hypothesis (H1). The $m_{f\ sampling}$ is significantly lower than the modelled $m_{f\ meteo}$. An advantage of using the m_f measurements, since they have lower values, is to increase the range of FWI variation, giving a higher sensitivity to the index to more easily discriminate the days with high fire danger and large burned areas.

2.2. Determination of the FFMC

The function defined by Van Wagner (1987) relating FFMC with the moisture content of the surface fuels is presented in Equation 2. In this equation $m_{f\ meteo}$ is estimated by meteorological data.

$$FFMC = 59{,}5 \times \frac{250 - m_{f\ meteo}}{147 + m_{f\ meteo}} \tag{2}$$

Viegas et al. (2004) have developed a calibration function that uses FFMC to estimate the m_f (Equation 3) for dead fuels in the Portuguese forests.

$$m_f = 9 \times 10^9 \times FFMC^{-4.56} \tag{3}$$

In Figure 5 data of m_f obtained in the study period is plotted as function of FFMC measured at Lousã. The curves corresponding to equations 2 and 3 are plotted in the Figure 5.

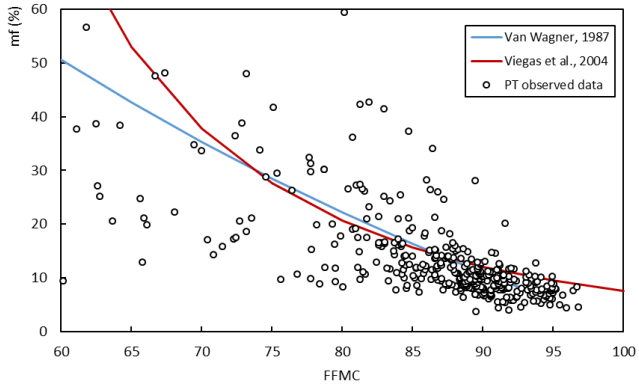

Figure 5 – Relation between m_f and the FFMC in Lousã – PT observed data. Functions proposed by Van Wagner, 1987 and Viegas et al., 2004.

The m_f measurements to be used in this study are distributed according to both models.

Figure 6 presents the relation of the m_f determined for each model (Van Wagner (1987) and Viegas et. al. (2004) with m_f measurements in Lousã (observed data) for values of mf<30% (335 days).

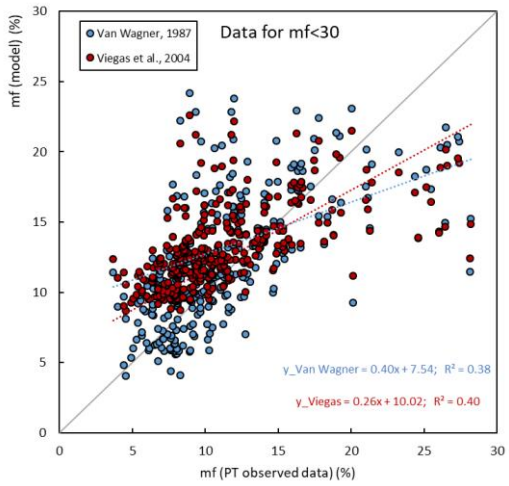

Figure 6 – Relation of the m_f proposed by Van Wagner (1987) and Viegas et al. (2004) with the m_f measurements in Lousã (observed data).

Both models have a similar relation with the observed data and similar coefficients correlation. We will maintain the Equation 2 to determine FFMC since its validity was verified for the Portuguese data and it is the original equation of the FWI system.

2.3. Determination of the FWI

Two methods are addressed to determine the FWI value:

a) FWI calculated as defined in Van Wagner, 1987 (only meteorological data).
b) FWI calculated with m_f measurements - m_f is used as input parameter in the FFMC calculation through Equation 2; the remaining moisture content codes (DMC and DC) are determined using meteorological data as defined by Van Wagner. After this step the system runs according with Van Wagner equations giving the final output – FWI.

2.4. Relation of the results with the number of fires and burned area

In order to calibrate the different methods (***FWI a*** and ***FWI b***) in terms of number of fires (NF) and burned area (BA) we used the fire history of the municipalities surrounding Lousã (Coimbra, Miranda do Corvo, Penacova, Góis, Penela, Vila Nova de Poiares, Arganil e Pampilhosa da Serra) as presented in Table 1.

Table 1 – Municipalities surrounding Lousã considered to calibrate the methodology regarding the number of fires (NF) and burned area (BA) between 2018 and 2021. Source: NF and BA provided by ICNF.

Municipality (area)	NF (2018-2021)	BA (ha) (2018-2021)
Lousã (138.40 km²)	32	11.6
Coimbra (319.40 km²)	159	21.0
Miranda do Corvo (126.38 km²)	44	570.4
Penacova (216.73 km²)	5	1.5
Góis (263.30 km²)	27	2.8
Penela (132.49 km²)	35	5.8
Vila Nova de Poiares (84.4 km²)	9	0.9
Arganil (332.84 km²)	36	5.1
Pampilhosa da Serra (396.46 km²)	22	26.8

We followed the methodology proposed in Viegas et al. (2004) and replicated in Alves et al. (2018, 2021) that requires the following parameters:

- Daily FWI values;
- Daily NF, and
- Daily BA.

A new field called Probability (P) was determined (Equation 4). This field reflects the weight that a given day (and its respective FWI) has in respect to the total number of days. The higher the FWI, the higher the "incremental day" and the higher the respective "probability" of occurrence of values of FWI.

$$P = \frac{Incremental\ day}{Incremental\ day\ total} \tag{4}$$

After the ***P*** calculation we need to categorize the probability into classes which is equivalent to splitting the results by percentiles. For each one was calculated: maximum FWI value that limits the class, average FWI value, average of number of fires and average of burned area.

NF and BA, in terms of average values, were related with the original FWI (***FWI a***) and with the FWI calculated with m_f measurements (***FWI b***).

3. Results and discussion

In Figure 7 the relationship between the ***FWI a*** and ***FWI b*** is presented**,** as well as the respective correlation coefficient (R^2).

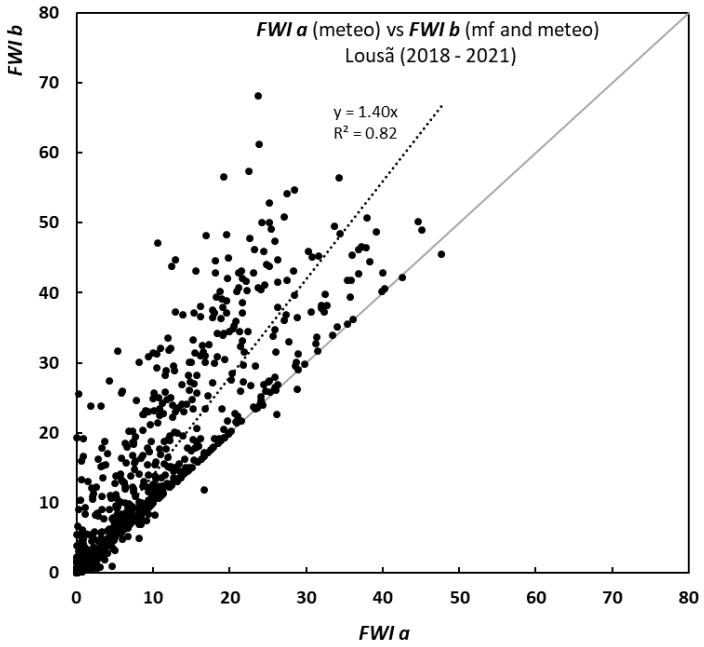

Figure 7 – Function of the original FWI calculated (FWI a) and FWI with m_f measurements (FWI b)

In Figure 7, the results show a good relationship between the two methods since the linearity is evident (high correlation coefficient) but the ***FWI b*** has higher values than the ***FWI a***.

Figure 8 presents an example of the values obtained for the two methods (***FWI a*** and ***FWI b***) for the main season in 2020 (15 May – 30 September). Also presents the values of m_f measurements in the secondary axis for the same period.

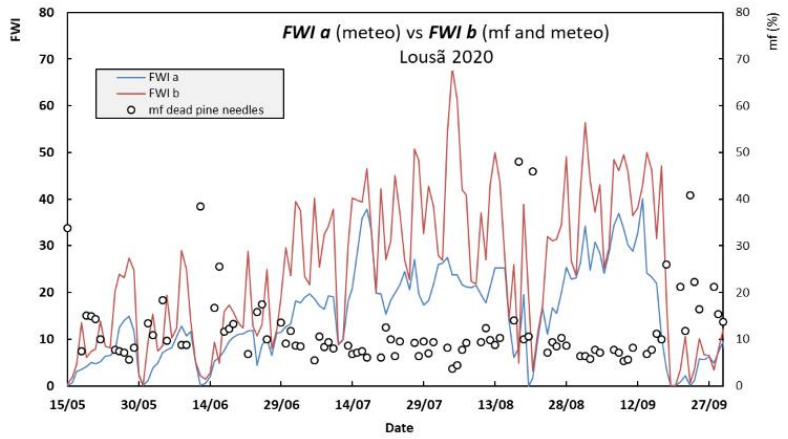

Figure 8 – Original FWI (FWI a) and FWI with m_f measurements (FWI b) – principal axis; m_f measurements – secondary axis.

The results show some differences between the two methods. FWI determined with direct m_f measurements were higher for days considered with "extreme conditions" since the m_f in Lousã was lower than 5% (Viegas et al., 2017). For example, on 4th of August, the m_f was 3.68% and for that day ***FWI a*** was 24 (high level according with Viegas et al., 2004 and EFFIS-JRC, 2022) while the ***FWI b*** was 70 (extreme level according with the same studies).

In Figure 9 is presented the average values of FWI determined for each percentile and the threshold for each danger class: low, moderate, high, very high and maximum.

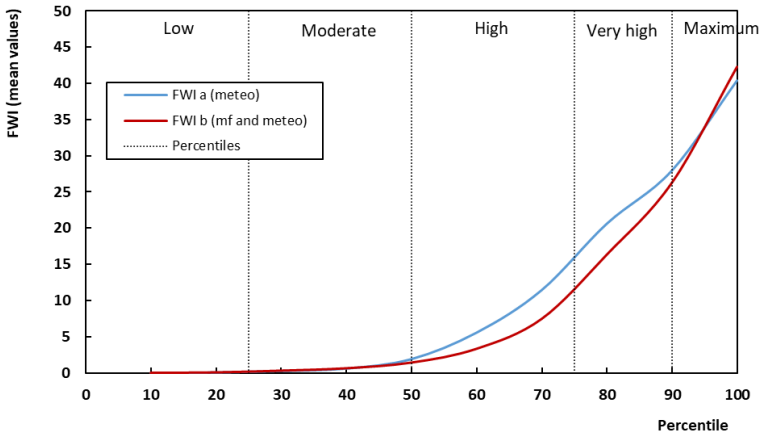

Figure 9 – Mean values of "FWI a" and mean values of "FWI b" calculated for each percentile. The vertical dotted lines define the threshold for each danger class: low, moderate, high, very high and maximum. "FWI a" is the FWI original calculated; and "FWI b" in the FWI with mf measurements.

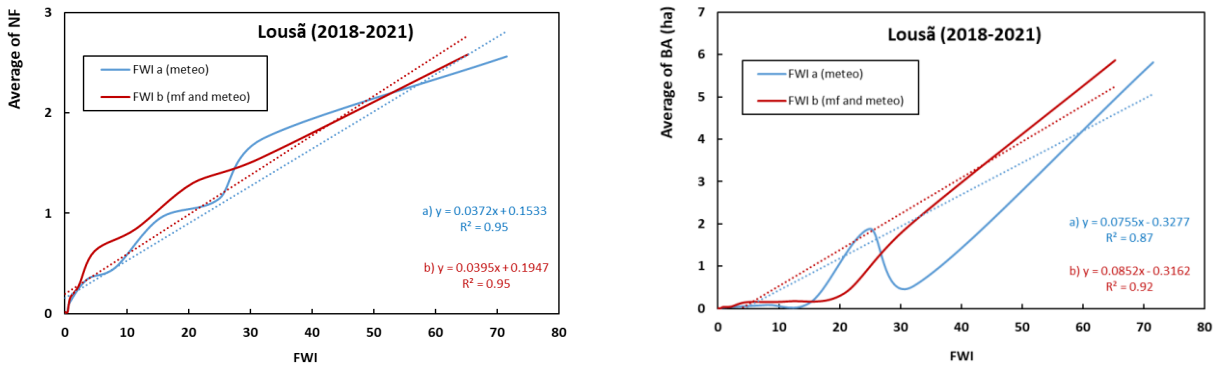
The distribution of the two methods is similar in the begin, but from P50 to P90 the FWI ***a*** is higher than the ***FWI b***. Around P95 the ***FWI b*** presents higher values which highlights the importance that direct *mf* measurements can have for the maximum fire danger classes. The measurements can have a higher effect on the numerical value of the FWI but this effect is "hidden" with the other codes (DMC and DC) that do not consider the real m_f measurements. As a future work, we propose the measurement of soil moisture at different depths and its inclusion in the calculation of DMC and DC.

Figure 10a) presents the relation of the two methods (***FWI a*** and ***FWI b***) with the number of fires and Figure 10b) presents the relation with the burned area. In both figures, the solid lines represent the real data and the dotted lines represent the correlation equation.



(a) (b)

Figure 10 – a) Relationship between FWI and the number of fires (NF); b) relationship between FWI and the burned area (BA).

The methods (***FWI a*** and ***FWI b***) have a similar behaviour for the NF (Figure 10a)), but for the BA the method considering m_f (***FWI b***) has a higher correlation coefficient than the method using only meteorological data (***FWIa***). In Figure 10b) it is verified that for FWI < 10 ***FWI a*** and ***FWI b*** are similar, but for high values of FWI, the ***FWI b*** crosses the ***FWI a*** curve and starts to represent larger burned areas, demonstrating the potentiality of using real measurements to represent the fire danger in terms of BA.

Figure 10 is an example for the calibration results that is typically made for this data, but we only considered the municipalities surrounding Lousã for 2018-2021.

4. Conclusion

Fuel moisture content is determinant in the extension of the burned area being a fundamental parameter in many aspects of fire danger.

The fire danger system used in Portugal – the Fire Weather Index (FWI), considers moisture indices or codes in their mathematical routine but estimates them through meteorological data. We presented a methodology to study the role that direct measurements of fuel moisture content can have in the FWI and its potentialities to predict large wildfires. Two methods were addressed: "***FWI a***" which represents the traditionally FWI determined only by meteorological parameters, and the "***FWI b***" which was determined with fuel moisture content measurements and with meteorological data for the days that we did not have measurements.

The fuel moisture content measurements, m_f, of dead pine needles collected in Lousã were used between 2018 and 2021. The preliminary results show that measurements can improve the FWI system to days with extreme weather (m_f<5%) since the FWI achieve higher values for lower m_f values. Also, the correlation between FWI considering m_f and burned area contributes to increase the correlation between the variables. Regarding the relation with number of fires seems to have not much differences between using only meteorological data or considering real measurements.

We will consider in future studies the extension of the temporal scale and the analysis of the dead eucalyptus leaves since they are also represent the dead blanket of Portuguese forests.

Abstract

Forestry is the science and craft of creating, managing, using, conserving and repairing forests, woodlands, and associated resources for human and environmental benefits. Forest management as one of the categories of forestry, is essential to exploit forest's full economic and environmental value while ensuring the safety and resilience of the territory against natural or anthropogenic threats such as wildfires. UAV-based remote sensing is a powerful tool for forestry related tasks and measurements. Various studies and experiments have been conducted by different teams all around the world; proving the effectiveness and efficiency of this remote sensing platform and the machine learning techniques used for the analysis of the acquired data. In this study a multirotor UAV equipped with a LiDAR sensor payload is used to produce a high density point cloud of a forested area in Coimbra, Portugal. The acquired data is then used to produce point cloud-driven digital models for various forestry tasks including individual tree detection and total height. The calculated results are then validated by comparing them to the field data. The proposed methodology has potential applications for the detailed mapping of forest and wildland urban interface environments using autonomous, time and cost-effective means, towards proper forest land management for profitability and wildfire risk assessment.

1. Introduction

With the ever-increasing numbers of wildfires all over the world, as a result of human activity and climate change, now more than ever, forest management towards fire risk reduction has become a critical mission (Almeida et al., 2017), (Viegas et al., 2017). Deep knowledge about forest characteristics, more specifically vegetation parameters, is required for proper management. The trees' geometrical attributes are among the most important ones in terms of potential bio fuels for wildfires, as they govern the fire propagation through mechanisms such as crown and spot fires. Traditionally, fieldwork is required to obtain local vegetation and topography data. The extent and quality of the acquired data directly depends on the management and fire prevention plan for each municipality, and the experience of the landowner/service provider. It is also limited by its high logistic cost, in terms of time, money, and site access (Hernandez-Santin et al., 2019), often leading to insufficient or inadequate temporal and spatial data resolution.

Remote sensing, the process of obtaining information about an object or an area by measuring the radiation emitted by it from a distance (typically through airborne or spaceborne sensors), is a very useful technique to perform land mapping tasks and is a rapidly growing technology for forest monitoring (Adão et al., 2017; Müllerová et al., 2017; Nex & Remondino, 2014; Siebert & Teizer, 2014; Todoroff & Kemp, 2016). Many of these applications require individual tree detection (ITD), measuring their dimensions, state and assessing other relevant parameters.

Remote sensing can be divided into two general categories: data acquisition and data analysis. Data acquisition itself consists of two parts: remote sensing platforms (satellites, manned airplanes, high altitude balloons, unmanned aerial vehicles (UAVs) and terrestrial sensors) and sensor type. Satellites have allowed to monitor the entire world surface for different purposes (Tucker & Choudhury, 1987), (Tucker et al., 1984) and much of this data is freely available (www.copernicus.eu/en/access-data), but have coarse spatial and temporal resolutions. Aircraft systems offer increased spatial resolution, but at higher costs, often exceeding $20,000 per flight (Vandapel et al., 2004). Terrestrial delivery methods, such as handheld laser scanning devices or cameras mounted on tripods, offer high spatial resolution, but are limited in spatial extent and site accessibility.

With the need of a high spatial resolution and on-demand data, the use and development of UAVs have increased. Despite their shortcomings, which include low flight autonomy and payload capabilities, these platforms offer a complementary solution that is significantly better in terms of resolution and accuracy compared to satellites, costs less than aircraft systems and can be as precise as terrestrial delivery methods (Scholten et al., 2019). These set of advantages i.e., on demand data acquisition, high spatial and temporal resolution and relatively lower cost make UAVs very popular for forestry applications.

2. State of the art

Four types of sensors are commonly used with UAV platforms in Forestry applications; RGB cameras, Multispectral cameras, Hyperspectral cameras and LiDAR (Light Detection And Ranging) sensors. In case of the first three, the output is an image in the format of a multi-layered tensor, each layer representing a certain spectral band (3 for RGB, normally between 4 to 15 for multispectral and between 100 to 200 for hyperspectral). In case of laser scanners, the output is a point cloud; a set of data points in three-dimensional space that beside the cartesian coordinates each point can have various attributes that are built into the data structure (timestamps, labels, etc.). These datasets are pre-processed to perform various measurement, segmentation and classification tasks.

In the field of forest remote sensing, one of the most widely used models is the Canopy Height Model (CHM) (Gu et al., 2020; Ma et al., 2022; Miraki et al., 2021). This model consists of a digital surface constructed by rasterization of a point cloud set. First, the Digital Elevation Model (DEM) and Digital Terrain Model (DTM) are created; DEM and DTM are raster grids referenced to a vertical datum, DEM represents the whole scenery (ground and any observed object) while DTM only represents bare-ground; the subtraction of the two is the CHM (Figure 1). The CHM is the basis for various tree attributes measurements such as Diameter at Breast Height (DBH), Above Ground Biomass (AGB) (Wang et al., 2017) and Height Percentiles (Puliti et al., 2020).In this study a multirotor UAV platform equipped with a LiDAR payload is used to generate high density point cloud of a forested environment. This point cloud is then used to create DEM, DTM and CHM. Based on the CHM, ITD and individual tree height measurement tasks are done. The obtained data has multiple applications, including forest biomass monitoring and management for profitability and wildfire risk assessment.

3. Materials and Methods

3.1. Study area description

The study site is located in the city of Coimbra, Portugal. The area is at an elevation of 40 m above sea level, cantered at a western latitude of 40° 11' 05.8" and a northern longitude of -8° 24' 54.9" (see Figure). The climate is classified as Mediterranean climate according to Köppen climate classification (Beck et al., 2020). In the region, the dominant tree species are *Eucalyptus Globulus* and *Pinus Pinaster*, but the trees existing in the study site are *Olea europaea*. The study site is a flat ground with spaced trees and has an area of $4{,}900\ m^2$ which makes it ideal for validating the capability of the UAV payload for mapping trees.

3.2. Data Acquisition

3.2.1. Ground level measurements

Manual ground level measurements were conducted to obtain the tree height and record their location with a GPS locator. A total of 8 randomly selected trees were measured using a *Nikon® Forestry Pro* hypsometer, to serve as the ground truth. This hypsometer has an accuracy of $\pm 0.3\ m$ for distance measurement and 0.1° for angle measurement when the target object's distance is shorter than 1,000 meters, therefore height measurement accuracy is $\pm 5.2 \times 10^{-4}\ m$ (www.nikon.com).

3.2.2. UAV Data Acquisition

The UAV platform used in this study is a DJI Matrice 600 pro, a Hexacopter UAV with the payload capacity of up to 6 kg. This battery powered UAV has a triple redundant positioning system which makes it ideal for topography and mapping applications. The flight took place in June 2022.

The LiDAR sensor payload used in the study is a multisensory payload developed at Carnegie Mellon University's Robotics Institute and consists of a LiDAR scanner (*Velodyne® Puck lite*, this scanner has 16 channels, vertical and horizontal field of view of 30° and 360° respectively and vertical and horizontal angular resolution of 2.0° and 0.1° – 0.4° respectively), an IMU unit (*XSENS® MTi-30, a 9 axis high performance IMU*), and a computer (CPU: *Intel® core™ i7 8th generation*, Motherboard: *Mini-ITX Gigabyte Z390 I Aorus Pro WiFi*, RAM:*16 GB DDR3*) that does onboard data processing, producing high density point clouds that are noise filtered and down-sampled. Figure shows the hardware that was used. The point cloud's mean surface density is 45 p/m^2.

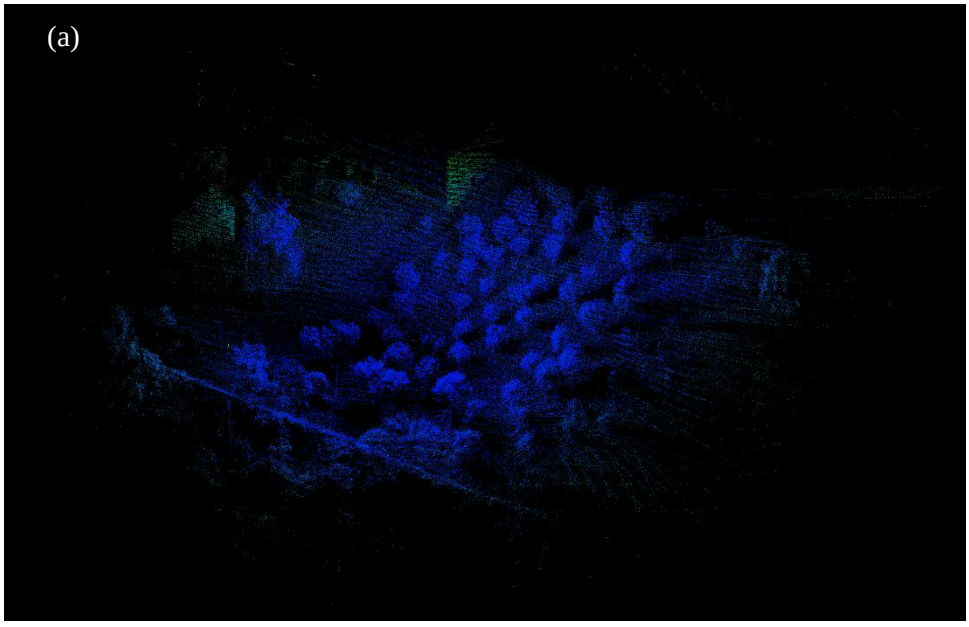
4. Results

4.1. Data pre-processing

The acquired point cloud map is shown in Figure . An open-source point cloud processing software (Cloud Compare, v 2.11.3) was used for point cloud filtering and rasterization.



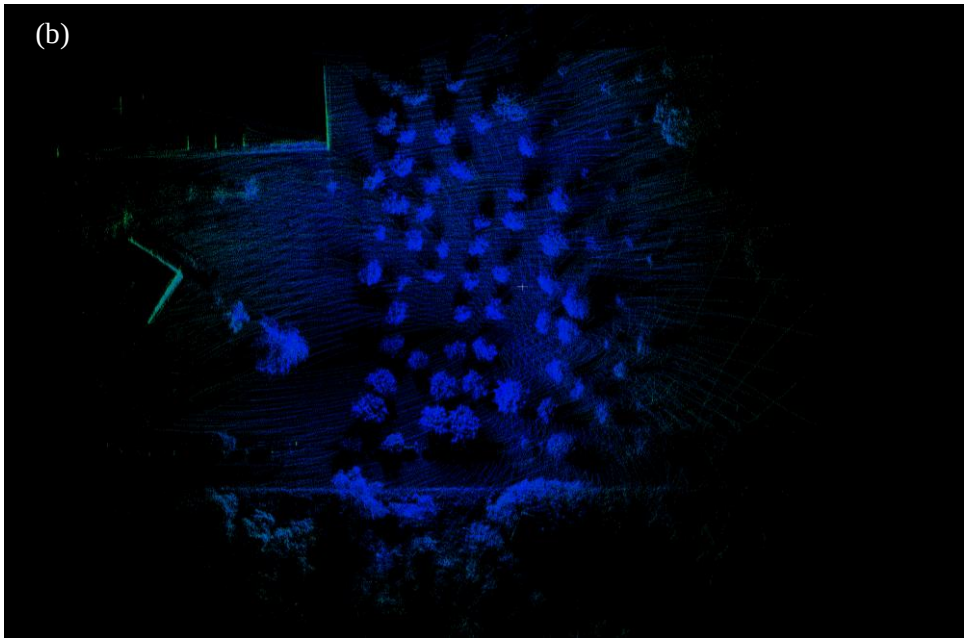


Figure 3 - Point cloud data of the study area (a) Isometric view and (b) Top view

First, the acquired point cloud map was pre-processed. The pre-processing included the following stages: 1- a noise filtering algorithm (Statistical Outlier Filter or SOR) was applied to the point cloud data to remove the points that were too far away from their neighboring point clusters. 2- After trimming the data to achieve the area of interest (AOI), a second filtering algorithm was applied on the data called Cloth Simulation Filter (CSF) to separate the ground points and above-ground points. This filter creates a mesh based on extrapolation of ground points to simulate the ground (see *Figure*). For more details about the algorithm please refer to (Zhang et al., 2016).

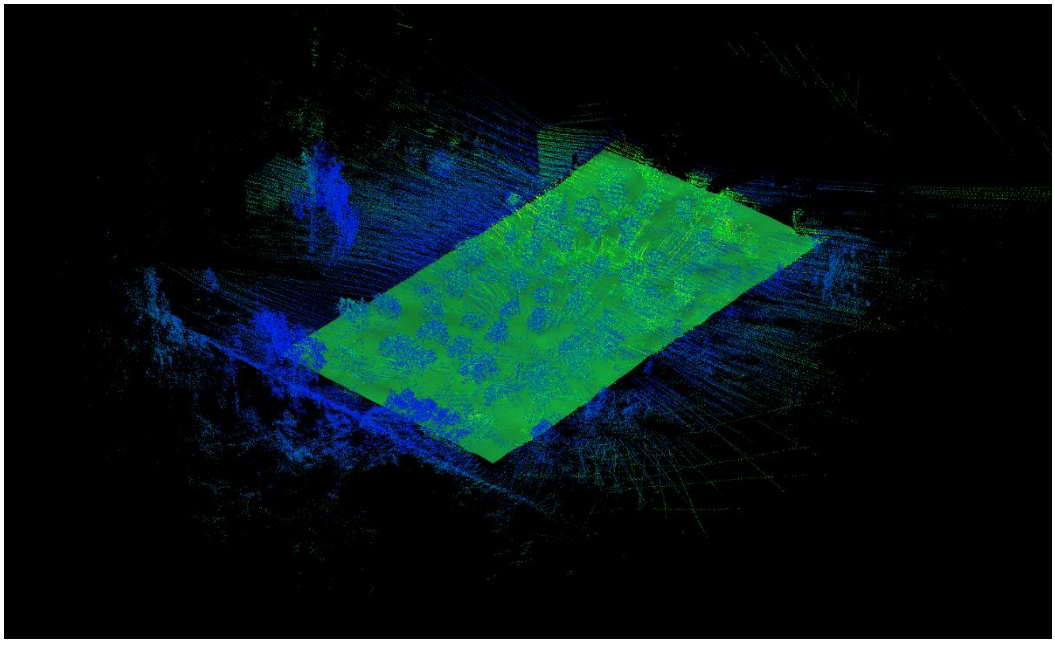

Figure 4- Generated mesh representing the ground, using CSF algorithm

The generated mesh serves as the simulation of the ground (DEM) and is used as the reference for measuring above ground points' elevation (*Figure*).

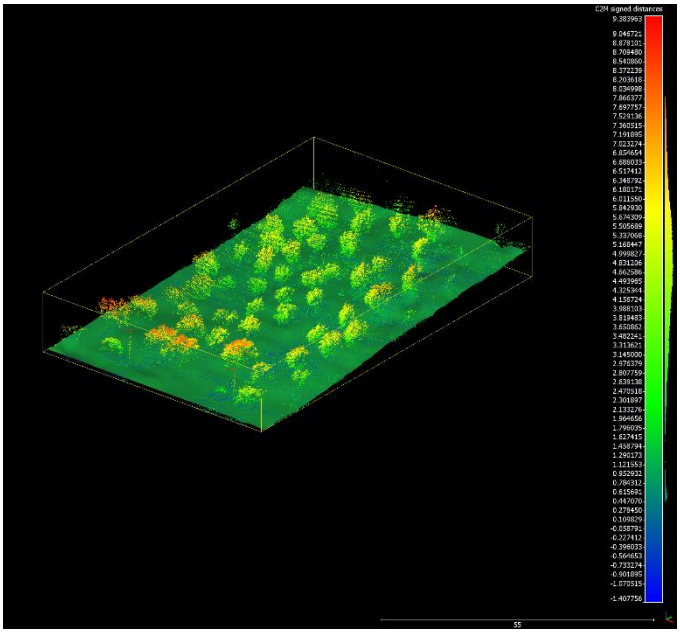

Figure 5- Pre-processed point cloud (colors indicate distance from ground)

4.2. Data Processing

After the above-ground points were annotated with their elevation relative to the ground, the point cloud was rasterized, resulting in the CHM of area (Figure).

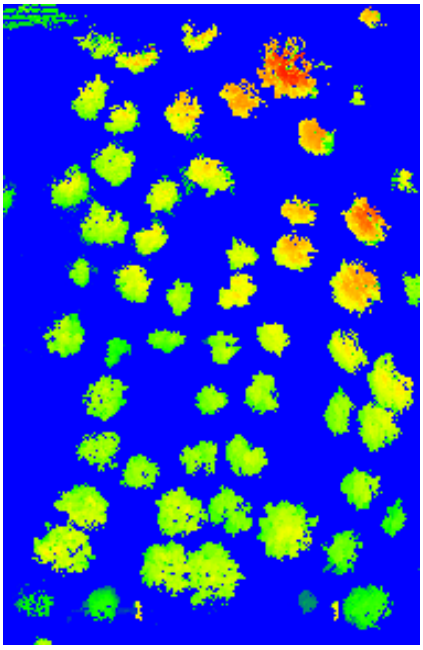

Figure 6- Canopy Height Model of the area

(R -v 4.2.0, 2021) was used for processing the CHM. To count the trees in CHM, a local maxima algorithm was used. The result is shown in Figure . Resulting height from this procedure is compared with the ground level measurements, obtained by the hypsometer, and shown in Table . The root mean square deviation (RMSD) from the height estimation is 0.11 m, demonstrating that this method is a viable solution to automatically measure tree geometrical attributes using UA 0V-born laser scanning.

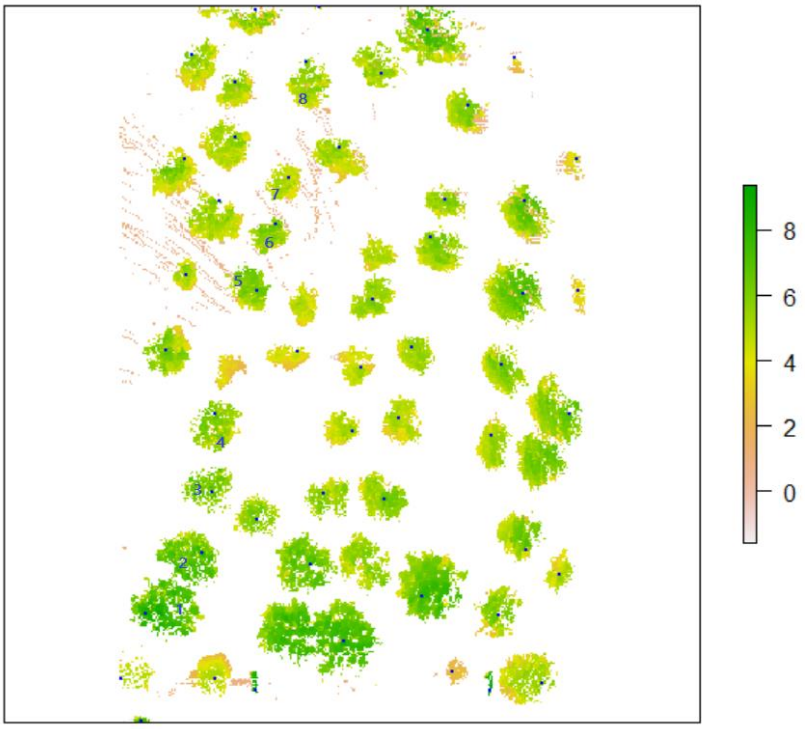

Figure 7- Tree Identification using local maxima filter

Table 1- Height measurement comparison

Tree Tag	Ground truth height (m)	Estimated height (m)
1	8.2	8.23
2	7.7	7.81
3	6.3	6.32
4	6.6	6.50
5	7.8	7.70
6	6.4	6.50
7	5.2	5.00
8	6.0	6.13
RMSD = 0.11 m		

5. Conclusion and Remarks

The comparison between the results from the UAV-born LiDAR scan processed data and the ground measurements reveal that UAV data is in good agreement with ground measurements, therefore the proposed system in this study can be used as a robust measurement tool for forestry applications. A few highlights of this study are listed as follows:

Down-sampling algorithm (point accumulation methodology) is a critical factor, density of point clusters has a direct effect on the quality of simulation of Object of Interest (OBI).

Flight and scanning scenario are the other deciding factors on the quality of obtained result. Depending on the defined task (specific forestry parameters to be measured), scan scenarios must be defined in terms of observed scenery, point density, energy and resources allocation.

The conducted flight and scan scenario is sufficient for an area with the similar characteristics as the one in this study. Denser and more complex environments require deeper and more complex scan scenarios.

A comparison between the manual field measurements time and drone flight is a good indicator of the efficiency of the proposed system; it took about 45 minutes to measure the heights of 8 trees (3 times each, for redundancy

and error reduction), while the flying time was about 8 minutes (capturing more than 50 trees in the area, not to mention part of the scanned area was trimmed and ignored).

Manual measurement time per tree: 5.5 min

UAV-born measurement time per tree: 0.16 min

Therefore, the proposed system is more than 30 times faster than manual field measurement.

wildfire simulation, deep learning, fire danger, potential fire size, fire weather, probability distributions

Abstract

Diagnostic of next day wildfire danger typically relies on computation of meteorological indices, usually derived from weather forecast. These indices may represent the danger of ignition, potential rate of spread or droughts, and while it takes into account the vegetation state it does not represent exactly how it will burn, as this is dependent of the fuel distribution and landscape at a scale much finer than weather model allows. On the other hand, overall landscape danger is more and more often evaluated statistically using mass simulation, with a very large number of fires simulated over a variety of weather situation to estimate effective fire area burned (in Ha), reaching a very fine scale at a cost of a computational time too long for next day forecast. Deep learning and model emulation can be used to overcome this computational problem and compute this next day fire size distribution a very high temporal and spatial resolution. Nevertheless, such simulation still comes at a cost, the amount of generated data is large and challenges on how to create a synthesis that may actually be helpful and insightful in operations. In this study, several approaches are proposed to analyze results and provide new range of fire danger maps and ratings, it is applied to the real forecasts of 13 relatively large fires that occurred in Corsica and compared to corresponding forecasts using standard fire danger index used in operational conditions.

1. Introduction

Diagnostic of wildfire danger for the next day typically relies on computation of meteorological indices, usually derived from weather forecast. These indices may represent the danger of ignition, potential rate of spread or droughts. Fire danger rating systems include assessment and forecast of one or several discrete indices, rated from "low" to "extreme", but the notion of "rating" may also refer to scalar values composing the system. These indices relate to the proneness for ignition, spread and/or intensity of a wildfire according to the state of vegetation and its environment at a given time. Well known examples are The Canadian Forest Fire Danger Rating System (CFFDRS, cf. Lawson and Armitage (2008)) and the National Fire Danger Rating System (NFDRS, cf. Bradshaw et al. (1984)). Fire danger maps may be available among other data via internet-based information systems; for instance, covering the US as part of the Wildland Fire Assessment System (WFAS, cf. Burgan et al. (1997)). While these systems take into account the vegetation state it does not represent exactly how it will burn, as this is dependent of the fuel distribution and landscape at a scale much finer than weather model allows. On the other hand, overall landscape danger is more and more often evaluated statistically using mass simulation, with a very large number of fires simulated over a variety of weather situation to estimate effective fire area burned (in Ha), reaching a very fine scale at a cost of long computational time. The strategy to rely on fire spread simulations is common to Burn Probability modelling (e.g., Parisien et al. (2005), Finney et al. (2011), Parisien et al. (2019)) although the goal here is to provide a fire danger index focusing on potential for fire spread, instead of potential for a location to burn.

We have recently introduced a method to overcome the computational problem and pinpoint where and when the most critical situation of next day may occurs. DeepFire (Allaire et al. (2022)), based on deep learning emulation of wildfire simulation, to compute this next day fire size distribution at a very high temporal and spatial resolution. Nevertheless, this simulation comes at a cost, the amount of generated data is large and pose the challenge of creating a synthesis that may actually be helpful in operations. In this study, several approaches

are proposed to analyze results and provide fire danger maps and ratings using this new simulation-based prediction system, it is applied to forecasts for 13 relatively large fires that occurred in Corsica and compared to corresponding forecasts using another fire danger index used in operational conditions.

2. Methodology

The new approach proposed to quantify fire danger consists in predicting, for a given time and location, the size of the burned surface that would result from one hour of free wildfire spread after an early stage where the fire has already ignited and spread over about one acre. Ignition probability is assumed homogeneous, except for locations without vegetation where it is considered null. A duration of one hour is generally more than the time necessary for the first attack on the fire to be carried out, even more so if one assumes that the fire has been detected in the early stage. These simplifying assumptions imply that fire danger mostly expresses potential for fire spread if it is not attacked rather than potential for ignition. The overall approach has already been presented in Allaire et al. (2022), tested and compared to the French IEP (Indice éclosion-Propagation, similar to the ISI Initial Spread Index) that range from low to severe in 5 classes. As DeepFire computes effective area burnt in one hour, there has been matched to fire size classes as in Table 1.

Table 1: Values of fire sizes used to determine a class of fire danger. The fire size classes follow the US classification and a correspondence of fire danger classes was made between DeepFire and IEP in the present study

Fire size (ha)	< 0.1	[0.1, 4.0[	[4.0, 40.5[	[40.5, 121.4[	[121.4, 404.7[	[404.7, 2023.4[	≥ 2023.4
Category	A	B	C	D	E	F	G
Corresponding IEP	None	very low (1)	low (2)	moderate (3)	severe (4)	very severe (5)	very severe (5)

3. Results

In Allaire et al. (2022), it has been shown that if the focus is on the vicinity of the ignition location, DeepFire predictions proved to be better (less false-positive area), or on par with standard index, with the added advantage of providing a quantifiable output. For the fire cases studied, we knew what were the when and where to focus on because the information was known a posteriori. However, in practice, information on the fires is not known before making fire danger predictions, and area of interest must be investigated on a full 24 hours ensemble simulation dataset that consists of 10.000 members (slightly different runs), 240 time steps on a 80m resolution grid. Computation is possible in 2 hours' time, but the analysis of this entire dataset is unrealistic in operational context unless it is guided with synthetic maps.

All these deepfires computations takes as input high resolution (600 m resolution) weather forecast initialized from the French Arome model. These computations are initiated at midnight (T0 here) and available at T6 (6:00UTC) all the evaluated forecasts are between T6 and T30 (6:00 of the first day to 6:00 on the next day).

These maps have been designed to attempt to address specific questions. First, what are the locations and time where/when fire danger is highest for the day to come? (cf. deterministic: Figure 1 & 2, and probabilistic: Figure 3 & 4) Then, starting from when and for how long is there high fire danger? (cf. Figure 5 and Figure 6.) Regarding these aspects, the question of uncertainty in the prediction is also addressed to some extent by comparing the deterministic maps to their probabilistic counterparts.

A focus on one small fire, Calenzana 2017

From the deterministic prediction of either DeepFire or IEP, the maximum value over the day can be computed easily for each location. The maps of the maximum between T+6 and T+30 of DeepFire (resp., IEP) and of the associated time of maximum are shown in Figure 1 (resp., Figure 2). On this fire day, a relatively strong south-westerly wind was definitely the driving factor, but this wind also brought some humidity, leaving area of high danger either where a downslope effect was strong. By looking at the time of the maximum of DeepFire on the right of Figure 1 it can be seen that although there is a high danger potential (some areas in red in map on the left), there is actually much contrast regarding time of highest danger in the area of Calvi, suggesting that if there is an event, a detailed local analysis is required. On the IEP map in Figure 2 such requirement is less

obvious, with large areas marked in orange and less contrast, indicating a dangerous but more general situation (less discriminant) with an event having strong probabilities of occurring in the morning.

If the maximum is obtained at several forecast times (T, with T+6), we show the earliest one. Because the IEP has only 5 categories, the maximum value will most likely be predicted at several times. Figure 2 shows that the time of maximum is T+6 for most locations, making it hard to tell when fire danger is highest. In practice, this issue can be avoided by identifying the time of maximum of another a continuous quantity, such as the FFMC which is one of the two components of IEP. In Figure 1, although the maximum is represented by a categorical color scale, it corresponds to a continuous index, so this issue does not occur. The time of maximum for DeepFire predictions is between T+8 and T+18 on the majority of the island, but for some locations (even among these predicted in class F) the time of maximum is after T+18, notably around the ignition location where the fire occurred at T+16 while the maximum is more around T+22.

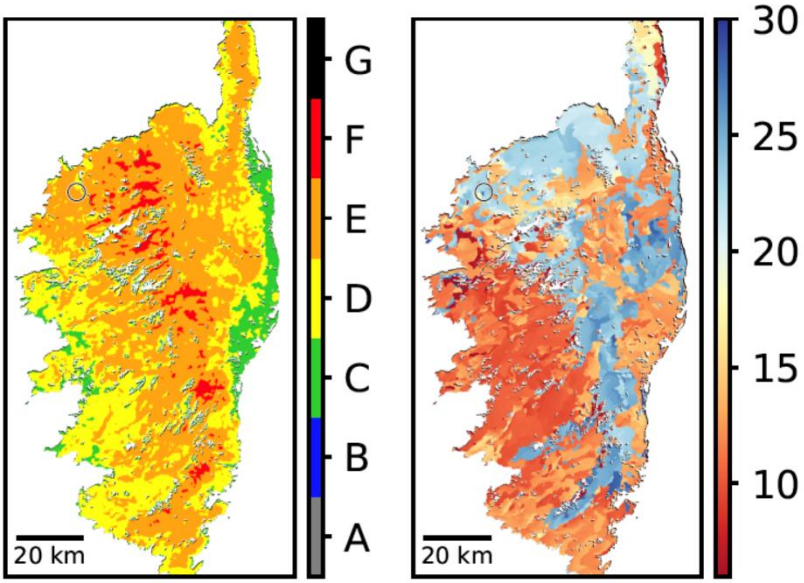

Figure 1: Maximum over the forecast between T+6 and T+30 (left) and time thereof (right) of the DeepFire prediction, location of actual fire in circle.

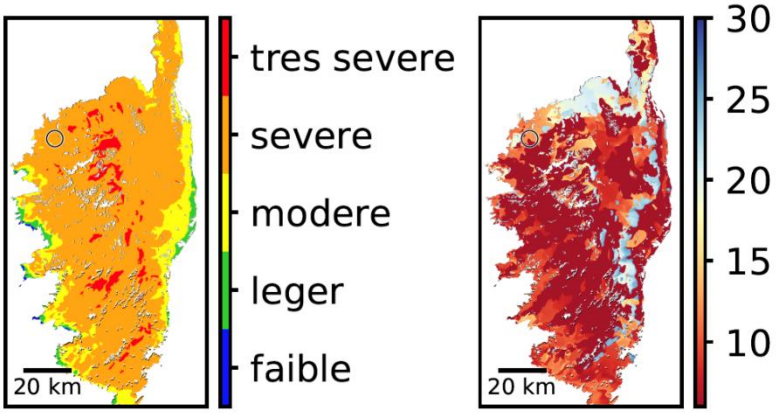

Figure 2: Same as Figure 1 but for IEP prediction

From the probabilistic forecast of DeepFire, the computation of a counterpart to Figure 1 is less direct. The ensemble can be summarized by a statistic such as the mean or a quantile. For either statistic, it makes more sense to first compute it for all locations and forecast times, then to identify the time of maximum. In the case of a quantile, for instance, the time of maximum can therefore be interpreted to that of a more or less optimistic predicted scenario. In Figure 3, the quantile for probability 0.8 was chosen. According to the Prométhée database, about 80% of the fires in Corsica have a final burned surface of 1 ha or less, which is quite low

considering the range of DeepFire predictions. Although it is untuitive to define quantile from a meaningful fire size derived from a database of observations, it does not seem relevant here, and it makes more sense to interpret the chosen quantile as a quantity that represents a quite "pessimistic" scenario. However, as can be seen in Figure 3 (middle map) there are still many locations where fire danger is at least in class D. It might be possible to make a distinction among the high-danger areas by looking at the less intuitive continuous value (left map). Regarding the time of maximum, it is similar to that of the deterministic counterpart in Figure 1.

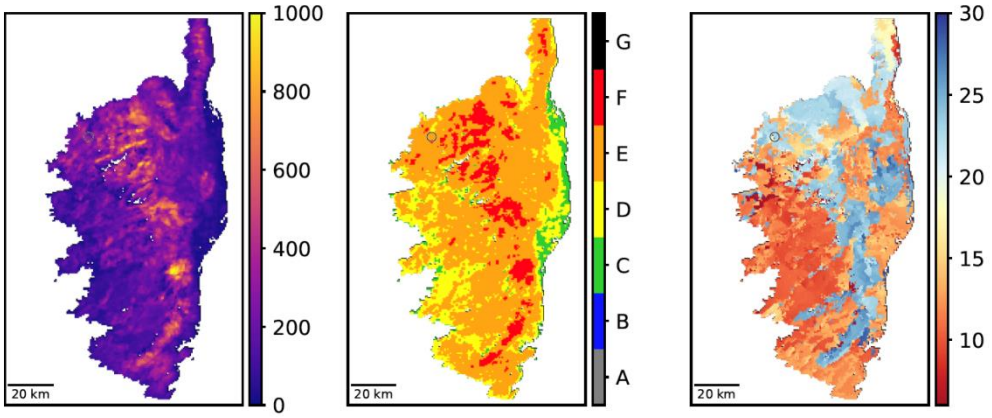

Figure 3: Maximum over the forecast between T+6 and T+30 of the quantile for probability 0.8 in the ensemble of DeepFire predictions. From left to right: continuous scale; categorical scale; time of the maximum.

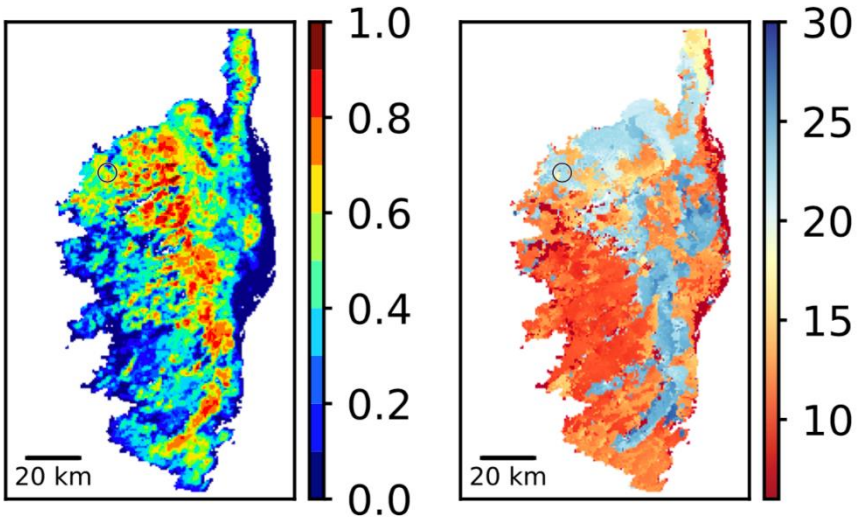

Figure 4: Maximum over the forecast between T+6 and T+30 of the probability of being into class E or higher (left) and time thereof (right).

Overview of the predictions for 12 fires

A number of numerical quantities that could serve as a daily indicator were proposed. Due to its ability to discriminate between locations with high fire danger in the cal_2017 fire case, the maximum over the forecast between T+6 and T+30 of the probability of being into class E or higher is chosen as a daily fire danger map for the 12 other fire cases. This map is shown for all 12 cases in Figure 5, together with the evolution of the proportion in the island of each class for both DeepFire and IEP according to the deterministic prediction to have an idea of how the overall spatial distribution of fire danger evolves over time.

Overall there is a general agreement in variations between T+6 and T+30 between IEP and DeepFire, with a general trend of more "contrasted" DeepFire predictions, indicating a better ability to pinpoint high danger locations (i.e. it is more discriminant). Alternatively, one may consider another maximum over time: that of the

probability (based on the ensemble) of being into class E or higher. The resulting map for cal_2017 fire case is shown in Figure 4 together with the associated time of maximum. Compared to Figure 3, the maximum probability seems better suited to discriminate among locations with high fire danger during the day, whereas the time of maximum appears similar overall, except for some locations where the predicted probability is 0 over all 24 hours, resulting in a time of maximum at the value of T+6 by default.

In terms of danger, Figure 5 has been separated into two main classes that corresponds to winter and summer fires. More than the season, a difference that can be observes is that for most summer fires, the peak in fire danger corresponds to noon (or the solar maximum), does not stay very long in peak value and overall, a situation that is bad over a large area. In winter, peaks do not have a clear time, with situation prone to large fires for a longer period. Moreover, for winter fire, there is a strong contrast between areas upwind and downwind, each of the winter situations happened in very strong winds.

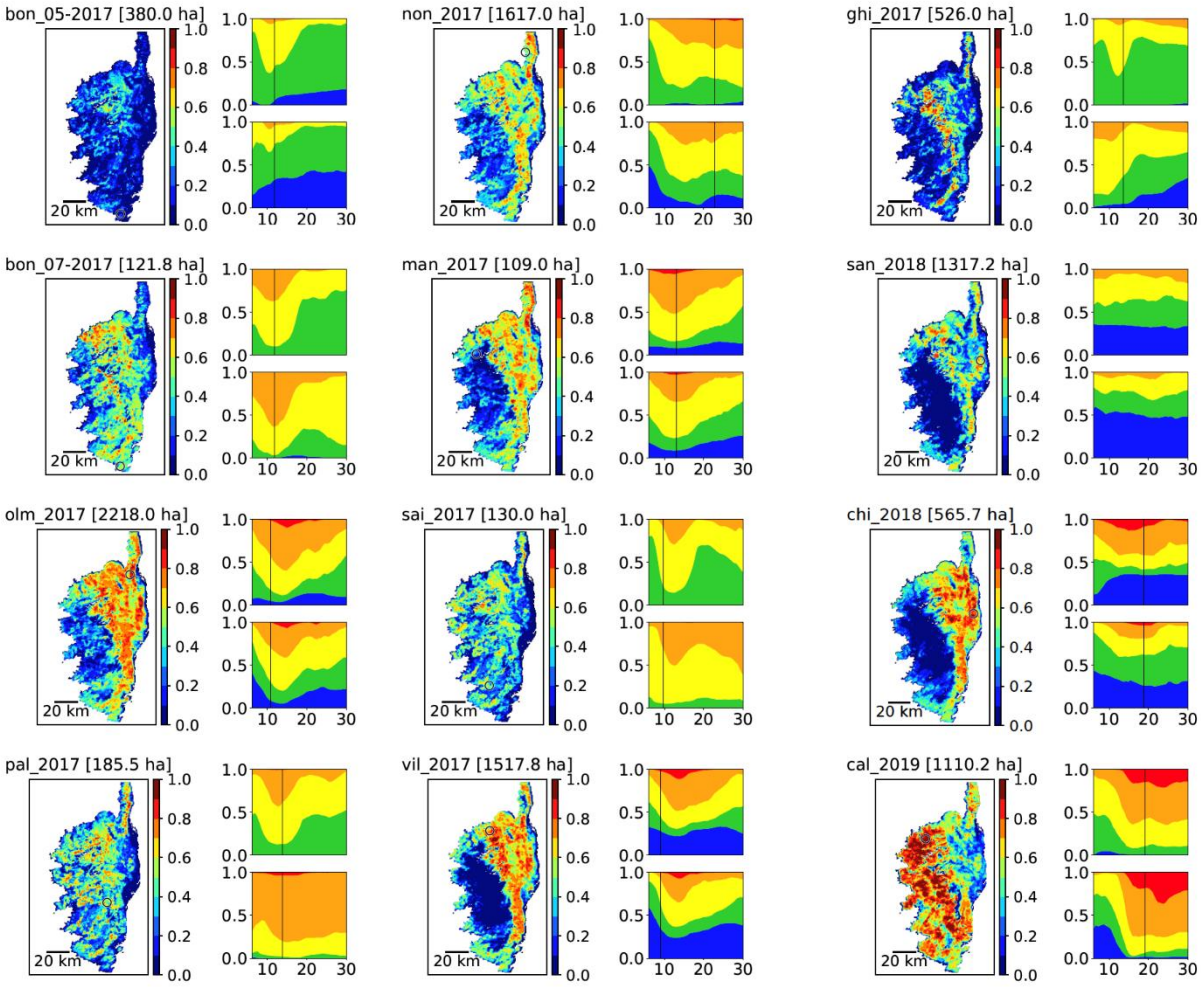

Figure 5: For all 12 complementary fire cases: maximum between T+6 and T+30 of the probability of being into class E or higher (left, cf. Figure 4), together with the evolution of the proportions over the island of DeepFire (top right) and IEP (bottom right) classes. First two columns: summer fires; last column: winter fires.

4. Conclusions

This works presents some insights on how to represent a synthesis of the large amount of data that results from fire danger predictions of potential fire size using DeepFire fire behaviour emulation.

Arguably, a daily rating of fire danger based on DeepFire should be computed on a relatively large area, at the sub-regional level for Corsica Island and the maximum value over the day can be considered. At this spatial scale, a representative fire danger rating could be the one associated to the DeepFire value that separates the 80% lower values from the 20% highest in a given area. As a complement to fire danger ratings, that are

associated to a low spatial resolution, it only makes sense to use these predictions with high spatial resolution and high frequency weather predictions to analyze the situation in more detail.

A major strength of the prediction using DeepFire seems to be its spatial granularity allowing to be more discriminant. Compared to traditional fire danger indices that mostly rely on weather forecasts, the potential fire size estimated by DeepFire accounts for the influence of terrain on fire spread at via the variability over space in type of vegetation, presence of non-burnable areas, and slope. The high-resolution maps could be used as complement of fire danger ratings, that generally attribute a single value to a large area, for better anticipation but potentially to help to decide firefighting actions after a fire has started spreading. For instance, the maps can be used to finely identify locations that, if reached at some point, the fire will spread even faster and become harder to control. Moreover, another strength regarding its design, compared to other fire danger rating systems, is that it is not based on empirical knowledge, except for the actual choices of fire size for each class, these results are not based on experience of past fires, nor on expert analysis.

Current work is focused towards removing a simplification. Separation in fire categories based on a size factor poses the problem of defining these classes. As a first guess, defining this threshold based on observed fire sizes seems a logical answer, but it may not be that representative. In Corsica and Europe, a vast majority of fires are attacked early enough and do not spread far, even when fire danger is high. It may make more sense to reanalyze the situation of a high number of days (e.g., a hundred) and provide a "reference" fire danger category, regardless of whether a fire occurred or not. Then, the thresholds could be adjusted so as to optimize the match between reference and predicted values of fire danger. Information on the intermediate sizes of the fires, rather than that of final burned surfaces, would be most relevant for evaluating the prediction performance of DeepFire, but most of the time the fire is stopped early and, otherwise, the 1-hour fire size is difficult to measure. This feedback would be very valuable to adjust the thresholds, but also to evaluate the usefulness of such a prediction system for operational use. Overall, the amount of information and complexity is increasing with the increase in resolution of most of the forecasting systems, and performing a synthesis that can leverage the advances offered by such systems is a major concern for any operational research.

Rate of spread, algorithm, extreme fire behavior, isochrones, wind direction

Abstract

Wildfires of recent years are unprecedented in terms of fire behavior and impacts all around the world. The wildfire community still needs to better comprehend the physics behind the phenomenon to reduce uncertainty and increase the response capacity during emergencies. Studying past fires becomes crucial for predicting future fire behaviors. However, often the description of fire behavior in past fires has been associated with a high degree of subjectivity according to responders' description. Here, we offer a new tool that enables the user to calculate the maximum rate of spread of wildfires according to an isochrones map of the fire. In addition, it includes the possibility to calculate this maximum rate of spread according to wind direction. We apply it to a set of four fires that occurred between the 29 and 31st December 2019 in Australia. We believe this can be a very useful tool for fire analysts to compare and analyze past fires and increase our global understanding of fire behavior.

1. Introduction

Wildfires of recent years are unprecedented in terms of fire behavior and impacts all around the world (Duane, Castellnou, and Brotons 2021). The wildfire community still needs to better comprehend the physics behind the phenomenon to reduce uncertainty and increase the response capacity during emergencies (Castellnou et al. 2019). Studying past fires is a crucial step for evaluating wildfire behavior, understanding the mechanisms and providing new theories for fire spread.

Current fire behavior research is based both on mathematical spread models and on witnessed evidence on wildfire spread. While the first one has a wide range of possibilities for analyzing fires, the latter has been mostly based on laboratory experiments. However, the observations in wildland fires differ far away from what has been traditionally observed during wildfires.

Reports on wildfires have always informed very important data about fire behavior, but that has been difficult to systematically collect, or liable to a high degree of subjectivity. Many studies and reports have published values for rate of spread, one of the most important variables that explain fire behavior. These values, although useful, become difficult to compare because of a lack of an objective method to calculate it. Although the literature has reported a rate of spread of about 33 km/h in grassland fires (Cruz et al. 2015), fires spreading at a 1 km/h are already above the suppression capacity for firefighters. The limit of 3 km/h has been proposed to define an extreme wildfire event (Scott and Burgan 2005; Tedim et al. 2018).

In this study, we present an algorithm that allows the user to calculate the maximum rate of spread of a wildland fire according to a map of isochrones of wildfire growth. With this new tool, we allow the scientific community to objectively compare the observed fire behavior of different fires and relate such information with the appropriate data to derive new knowledge on fire mechanisms.

More specifically, we apply the tool to a set of wildfires that occurred during the black summer 2019-2020 season in Australia.

2. Methods

2.1. Algorithm

The algorithm presented here is currently in the publication process. However, we provide some general traits that can help to understand the potentiality of the tool.

The goal of the algorithm is to provide a maximum distance run by the fire in a certain period according to wildfire isochrones. However, the potential also relies on the fact that this distance can be calculated according to the shape of the isochrones exclusively, or by following wind direction (+-5º) at the moment of the fire interval period. In case the polygon of a fire return interval contains unburnt areas in that fire interval period (i.e. "holes"), the algorithm assumes that the fire has had the capability to jump these areas in its maximum run.

The basic information required to run the algorithm are the isochron map (polygon file type) and a wind direction table associated with each interval. The algorithm is built in R (R Core Team 2021).

2.2. Selection of fires

We selected four that fires occurred in the region between Victoria and New South Wales on the days 29-30 and 31 December 2019 (Table 1). They all occurred in similar weather and drought conditions, and they affected areas with similar vegetation types.

Table 1- Characteristics of selected fires

Fire	Country	Region	Initial Date	Final Date (imagery based)	Total Burnt Area (ha)
1- Green Valley Talmalmo	Australia	NSW	31/12/2019	15/01/2020	471,398
2- Wadbilliga	Australia	NSW	29/12/2019	05/02/2020	373,246
3- East Gippsland – Goongerah	Australia	Victoria	30/12/2019	07/02/2020	645,618
4- East Gippsland – Mallacoota	Australia	Victoria	30/12/2019	07/02/2020	363,233

It is important to notice that the two Gippsland fires shared boundaries after a while of their beginning. However, since we aim at studying the behavior of fire and thus capturing the direction is important, we have considered both fires distinct fires four our propagation analysis.

2.3. Isochrones

We positioned fire fronts (isochrones) for each fire according to the hotspots reported by the VIIRS and MODIS sensors (Schroeder et al. 2014), building a VIIRS fire perimeter (polygon) using a minimum bounding geometry. We supported such polygons with Sentinel-2 and Landsat 5,6,7, and 8 images (we used whatever image was available for each fire interval period. The goal of these supporting images was to check the consistency of the delimitation made by the VIIRS sensor). The fire interval periods lasted between 11 and 13 hours, according to the VIIRS revisit time.

2.4. Weather data

We used hourly weather data provided by the Copernicus Data Store, specifically the reanalysis ERA5 hourly pressure dataset downscaled at 0.25º resolution. Data included the two components of wind (U,V) at 10 meters, from which we calculated wind direction.

3. Results

We calculated maximum runs according to the shape of the isochrones (Figure 1) and according to the wind direction and the shape of the isochrones (Figure 2).

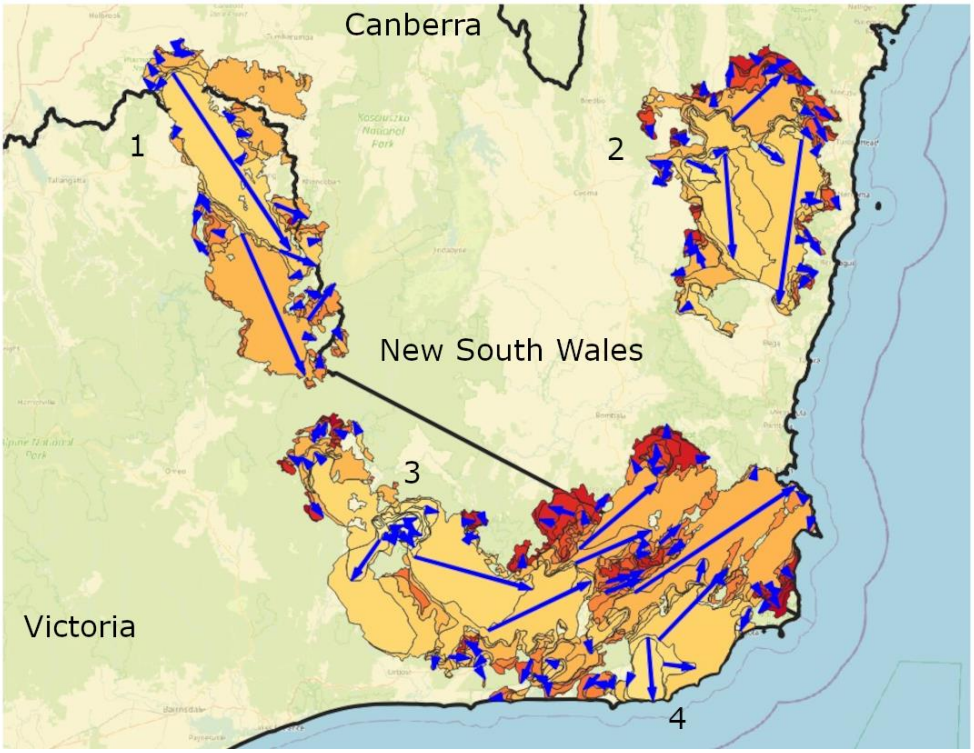

Figure 1. Maximum fire runs (blue arrows) according to the isochrone shape in the four major fires analyzed in Southeastern Australia. The Goongerah and Mallacota fires seem a single one because they share boundaries, but they are considered two different starting ignitions.

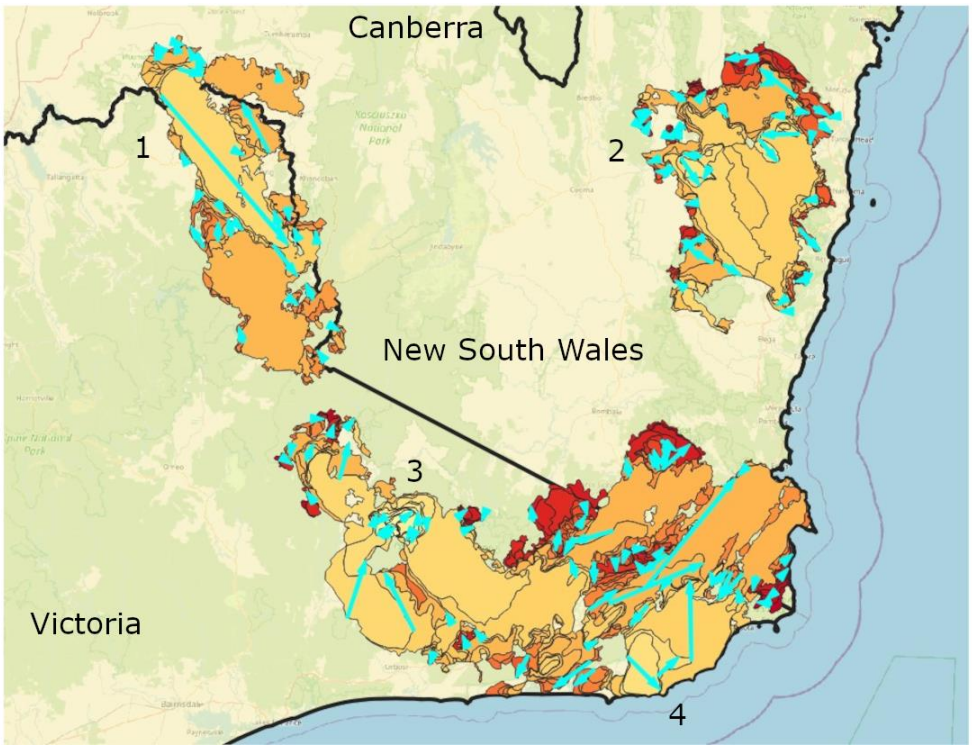

Figure 2. Maximum fire runs (light blue arrows) according to the wind direction and the isochrone shape in the four major fires analyzed in Southeastern Australia. The Goongerah and Mallacota fires seem a single one because they share boundaries, but they are considered two different starting ignitions.

We found that the most rapid fire runs where usually detected using only the shape of the isochrones (Figure 3). Maximum runs were calculated at around 6 km/h, being the fastest run in this analysis a run that took place in the Talmalmo fire on the 31st of December 2019 at 01:00 am, running at 6.535 km/h. However, when considering the total amount of runs, the average was usually higher when using the shape of the isochrones together with wind direction, although the differences where not significant (Figure 3). However, a paired analysis has not been considered in the present paper. Importantly, although the average speed was not very high when considering all runs (around 0.65 km/h), there were 21 runs exceeding the 1 km/h threshold, which can be considered a limit in fire suppression capacity. In addition, these 21 runs occurred mostly between the 31st of December 2019 and 5th of January 2020 and occurred in the four analyzed wildfires.

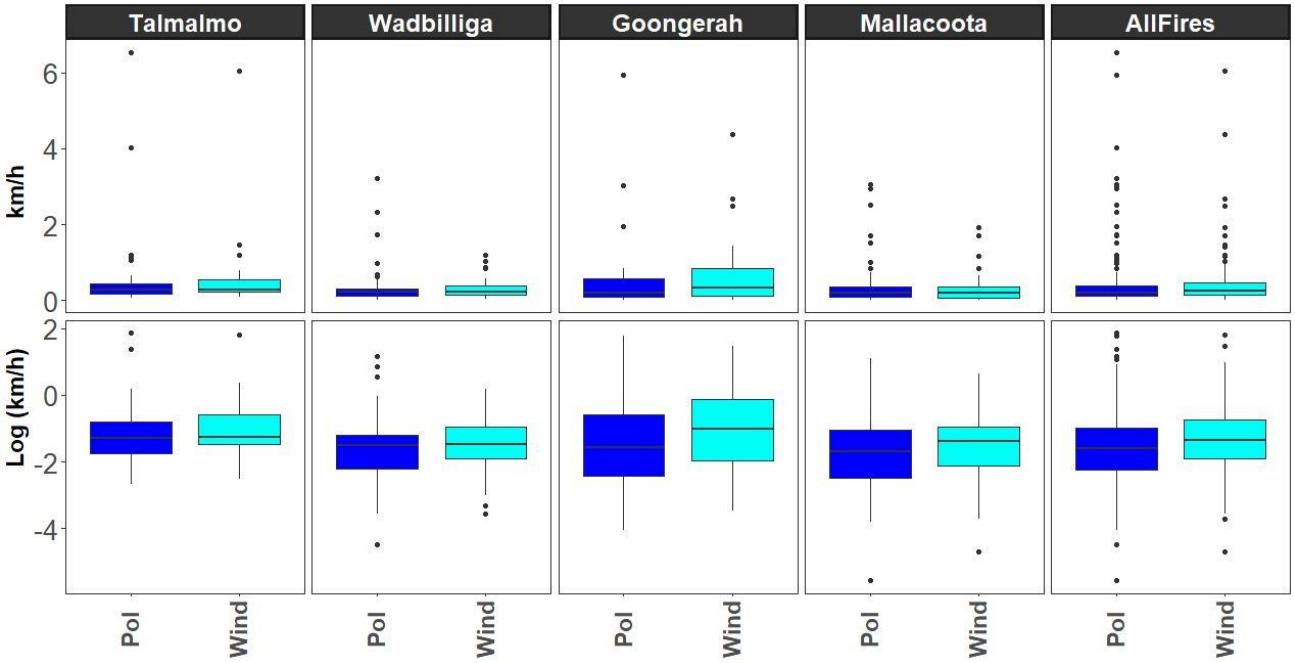

Figure 3. Maximum fire runs in each fire and considering all fires together. The upper panels show the actual values, whereas the lower panel show the logarithmic transformation to better appreciate the bulk of the data. Dark blue boxplots represent runs according to the shape of the isochrones ("pol"), whereas light blue boxplots according to the wind direction and the isochrone shape ("wind").

4. Discussions

We present the application of a new algorithm in a set of four wildfires that occurred in Australia during the black summer 2019-2020 season. The algorithm provided insightful results about fire rate of spread in these extreme fires. First of all, we detected very fast runs in the four fires: the maximum run reached 6.5 km/h in the Talmalmo fire. This is a very fast run for a forest fire: while in grass fires some rates of spread have been monitored at more than 30 km/h (Cruz et al 2015), in forest fires few runs exceed the 6 km/h threshold, only few of them in Eucalypt forests of Australia (Cruz et al 2020). Alexander and Cruz 2006 reported a 6.42 km/h fire in coniferous forests of Canada. We also obtained that a number of fire runs spread at more than 3 km/h (threshold to considered extreme), and several spread at more than 1 km/h, the limit of direct fire suppression. This indicates that the episode lived in Australia during the occurrence of these four fires was of extreme gravity given the fire behavior reported.

Our algorithm was able to calculate two different rates of spread for the same fire interval: according to the shape of the isochrones and according to the wind direction. In Figure 3 we compared both sets of results and we could see that there are not big differences between both ways of calculating rate of spread: while the major runs where always reported when considering only the shape of the isochrones, the average was higher when considering the wind direction. However, differences were not significative. It is important no notice that a "per pair" analyses would allow to obtain if per each run, the wind direction calculation gives larger or smaller rates of spread, because having all runs together does not allow to differentiate per each run.

Having a standard and homogenous way to report fire of spread opens the possibility to develop more in deep science about the factors behind fire behavior in a more general and objective way. We believe this is a simple exercise but can have a great potentially in applying it at different fires in which the progression of the fire is available.

The algorithm does not inform about the possible path of the fire inside the fire interval period, as this information is not derivative from the isochrones. The fire can change its direction because of wind direction changes in that time span, new slopes in different directions, interaction between wind and topography (Sharples et al. 2011), erratic atmospheric winds due to unstable atmospheres, fire suppression forces re-adjustments (back-fire), etc. But our analysis considers only straightforward runs as they represent the minimum distance travelled by the fire at least in that time (it might have gone faster, but we have no evidence). However, including wind direction in its calculation is an added value that can help to understand observed rate of spread and explain some of the behaviors that firefighters often report but that until now were not objectively measurable.

In this study, neither the fuel type, amount nor humidity, have been included. Although the objective was not to predict rate of spread rather than calculate the observations, we believe that mixing this type of data with other explanatory variables could increase the understanding of fire spread. By the obtainment of the rate of spread of past fires one can also analyze the spatio-temporal patterns of extreme runs around the world. For instance, the moment of the maximum rate of spread. It is commonly assumed that maximum rate of spread happens at the beginning of the afternoon, when temperature is maximum, relative humidity is minimum, and local winds and breezes achieve their maximum speed (van Wagner 1987). But recent extreme fires put into question this pattern: the Pedrogao Grande Fire occurred in June 2017 in Portugal reported an extreme run of 5.7 km/h at 20:00 hour local time (CTI 2017) generating a very serious civil entrapment with 64 fatalities. In the black summer season 2019-2020 in Australia, many of the pyrocumulonimbus events and their massive spread were reported at night (Peterson et al. 2021). At the same time, this analysis can help to disentangle the relation between fire spread direction, fire front, general wind, and many other spatial patterns of the fire.

Having an objective way of calculating rate of spread will likely help to understand wildfire behavior around the globe. This will ultimately help to develop appropriate prevention measures to diminish fire of spread and the negative impacts of wildfires.

Litter production, litter accumulation, years since fire, tree crown, ALS

Abstract

The continuity and depth of the surface litter and duff layers are major drivers of fire spread and fuel consumption. Nevertheless, its spatially explicit quantification over relatively large areas remains unresolved: local fuel heterogeneity introduces large uncertainties in estimates derived from field-based models and sparse data samples. Besides that, the sensitivity of remote sensors to surface litter loads is limited, particularly under canopy cover. In fire-maintained pine forests of the Southeastern US, surface fuel accumulation and its distribution over the forest floor are mainly driven by vegetation productivity, decomposition, and years since fire (YSF). Traditional ecological and stand-level models provide a means to equilibrate between opposing rates of deposition and decomposition as a function of YSF at the landscape level but don't account for spatial heterogeneity.

We developed a top-down, object-based approach for wall-to-wall estimation of surface litter loads using TSF records, the ecologically based Olson model, and tree crown objects derived from airborne laser scanning (ALS) data. The approach involves, first, the spatially explicit estimation of litter production through a tree crown production model. This model is driven by tree crown attributes extracted from the ALS point clouds, and it is informed by tree inventory data and allometric equations, including vegetation leaf turnover rates. Second, litter accumulation is estimated using the fire-driven Olson equation, which models accumulation progressively with time until decomposition balances deposition and a steady state of accumulation is reached. The methodology is demonstrated at several fire-maintained longleaf pine forest management units in southeastern USA, where tree inventory data, surface litter loads, prescribed fire records, and ALS data are available for testing and validation of the methodology. Comparison between modeled estimates and observed litter loads shows a relatively good agreement (RMSD=0.24 [kg m-2]; BIAS 0.004 [kg m-2]). This suggests that the proposed approach to indirectly map patterns of litter production and litter accumulation can provide a realistic means to map the continuity of the litter layer, thus overcoming the limitation of traditional ecological landscape models to account for spatial heterogeneity. This high-resolution map of litter loads will be further valuable as input to physics-based fire behavior and spread models and to improve the spatially explicit characterization of the duff layer.

1. Background and goals

High spatial resolution maps of surface fuels are critically needed by the carbon and fire communities, being especially relevant for forest managers that operationally use prescribed fires to maintain forest health and wildlife habitat in the longleaf pine forests of the southeastern US. Unfortunately, such maps are missing for most forested sites: the sensitivity of remote sensors to surface litter loads is limited, particularly under canopy cover, and the high heterogeneity of surface fine fuels and the lack of enough reference data (i.e., field measurements) limits the scope of data-driven modelling techniques (Keane, 2015; Keane et al., 2001).

In these longleaf pine forests, surface fuel accumulation and its distribution over the forest floor are mainly driven by vegetation productivity, decomposition, and years since fire (YSF) (López-Senespleda et al., 2021; Prescott, 2002; Zazali et al., 2020). Traditional ecological models such as the Olson model (Olson, 1963)

provide a means to equilibrate between opposing rates of deposition and decomposition as a function of TSF at the landscape level but generally don't account for spatial heterogeneity.

In the absence of disturbances at a specific location (e.g., under a specific tree crown), litter accumulates proportionally to the foliage biomass (FB) produced aboveground and deposited on the ground as litterfall until it decomposes into duff (Zazali et al., 2020). Therefore, characterizing the spatial variability of FB driven by the forest canopy would provide a means to describe surface fuel dynamics at the tree-level scale. Nowadays, remote sensing, and particularly airborne laser scanning (ALS) data, provides the most practical means to characterize tree aboveground biomass across entire forest landscapes at high spatial resolution, as shown in the many studies on tree detection and crown delineation, and on modelling tree attributes including height, volume, and/or biomass (e.g, Chen et al., 2007; Hudak et al., 2008; Jakubowski et al., 2013; Li et al., 2012; Roussel et al., 2020; Silva et al., 2016; Wan Mohd Jaafar et al., 2018).

In this study, we propose an object-based approach to map litter loads at high spatial resolution by mapping patterns of tree leaf litter production (i.e., litterfall) and quantifying litter accumulation through time with a spatially explicit implementation of the Olson model. This approach assumes that, locally, the amount and distribution of litter over the forest floor are mainly driven by litter production, i.e., by aboveground biomass and canopy characteristics (López-Senespleda et al., 2021; Prescott, 2002), and that due to the overstory inputs, litter loads are higher under trees than in gaps and edges.

2. Materials

The methodology was tested in three forest management units (i.e., 608A, 703C, L2F) at Eglin Air Force Base (AFB) in the panhandle of Florida (Figure 1). These sites undergo frequent prescribed burning that serves to maintain the native wildlife of the predominant longleaf pine ecosystem and facilitate military training.

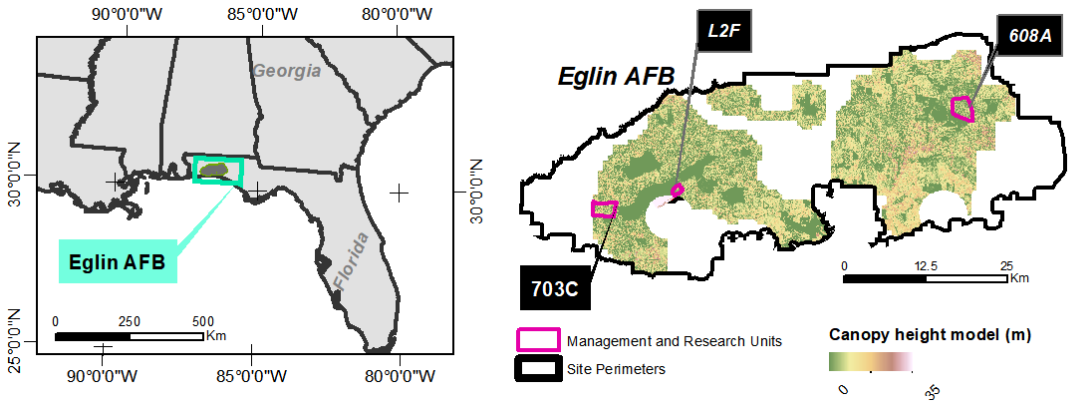

Figure 1. Location of the L2F, 608A, and 703C management units at Eglin Air Force Base (AFB). The canopy height model derived from airborne laser scanning (ALS) is displayed as background where ALS data is available.

ALS data were acquired in 2018 and points clouds were delivered by the provider in binary format (.las) with ground points labeled. The point cloud was normalized, converting points to height above ground, and a canopy height model (1-meter spatial resolution) was created.

A total of 166 litter biomass samples within the three management units were collected over square litter clip plots (0.25-1 m^2) in the framework of the RXCADRE project (2008-2012) (Ottmar et al., 2015) (Table 1, Figure 2). These data were used for accuracy assessment of the proposed methodology.

Table 1. Number of field clip plots, and minimum, mean, maximum, and standard deviation of the litter biomass (LB) [kg m^{-2}]. YSF: years since fire in the management unit at the time of the data collection.

Units	Sampling Year	YSF	# samples	Min LB [kg m^{-2}]	Mean LB [kg m^{-2}]	Max LB [kg m^{-2}]	Std Dev. [kg m^{-2}]
L2F	2012	3	66	0.04	0.48	1.27	0.31
608A	2011	2	60	0.05	0.34	0.75	0.15
703C	2011	2	40	0.07	0.33	0.72	0.16

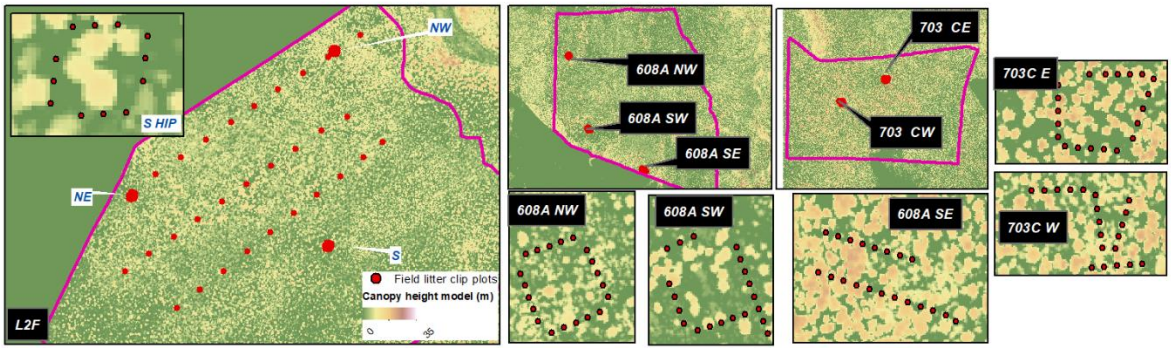

Figure 2. Location of the 166 litter clip plots established in 2011 and 2012 within the L2F, 608A, and 703C units at Eglin AFB.

3. Methods

Our proposed methodology involves the spatially explicit estimation of annual litter production following a biomass abundace approach in which littefall is proportionally estimated from tree FB. FB is modelled at the crown level from ALS data and random forest (RF) modelling, and informed by tree inventory data. Litter production maps are rasterized (5 m) and used, together with decomposition rates, to quantify litter accumulation after fire with a spatially explicit implementation of the Olson model (Figure 3).

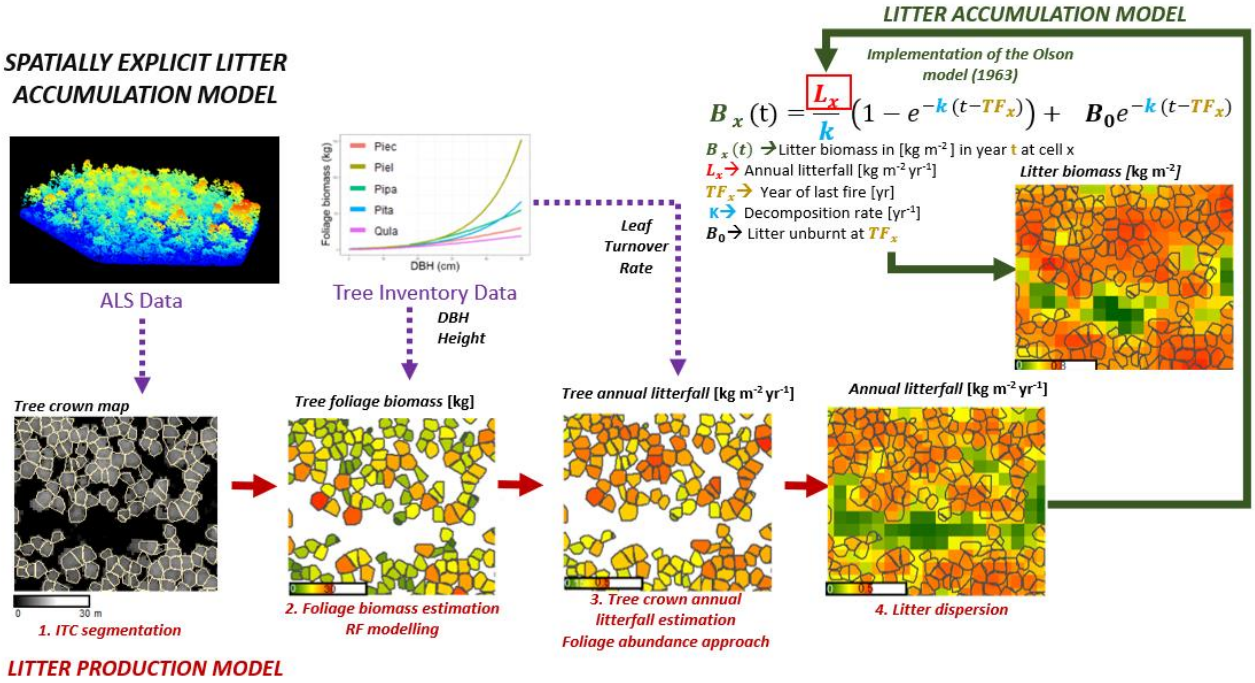

Figure 3. Workflow of the spatially explicit model of litter accumulation based on a tree crown-level litter production model.

3.1. Litter Production model

The spatially explicit estimation of litter production involves four processing steps: (1) generation of a tree crown map through segmentation of the ALS data, and computation of tree crown attributes also from the ALS data; (2) estimation of the total foliar biomass of each tree crown, by applying a RF model; (3) estimation of annual litterfall at the crown level following a FB abundance approach; and (4) annual litterfall distribution over the forest floor using a convolution filter (Figure 3).

Individual tree crown delineation was performed on the ALS canopy height model applying Silva's tree segmentation algorithm (Silva et al., 2016). A set of attributes was obtained for each crown from the 3D point cloud, and a RF model (Breiman, 2001) was calibrated to estimate crown FB. We used tree field inventory data

to determine FB from dbh-height allometric equations. These FB estimates were used as the response variable in the RF model, and the corresponding crown attributes were used as the predictor variables.

Once FB was estimated at the crown level, litterfall was proportionally estimated from tree FB applying leaf turnover rates that were based on leaf longevity of the dominant species observed in the study area (Neumann et al., 2018; White et al., 2000). Estimates of litterfall from tree crowns were rasterized and mapped at 5 m spatial resolution which approximates the size of the dominant tree crown in this ecosystem. Finally, to consider a dispersion rate of litterfall from the tree driven by external factors such as topography or weather, a convolution filter was applied.

3.2. Litter Accumulation

Total litter accumulation after fire was calculated through a spatially explicit implementation of the Olson model (Eq. 1):

$$B_x\,(t) = \frac{L_x}{k}\left(1 - e^{-k_x\,(t-TF_x)}\right) + B_0 e^{-k_x\,(t-TF_x)} \qquad (Eq.\,1)$$

where $B_x\,(t)$ [kg m^{-2}] is litter biomass accumulated in a cell x in year t; L_x is the steady annual accumulation rate, i.e., annual litter production or litterfall [kg m^{-2} yr^{-1}]; TF_x is the year of the last fire in a cell x; k is the decomposition rate in a cell x [yr^{-1}]; and B_0 is litter remaining after the previous burn [kg m^{-2}]. Based on the post fire litter samples collected at Eglin AFB, B_0 was established at 0.04 [kg m^{-2}] (Ottmar et al., 2015).

Climate and litter quality (e.g., percentage of lignin) and litter traits (e.g., leaf area) are main drivers of decomposition (Berg, 2014; Gholz et al., 2000; Meentemeyer, 1978). The dominant species on the study sites was longleaf pine. Accordingly, decomposition was calculated applying the single regression model calibrated for pine needles as part of the Long-term Intersite Decomposition Experiment (LIDET) that uses actual evapotranspiration (AET) as the only predictor variable. AET was obtained from the Moderate Resolution Imaging Spectroradiometer (MODIS) derived product available at https://earlywarning.usgs.gov (accessed on 9th of September 2021) (Senay et al., 2013).

The model was run for 2 YSF at the 703C and 608 A units, and for 3 YSF at the L2F unit, with YSF calculated at the time of the field data collection (Table 1).

3.3. Model assessment

Accuracy assessment was performed by comparing the litter loads observed at each of the 166 litter clip plots (Figure 2) with the predicted litter loads on the litter accumulation map. Model accuracy was evaluated using Root Mean Square Difference (RMSD) and BIAS statistics:

$$RMSD = \sqrt{\frac{\sum_{i=1}^{n}(\hat{Y}_i - Y_i)^2}{n}} \qquad (Eq.\,2)$$

$$BIAS = \frac{1}{n}\sum_{i=1}^{n}\left(\hat{Y}_i - Y_i\right) \qquad (Eq.\,3)$$

where n is the number of field litter clip plots, Y_i is the observed litter biomass for a given clip plot *i*, and $\hat{Y}_i$ is the predicted litter biomass corresponding with the cell value spatially intersecting the center of the field litter clip plot.

4. Results

The average litter production at the 608A, 703C, and L2F units was 0.13, 0.18, and 0.17 [kg m^{-2} yr^{-1}] respectively (Figure 4).

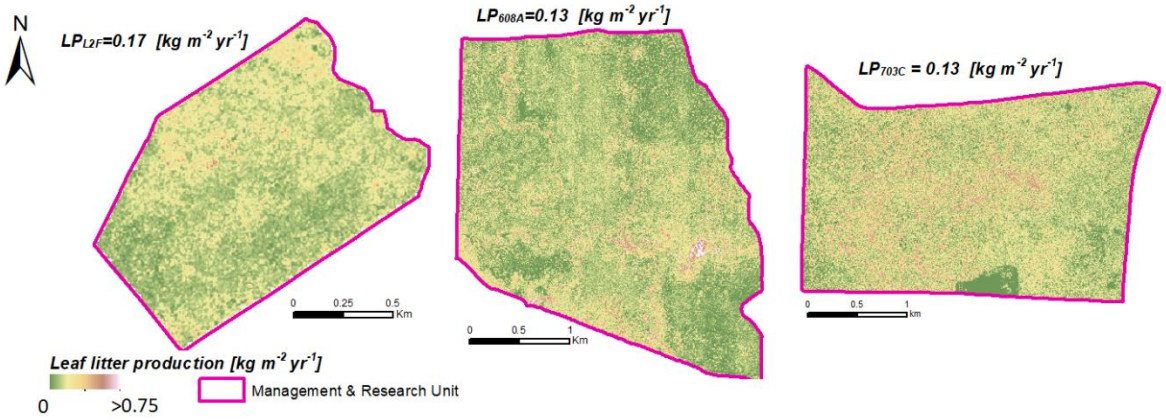

Figure 4. Annual litterfall [kg m^{-2} yr^{-1}] at the L2F, 608A, and 703C management units.

Average actual evapotranspiration within Eglin AFB was 714 mm, and the average decomposition rate was 0.13 [kg yr^{-1}]; therefore, the expected time necessary to reach 90% of the accumulation based on the Olson model was ~17 years. Average estimated litter loads at the L2F unit after 3 YSF was 0.38 [kg m^{-2}], and 0.26 and 0.35 [kg m^{-2}] at the 608A and 703C units after 2 YSF (Figure 5).

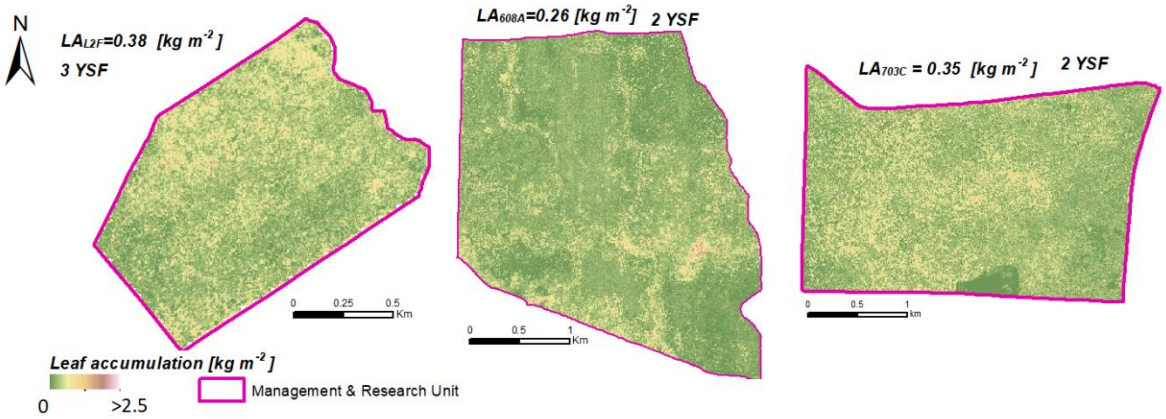

Figure 5. Litter loads at the 608A and 703C management units after 2 years since fire and after 3 years at L2F unit.

Table 2. R Pearson's correlation (R), RMSD, and BIAS of the litter biomass observed (Y_i) in the clip plots (0.25-1 m^2) sampled pre-fire at the L2F, 608A, and 603C units and the estimated ($\hat{Y}_i$) litter biomass corresponding with the cell value spatially intersecting the center of the field litter clip plot (0.25-1 m^2); n indicates the number of clip plot measurements evaluated at each time

Unit	n	$\frac{1}{n}\sum_{i=1}^{n}(Y_i)$ [kg m^{-2}]	$\frac{1}{n}\sum_{i=1}^{n}(\hat{Y}_i)$ [kg m^{-2}]	R	RMSD [kg m^{-2}]	BIAS [kg m^{-2}]
L2F	66	0.48	0.43	0.58	0.27	-0.05
608A	60	0.34	0.35	0.63	0.20	0.01
703C	40	0.33	0.42	0.32	0.24	0.09

Overal RMSD and BIAS were 0.24 and 0.004 [kg m^{-2}]. By unit, RMSD and BIAS were 0.27 and -0.05 [kg m^{-2}] at the L2F unit, 0.20 and 0.01 [kg m^{-2}] at the 608A unit, and 0.24 and 0.09 [kg m^{-2}] at the 703C unit. Accuracy assessment revealed a moderate R Pearson correlation between predicted ($\hat{Y}_i$) and observed (Y_i) litter loads (R=0.52) (Figure 6), which was expected given the large variability observed on the field data (Table 1). The correlation was higher at the L2F and 608A units (R=0.63, and 0.58) compared to the 703C (R=0.32), where the number of field samples was lower (n=40) (Table 2).

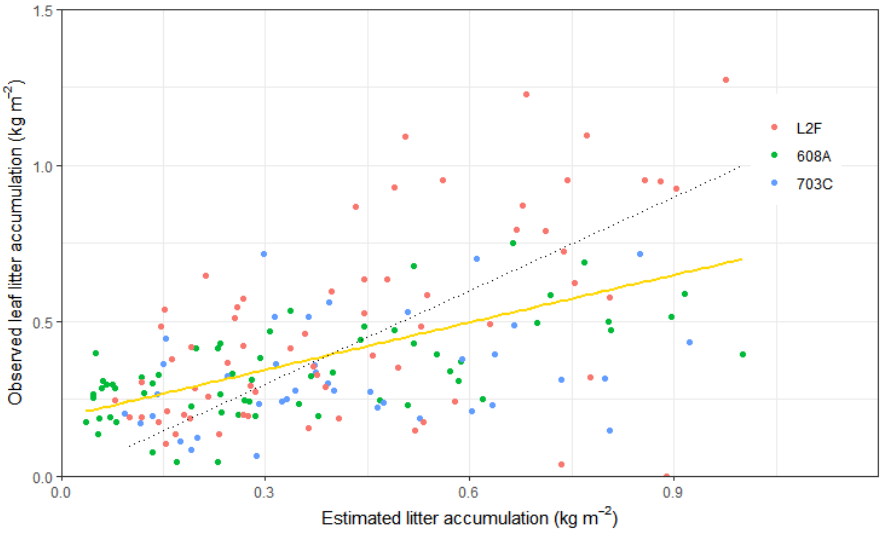

Figure 6. Litter biomass observed on the 166 litter clip plots (0.25-1 m^2) sampled pre-fire at Eglin AFB (y axis) and estimated litter biomass corresponding with the cell value of the litter accumulation map (25 m^2) spatially intersecting the center of the field litter clip plot (x axis). In each case, the spatially explicit implementation of the Olson's model was run for the same YSF observed on the units at the time of the data collection. The yellow line represents the best fit of the linear model between estimated and observed values, and the grey dashed line represents the 1:1 relationship.

5. Discussion

We mapped litter accumulation at high spatial resolution (5 m), developing a conceptual approach to estimate annual litterfall patterns at the tree level using 3D remotely sensed data and using the fire-driven Olson accumulation model to subsequently estimate litter loads. Our results support our initial hypothesis that, on these frequently burned forest ecosystems and up to 3 YSF, tree leaf litter accumulation and its distribution over the forest floor are mainly driven by tree foliar biomass and YSF, as indicated by the relatively good agreement between predicted and observed accumulated litter loads (R=0.52) (Figure 6). While it is a moderate correlation, it is relevant considering the large heterogeneity of litter loads observed over the forest floor at the local scale (Table 1), and the difference in size of the litter clip plots (0.25-1 m^2) and the pixel size of the leaf litter map (25 m^2).

The methodology can be transferred to other study sites and ecological regions where ALS data and the time since fire are known. Nevertheless, further research is needed to assess the performance on the model over a longer term (> 3 YSF). Our methods provide a realistic means to map the continuity of the litter layer conditioned on overstory tree crowns, thus overcoming the limitation of traditional ecological landscape models to account for spatial heterogeneity. This high-resolution map of litter loads will have further value as input to physics-based fire behavior and spread models and to improve the spatially explicit characterization of the duff layer.

Fuel break networks, Mediterranean wildfires, wildfire simulation

Abstract

The impact of rural fires in the Mediterranean Basin is rapidly increasing as extreme fire seasons become the new norm. Following the catastrophic 2017 fire season in Portugal, a national-scale fuel break network (FBN) was designed by the Rural Fire Management Agency (AGIF), and the implementation of fuel treatments along the fuel break network was initiated. Despite growing interest in developing extensive fuel treatment programs to prevent catastrophic wildfires and reduce exposure and risk in the Mediterranean region, there is still little information on the effectiveness of such programs. The Portuguese nation-wide FBN is part of the fuel management plan aiming to prevent loss of lives, reduce large fires (> 500 ha) and decrease annual burned area is under implementation. In this study, we used Monte Carlo methods and mechanistic wildfire spread modeling to simulate plausible wildfire events in Portugal. The modeling system was calibrated to local fuels and weather at monthly time steps. We then examined how the proposed fuel break network was intersected by simulated fires and the effectiveness in terms of protecting residential buildings and designated protected areas. The fuel breaks burn over percentage, i.e. the percentage of fires that are not contained by the FBN was modeled as a function of pre-defined flame length thresholds for individual FBN segments. From these outputs, we were able to compare priorities as determined from the simulation system to the FBN implementation plan by AGIF. Our results show that the full implementation of FBN can provide tactical opportunities for rural fire suppression and containment. The FBN has the potential to reduce up to 1) 13% in the annual burned area due to large fires; 2) 8% in the annual number of residential buildings exposed, and 3) 14% in the annual burned area in protected areas. However, the results also reveal that in many cases the FBN intersects fires after they have grown to over 500 ha, hence representing minimal potential in preventing large fires. The expected burn-over percentage was highly variable among the segments. An overall average decrease of 40% of the total benefits was estimated, with the most important fuel breaks typically showing a high percentage of fire burn over. Our results suggest that additional landscape-scale fuel reduction strategies are required to meet short-term national wildfire management objectives.

1. Background

Recent extreme wildfire events marked a turning point for Portuguese society and motivated a coordinated national response aimed at preventing catastrophic wildfires. The 2017 fire season was particularly harsh, with a record-breaking area burned of 557 thousand ha, 119 fatalities, thousands of structures destroyed, and over 1456 million euros in economic losses (Castellnou and et. al., 2018; Guerreiro et al., 2018). After this disaster, the Portuguese authorities were widely criticized for their lack of response and initiatives to reduce the potential for future catastrophic wildfires (Guerreiro et al., 2018). These and other factors led to the development of a new 10-year fuel management plan to reduce national wildfire risk (AGIF, 2020). The plan proposed three strategic targets: 1) the loss of lives in rural fires is reduced to a rare event; 2) the percentage of fires larger than 500 ha is reduced below 0.3 % of the total number of fires; and 3) the cumulative burned area over a period of

a decade is less than 660,000 ha. To achieve these, the plan proposes (among other fuel reduction actions) the implementation of a nation-wide fuel break network (FBN).

Fuel breaks are defined as "a strategically located wide block, or strip, on which a cover of dense, heavy, or flammable vegetation has been permanently changed to one of lower fuel volume or reduced flammability" (Green, 1977). Ultimately, fuel breaks are expected to facilitate fire containment and consequently decrease burned area, by providing safe conditions to engage in firefighting (Syphard et al., 2011a, 2011b).

In this study, we used simulation modelling and scenario analyses to evaluate the effectiveness of the Portuguese national 125-meter-wide FBN in terms of potential reduction burned area and in exposure of communities and protected areas to rural fires. We further quantified the probability of failure in containing the fire for each FBN segments based on the estimated flame lengths in the adjacent vegetation areas. We also added a simulation scenario we prioritized the implementation of the FBN over a period of five years according to estimated effectiveness of each FBN segment.

2. Methods

We used wildfire simulation data from Alcasena et al. (2021), representing 10,000 simulated fire seasons comprising a total of 1,654,448 simulated fires for mainland Portugal. The corresponding fire perimeters were intersected with the FBN to quantify the avoided burned area, reduced exposure of communities and avoided burned area in protected areas under the assumption of fire containment. Given the effectiveness of each FBN segment, we created a 5-year plan of FBN implementation for each objective, where the scheduling of the implementation of FBN segments follows their importance. We created two scenarios of FBN effectiveness: i) we assumed that fire spread stops at the FBN due to the full readiness of fire brigades; ii) we complemented this analysis by estimating the burn over percentage of each FBN segment, i.e., the percentage of times that each FBN segment may not allow for safe firefighting, failing to stop the fire spread. The burn over percentage was estimated using the simulated Flame Length Probability (FLP). We considered flame lengths longer than 2.5 m to represent surface fires likely to generate torching and crown fires, which are extremely difficult to suppress, and that have high spotting activity and spotting distances may be longer than 100 m (FBN is 125 meter wide). Hence, high intensity fires can decrease opportunities for fire control and originate embers that cross the FBN segment, reducing the effectiveness of the FBN.

3. Results and discussion

Our results showed that assuming maximum effectiveness of the FBN (i.e., fire containment) the full implementation of the Portuguese FBN could make a significant contribution to all fire management objectives of the country, with 13 % reduction in annual burned area due to large fires, 8 % reduction in the annual number of residential building exposure, and a reduction of 14 % in annual burned area in the protected areas. Nevertheless, the effect of the FBN in reducing large fires (> 500 ha) was minimal.

When the implementation of the FBN is scheduled following the prioritization given one of the three objectives cited above, its effectiveness showed an inverse exponential curve for all objectives with a sharp increase in the early years of implementation. The objectives of avoiding burned area due to large fires and avoiding exposure of residential buildings were more dependent on the complete implementation of the FBN. This reflects the known widespread risk of large fires and fire exposure of residential buildings across the country. Our analysis also revealed that the effect of the FBN segments already implemented is not different from a scenario of random scheduling (Figure 1).

In this study, we also identified the FBN segments with high burn over percentage caused by extreme fire behavior. Extreme fire behavior (as indicated by the burn over percentage) can jeopardize the safety of firefighters and ignite new fires over the FBN through intense crowning and long-distance spotting events (Alexander and Cruz, 2018; Alexander and Lanoville, 1989; Tedim et al., 2018). When assessing the effectiveness of FBN while acknowledging the possibility of burn over, the benefits of the FBN were dropped by almost 40 % on average for the three objectives studied, even assuming full readiness of fire suppression operations (Figure 1, dashed line).

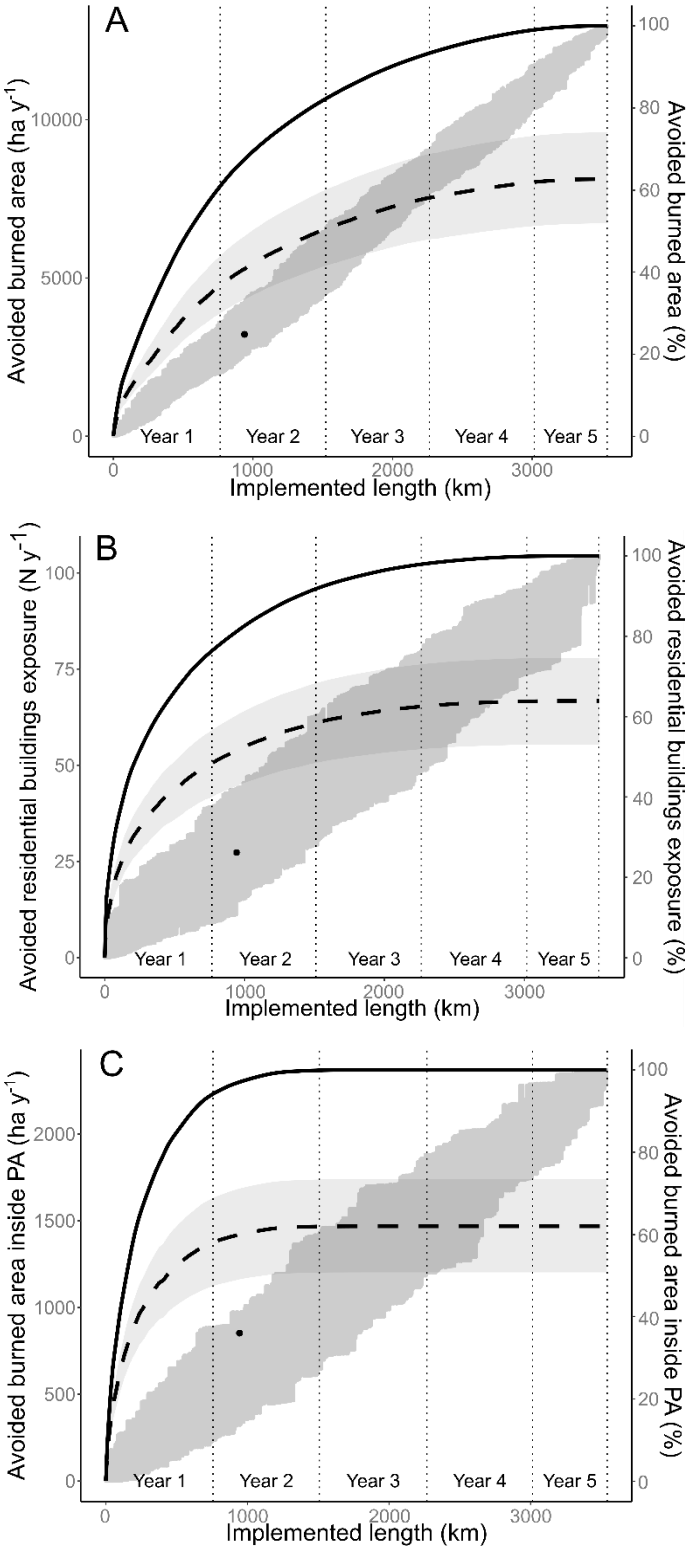

Figure 1. Cumulative annual effect of FBN implementation for avoided burned area due to large fires (A), avoided exposure of residential buildings (B) and avoided burned area inside protected areas (PA) (C). The solid line represents the optimal implementation scenario for each criterion; the dark grey area represents 100 random scenarios of implementation; and the solid dot represents the current stage of FBN implementation (identified in Figure 1). The dashed line represents the optimal scenario of implementation after adjusting the effectiveness of each FBN segment given the fire behavior and spotting distance in its surroundings (i.e. burn over percentage); the light grey area following the dashed line represents the 95% confidence envelope.

Finally, we show that a small portion of the FBN is responsible for great contributions to reduce the wildfire risk and exposure. This highlights the importance of strategically prioritize the FBN segments. These highly importance segments should also be monitored regularly to avoid fuel build-up, as they often have high values of burn over percentage. The widespread high burn over percentages indicates that the FBN itself may not be sufficient to substantially reduce large fires and wildfire risk. This, there is a clear need to integrate ecological restoration treatments in key areas close and adjacent to the FBN. We suggest that prescribed burning and preventive silviculture should be implemented in a synchronized way with the FBN to decrease fire spread and intensity, enhancing the safety of fire suppression operations (Alcasena et al., 2018). We further advocate that the afforestation of the areas surrounding the FBN with fire prone tree species that are either ignited by embers must be avoided (Viegas et al., 2014). We demonstrate how this framework can be used to design, evaluate, and implement future national fuel break programs in any fire-prone region.

Forestry biomass; combustion; microcogeneration

Abstract

Energy from biomass obtained in rural areas provides a sustainable alternative for heat and power production. In particular, the combustion of biomass in boilers represents the most widely used valorization route for the production of thermal energy. Furthermore, cogeneration has proven to be an efficient and clean way of simultaneous production of electricity and useful heat in the place of consumption, with the consequent saving of primary energy and emissions.

The specific aim of this experimental work is to study the feasibility of employing forestry wastes as feedstock for microcogeneration (electrical power <15 kW) processes for small scale (residential and commercial level) applications in order to avoid problems associated to their accumulation, mainly risk of fire.

Three forestry biomasses (Pinus pinaster, Eucalyptus globulus, and Acacia melanoxylon) abundant in Galicia, north of Spain, were selected as fuels to be used in the above-mentioned processes. An organic rankine cycle (ORC) coupled to a biomass boiler (60 kWt) were used to carry out the experiments. Cogeneration yields (thermal + electrical), as a function of temperature difference between cold and hot focus, were studied.

1. Introduction

Among all the countries of the European Union, Spain and Portugal are two of the most vulnerable against the climate change. In fact, in the last 30 years, both countries have suffered numerous wildfires which destroyed a large fraction of the local vegetation. In this context, the FIREPOCTEP project aims to: 1) Identify strategic management areas to minimize the risk and impact of large fires throughout an integral management of the landscape in relation to global climate change; 2) Promote public and private investment through pilot experiences in the framework of Green Circular Economy and investigation of new market opportunities; 3) Educate the permanent and occasional rural population about the risk of large forest fires, preventive practices and self-protection.

One of the main causes of these fires is the accumulation of forestry biomass derived from tree-pruning operations, due to the large quantities of dry material that can is left in-situ. Therefore, research on alternative uses of forestry wastes is mandatory to prevent beforementioned risks.

One alternative is represented by the biomass cogeneration, which allows the simultaneous production of electricity and useful heat in the place of consumption, with consequent saving of primary energy (up to 40%) and emissions into the atmosphere. In fact, cogeneration is considered as the main option for the replacement of traditional energy systems (D'Accadia, 2003). Taking this into account, microcogeneration (referred to small power equipment, less than 50 kW) is emerging as a suitable alternative in the aforementioned small-scale applications (Fenercom, 2012). One of the most promising techniques for electrical energy obtention through biomass is the so-called organic rankine cycle (ORC) (Qiu, 2012). The ORC follows the same principles as the traditional steam Rankine cycle used in most thermal power plants to produce electricity but uses an organic fluid instead of water. This fluid (generally a fluorocarbon) has a high molecular weight and a boiling point below 100°C, which allows to considerably simplify the traditional process in terms of complexity and cost.

In this work, carried out in the framework of the FIREPOCTEP project, the potential of three forestry biomasses (*Pinus pinaster, Eucalyptus globulus* and *Acacia melanoxylon*) as fuels for energy recovery through

microgeneration was investigated. This was done employing those biomasses in a pilot ORC module coupled to a boiler in order to determine microcogeneration feasibility in terms of global efficiency.

2. Materials and methods

To demonstrate the feasibility of the use of microcogeneration as a system for energy recovery of the biomass previously presented, a pilot plant was used with the main following elements:

- A 60-kW multi-fuel boiler (hot source) equipped with a caterpillar burner, fed by a hopper and responsible for generating the thermal energy needed to produce electricity in the ORC (provided by hot water up to 90°C).
- An ORC module thermal machine based on an organic Rankine cycle with a maximum power of 4 electric kW and designed for the use of heat at low temperature (up to 100°C in water) by its conversion into electricity. This system employs an organic refrigerant fluid (R245fa).

Despite being a plant for cogeneration, the experimental system has an aerorefrigerator (cold source) to evacuate the heat from the condenser through a water circuit. This equipment is an air/water heat exchanger that drives air by forced convection to cool the incoming water. The system also has a heatsink in the form of resistors to prevent the injection of electricity generated by the grid. Finally, the plant has a data control and visualization system where all parameters relevant to the operation of the plant are displayed and recorded.

Figure 1 shows the scheme of the ORC module employed.

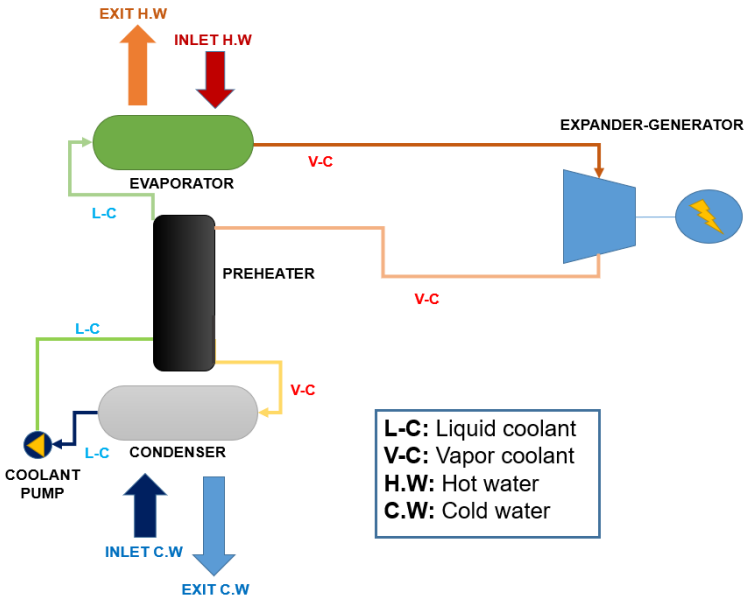

Figure 1- ORC.

As it can be observed in Figure 1, once preheated, the liquid refrigerant is conducted to the evaporator where it changes its state to the vapor phase. It is then led to an expander on whose axis mechanical work is generated. That expander is coupled by a mechanical transmission to an asynchronous generator, producing electrical energy. Once the fluid leaves the expander, already with a reduced pressure, it gives part of the heat in the regenerator or preheater and then goes to a condenser where the vapor – liquid phase change occurs and the cycle can start again in the coolant pump.

Microcogeneration performance is assessed based on the global efficiency obtained (electrical plus thermal). Equations (1) and (2) show the electrical and thermal efficiency calculation.

η_{el}= electrical power on terminals generator (kWe)/thermal power apported by the evaporator (kWt) (1)

η_t = heat provided by the condensator (kWt)/heat captured by the evaporator (kWt) (2)

3. Results

As confirmed by other authors (Peris, 2015), the greater the temperature difference between the hot and the cold source, the greater the electrical power generated by the module studied. This behaviour was also observed for the generated power.

In the tests conducted, values around 4 kW were obtained in all evaluated cases. Using the ORC module used in the present investigation, cogeneration efficiencies close to 97% can be achieved, demonstrating its suitability for energy recovery with the forestry biomasses studied.

4. Conclusions

The results obtained during the preliminary microcogeneration tests show that it is feasible to valorize the selected biomasses (*Pinus pinaster, Eucalyptus globulus* and *Acacia melanoxylon*). The tests carried out make it possible to determine that the temperature differences between the hot and the cold source had a significant influence on the results obtained. In the conditions used in this work, cogeneration yields close to 97% can be obtained (around 9% net electric yield and around 88% thermal yield). Those results are highly promising as micro-cogeneration allows simultaneous heat and electricity production, which opens the door to an interesting way to use forestry wastes for energy production instead of its accumulation and the risk of fire associated.

Atmosphere, turbulence, fire observations, flaming zone

Abstract

Wildfires propagate across vegetated canopies exhibiting complex spread patterns. Wind gusts at the fire-front extend/intensify flames and direct convective heating towards unburnt fuels resulting in rapid acceleration of spread. This behavior could be modulated by ambient atmospheric boundary layer wind turbulence. Our aim is to characterize ambient turbulence over gorse shrub experimental burns and explore how this contributes to fire behavior. Developing coupled fire-atmosphere numerical models capable of resolving most turbulent energy scales is important for understanding rapid and small-scale dynamics. However, it is equally as important to design fire-burn experiments that allow for simultaneous measurements of fire behavior and atmospheric turbulence covering a range of the turbulent spectra. We have completed six experimental burns (24-hectares) in Rakaia, New Zealand under varying wind speed and direction and atmospheric stability regimes. The ignition process ensured a fire-line propagating through dense gorse bush (1m high). Two 30m high sonic anemometer towers measured turbulent wind velocity (20Hz) at six different height levels. Visible imagery was captured for all burns by cameras mounted on Un-crewed Aerial Vehicles (UAV) at 200m AGL. Using wavelet decomposition, we identified different turbulent scales that varied relative to height above vegetation and boundary layer thermal regimes. Quadrant analysis identified statistical distribution of atmospheric sweeps (downbursts of turbulence towards vegetation) and ejections (detachment of turbulence from vegetation). Discrete analysis of sweep/ejection events revealed their temporal and spatial scales and tracked their progression as the flaming zone approached the towers. Undergoing work aims to discern these interactions with observed fire sweeps from aerial imagery by applying image velocimetry techniques and sweep structure tracking.

1. Introduction

Turbulence is a ubiquitous property of the Atmospheric Boundary Layer (ABL) that extends up to 1 or 2km above ground level. ABL turbulence modulates how the near-surface atmosphere interacts with the anomalous/introduced energy perturbations caused by wildfires over timescales of minutes to hours (Stull, 1988). Closer to the surface, turbulent processes control heat, momentum and moisture transport between vegetated surfaces and the overlying Atmospheric Surface Layer (ASL) that extends between 100 and 200m above the surface and strongly influenced by wind shear or mechanically induced turbulence (LeMone et al. 2018). Wildfires produce positively buoyant turbulent motion that can lead to significant downward surges of momentum, interacting with ASL turbulence and potentially modulating a fire's rate of spread over short periods of time. (Heilman et al. 2019; Cunningham & Linn, 2007; Sun et al. 2009). Identifying these processes and studying their characteristics under environmental conditions can lead to better understanding erratic fire behavior.

Experimental field scale fires designed to measure turbulent flux at the fire-atmosphere interface can provide insights into the atmospheric processes controlling fire behavior. These experiments include in-situ tower-mounted sonic anemometer measurements from spreading fires in low grass to higher canopy fuels (Clements

et al., 2006, 2007, 2008; Heilman et al. 2019). Sonic anemometry allows for the ability of measuring 3-dimensional wind velocity, air temperature and humidity at high sampling rate, and quantifying momentum and moisture fluxes between the fire and the integral atmospheric scales measured across an averaging interval. Conclusions are then made regarding the amount of energy exchanged between the fire and the overlying atmosphere, the role of near-surface environmental shear and static stability on fire behavior (Potter, 2012). Other studies (Heilman et al., 2015, 2019) carried out measurements of vertically distributed turbulent heat and momentum flux during a surface fire progressing under 23m high pine trees. Their results confirmed that the largest enhancement of vertical turbulent flux happens at or above canopy levels. Spectral analysis of momentum and heat flux suggested that fire-atmosphere interactions can happen across a wide range of frequencies and further studies are needed to assess how those fluxes feedback into fire behavior. Complex vegetation cover, including spatial density variations, forest gaps and edges, and steep topography will produce spatially complex turbulent interactions. The presence of dense vegetation acts to increase wind shear and the production of turbulent kinetic energy, reduce the mean wind speed and increase gusts, and enhance vertical motion allowing for enhanced downward momentum transfer from the atmospheric surface layer (Kiefer et al. 2018; Schlegel et al. 2012, 2015).

The impact of atmosphere driven momentum surges on fire behavior has not been extensively studied. For grass fires, we now can hypothesize that convective heating pulses originating from the flaming zones are responsible for fuel heating and could play a large role in fire spread in any direction along the fire line (Cunningham & Linn, 2007). These processes have been (Cunningham & Linn, 2007) modelled by couple LES atmospheric-fire models like FIRETEC and observed in laboratory experiments (Finney et al., 2015; Tang et al., 2019). Turbulent flaming zone dynamics can now be observed using thermal image velocimetry techniques for real landscape scale experiments (Katurji et al., 2021), and have been shown to be related to overlying wind turbulence spectra. However, the role of atmospheric source momentum downward surges and their associated turbulence structures have not been studied in relation to fire horizontal convective heating dynamics. In this paper we present observations of characterized atmospheric turbulence strictures over a fast-spreading shrub fire and discuss their implication on fie behavior.

2. Methodology

2.1. Experimental Burn Design

The experimental burn layout is shown in Figure 1 and included 4 burn blocks hereafter referred to as plots P1, P2, P3, and P4. The experiments were carried out on the 2nd and 6th of March 2020 in the Rakaia Valley in New Zealand. Plots 3 and 4 were instrumented with a 30m sonic anemometer tower shown in Figure 1 and instrument setup details are shown in Table 1. The two towers were nearly centered in the burn blocks while the fire line and flaming zone passed across the towers.

Table 1. Observational systems and corresponding measurement parameters and specifications

Observational System	**Instrument**	**Accuracy, range (sensitivity, resolution)**	**Measured variable**	**Installation details**
Nadir visible video acquisition	Video camera (DJI Ltd.12MP RGB)	100m AGL 1920 x 1080 pixels Spatial resolution (pixels/m)	Visible video at 30fps	On Un-crewed Aerial Vehicle (UAV)
In-fire wind turbulence tower	Applied Technologies, Inc. 3-dimensional ultrasonic anemometer – SATI/3(K) series, Campbell Scientific CR6 datalogger	K-probe - 150 mm vertical and horizontal measurement path length. Sampling frequency 20Hz	U (+ve towards east), V (+ve towards north), W (+ve vertically upwards) [ms^{-1}]	1.6m (6h, 6.4h), 5m (18.9h, 20h), and 10m (37.7h, 40h) AGL and perpendicular to fire line

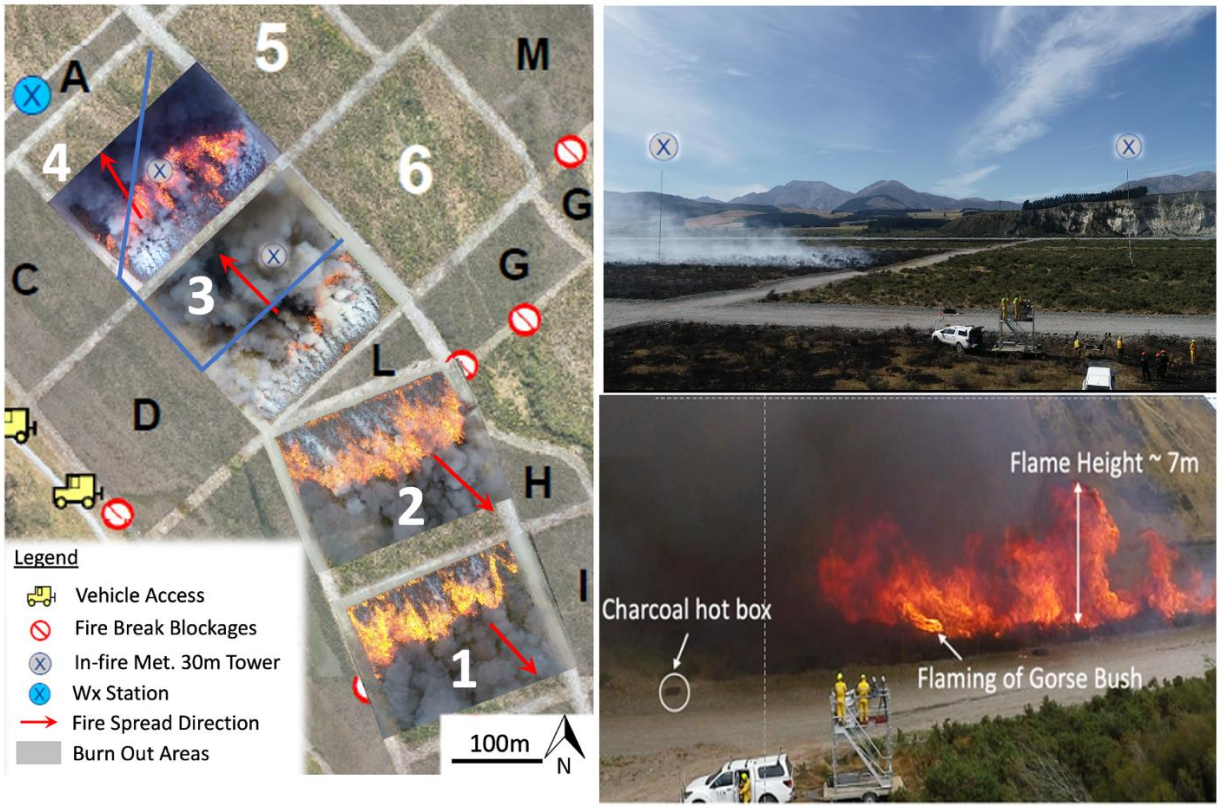

Figure 1- Experimental burn layout showing plot layout, fire spread direction and some site pictures The top view pictures of the flaming zone were taken from a UAV and overlaid on the map at the 2-minute point after the ignition of each plot

2.2. Data Processing

Data de-spiking, sonic tilt and orientation corrections were carried out on the sonic anemometer data – as in Katurji et al. (2021). The streamwise (U), velocity component was then geometrically projected to align with the mean wind direction for all the plots. Aerial video data was collected from nearly 200m above the plots.

2.3. Atmospheric Turbulence Analysis

2.3.1. Wavelet Transform

This study used the python package PYCWT to calculate the wavelet transform for time frequency analysis. Unlike Fourier transform, wavelet transform reserves the temporal information alongside the frequency information and is more suitable to look at the temporal variations of coherent structures in the turbulence time series from the streamwise and vertical wind velocity.

2.3.2. Quadrant Analysis

Wavelet transform can give temporal coherency information at difference frequency scales, but the method cannot distinguish different types of turbulent coherent structures. These involve “ejection motion” associated with turbulent eruption of low momentum streaks away from the surface; “sweep motion” or deceleration of the flow caused by the turbulent motion towards the surface; “outward motion” associated with the acceleration of the flow away from the surface due to low-level convergence; and “inward motions” associated with deceleration of the flow moving towards the surface due to low-level divergence (Christen et al., 2007; Li & Bou-Zeid, 2011; Wallace, 2016). The quadrant analysis in this study uses the instantaneous product of the streamwise (u′) and vertical velocity (w′) perturbations. For momentum flux, if we plot the velocity component pair (u′w′) into the Cartesian plane (abscissa for w′ and ordinate for u′), the first (I) quadrant (+w′-u′) will be outward quadrant while II, III and IV would be sweep, inward and ejection respectively (a sample from the tower data shown in Figure 2.

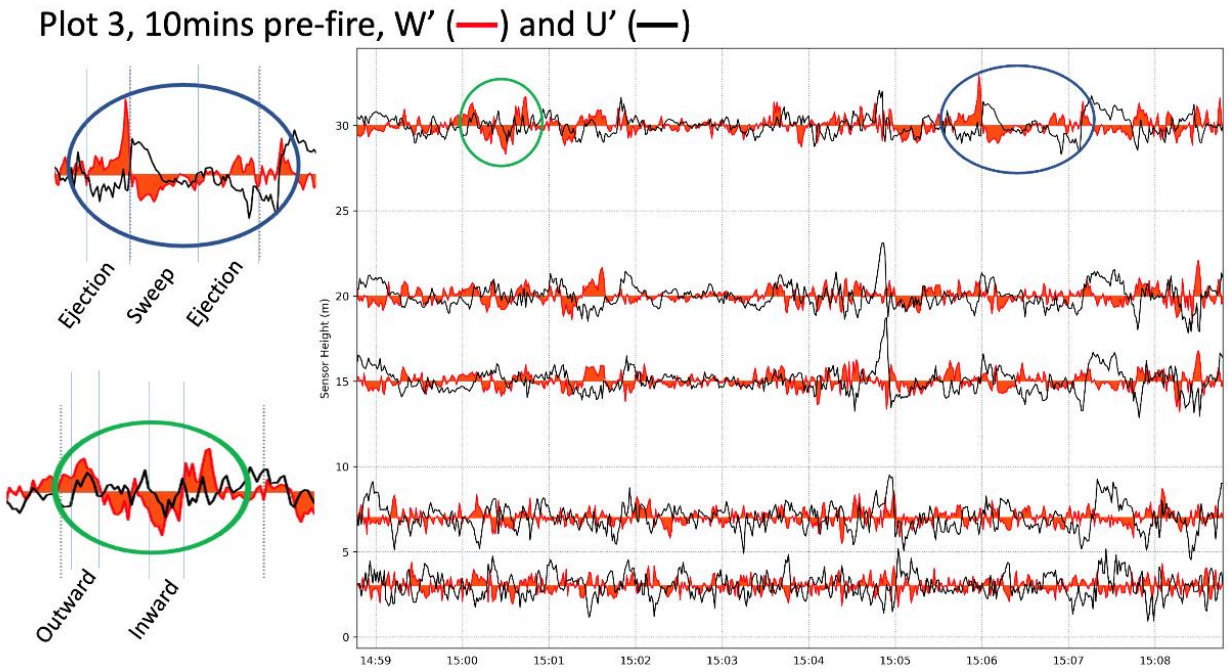

Figure 2- Vertical (streamwise) velocity perturbations from the 30m tower in plot 3. 20Hz perturbations were calculated from a 1-min rolling average window then subsampled with a 1s window average. Examples of sweep, ejection, inward, and outward motions are extracted in the left panel.

2.4. Flaming Zone Observation and Image Velocimetry

Image Velocimetry (IV) (Katurji et al. 2021) was applied on UAV overhead fire videos in order to derive and map the displacement of flame structures shown later in Figure 7. These structures manifest as diverging flame streaks that ignite fuel (example shown in Figure 3b, c). It was found that first-order physical characteristics of the observed fire sweeps, namely divergent fire flow from a near static center, were successfully captured and represented using IV. The ability of image velocimetry to capture physical characteristics of the fire sweeps was leveraged to develop a methodology capable of identifying fire sweeps from overhead UAV videos. This methodology applies a 2D convolution on the displacement vector field, and uses a kernel carefully designed to highlight the characteristics of fire sweeps spatially and temporally. The resultant scalar field represents a 2D map of the likelihood of occurrence of fire sweep, which is mainly limited by the size of the kernel and by the difficulty to calibrate it other than by visual inspection.

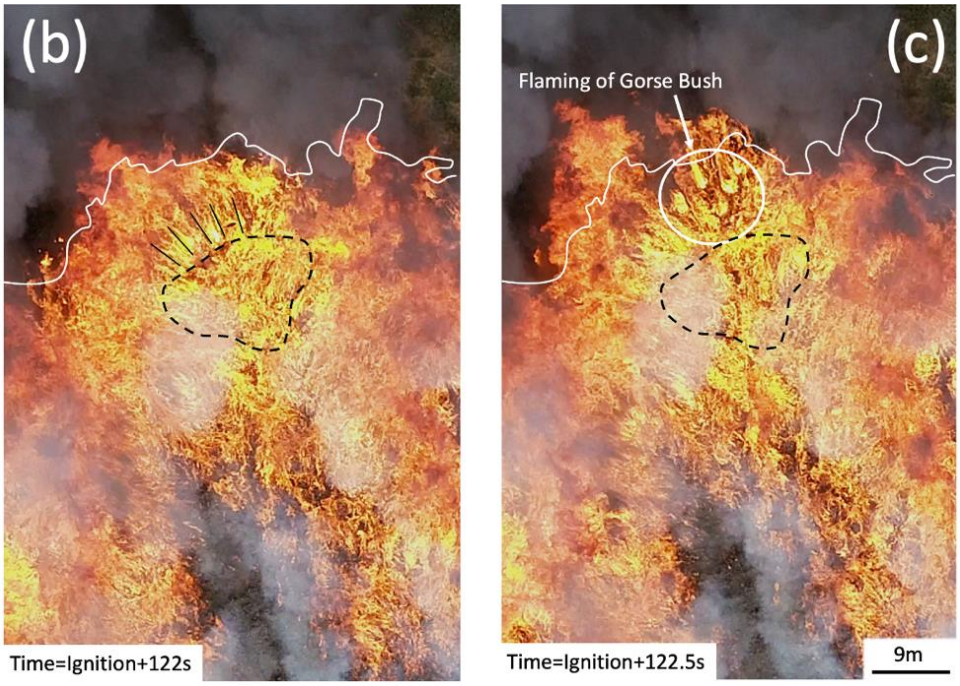

Figure 3- Observed flaming zone from nearly 200m AGL using a UAV. The black dotted outline in (b) and (c) shows the area of a fire "sweep" and its impact on vegetation ignition.

3. Results and Discussion

3.1. Meteorological and Burn Conditions

Burn events for plots 3 and 4 were associated with a typical up-valley afternoon air flow up to 1.5 ºC fluctuations in air temperature associate with the convective boundary layer (see third panel of Figure 4). Plots 1 and 2 were conducted under a synoptically driven nor-wester wind regime that produced orographically channeled down-valley winds, and warmer and drier air conditions as the airflow descended from the New Zealand Southern Alps towards the Rakaia valley. The burn time for all plots varied between 3 and 5 mins with an initial straight-line ignition and a wind driven flaming process.

Table 2. Fire behavior, and meteorological conditions (averaged over duration of burns) recorded at from the weather station tower marked by a blue circled "x" in Figure 1

Plot	Ignition time (plot edge reached) [NZDT]	Tair [°C] (RH) [%]	Wind speed [ms^{-1}] (direction) [°]	Mean gorse height [m]	Pre-burn gorse (grass, litter, debris) fuel load [kg m^{-2}]	Total fuel consumption [kg m^{-2}]	Rate of spread [m/s]	Flame height [m]
P1	02/03/2020, 10:10 (10:14)	20.7, (36)	8.27 (310)	0.83	1.8 (0.1,0.7,0.8)	2.5	0.89	4.9
P2	02/03/2020, 12:11 (12:14)	22.9, (33)	9.8 (311)	1.10	4.1 (0.3,1.3,1.7)	6.7	0.92	3.7
P3	06/03/2020, 15:08 (15:12)	21.6, (41)	6.8 (146)	0.84	2.2 (0.2,0.6,0.4)	2.4	0.9	5.4
P4	06/03/2020, 13:31 (13:36)	20.0, (43)	5.0 (142)	0.85	2.5 (0.7,0.7,1.0)	3.4	0.75	5.6

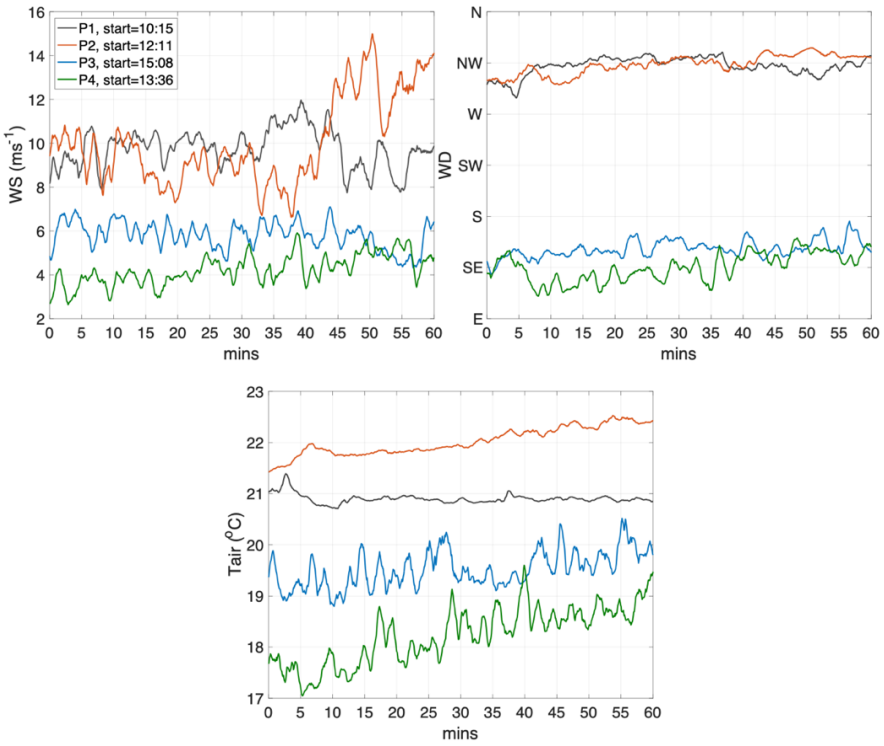

Figure 4- Time series of wind speed (WS), direction (WD), and air temperature (Tair) for 1-hour pre-fire at 30m AGL and 1min average interval. Plots 1 (P1), P2, P3, and P4 are shown indifferent colors with the start time hh:mm in NZDT indicated for each

3.2. Wind Turbulence Spectra

For all the plots, the integral time scales (usually detected when a power peak is evident) of turbulent wind velocity appear to get shorter as the measurement gets closer to the canopy (Figure 5), which is in accordance with boundary-layer turbulence theory. For heights less than 15m, where the observed flame heights (Table 2) occurred between 3 and 6 m, the results suggest that the energetic turbulent motion along the streamwise wind direction can occur between 2 and 32s. These results also show that the turbulent time scales vary between the atmospheric stability regimes of plots P1 and P2 compared to P3 and P4. Results from the vertical wind spectra, not shown in this extended abstract, reveal much shorter integral time scales for P1 and P2 (around 1 s) compared to P3 and P4 (between 3 and 5 s) when atmospheric turbulence was largely dominated by a thermal regime as opposed to the wind shear dominated regime of P1 and P2.

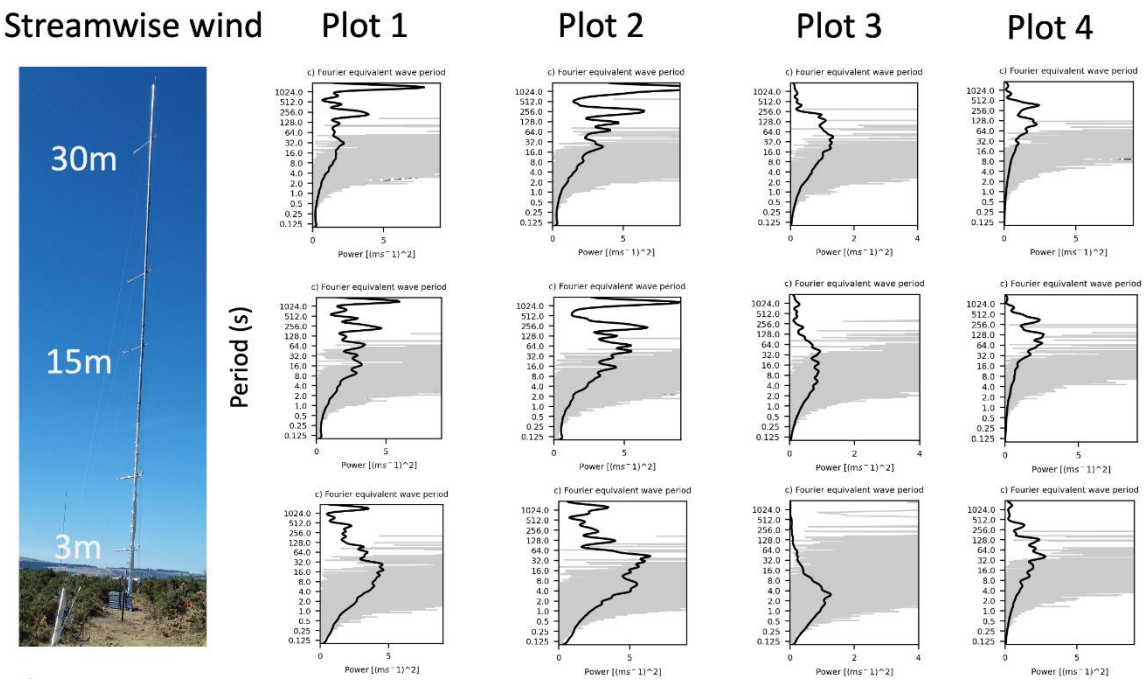

Figure 5- Black line shows the time integrated spectra across the wavelet time frequency decomposition showing the integral time scales (period on the y-axis) versus spectral power (on x-axis) for plots 1, 2, 3, and 4 and for three selected height levels on the tower (3, 15, and 30m). The gray line shows the Fast Fourier decomposition inserted for reference but not used in the analysis.

3.3. Atmospheric Sweep, Ejection, Inward and Outward Motions

Atmospheric turbulent structures plotted against time for all the plots (Figure 6) show more sweep and ejection events than inward and outward events. It has been previously suggested that coherent sweep (gust) and ejection (burst) motions dominate near-surface momentum and scalar fluxes(Li & Bou-Zeid, 2011). The reduction of the number of inward and outward motions for P1 and P2 compared to P3 and P4 does support the earlier findings of the integral time scale difference between the shear driven surface layer condition of P1 and P2 and the thermally driven surface layer turbulent motion of P3 and P4. Forward slanting coherence of sweep and ejection structures (highlighted in yellow - Figure 6) across the 30m tower height suggest that events can originate from within the surface layer (above the observed 30m roughness boundary layer) and impinge on the surface. These types of interactions will have a time scale associated with them (the width of the black boxes) and are being investigated as part of the ongoing work for this research. These events can be significant as it is our hypothesis that fire "sweeps", explained in the following section, can be impacted by these atmospheric turbulent structures by prolonging their duration and/or expanding the flame-vegetation interaction zone.

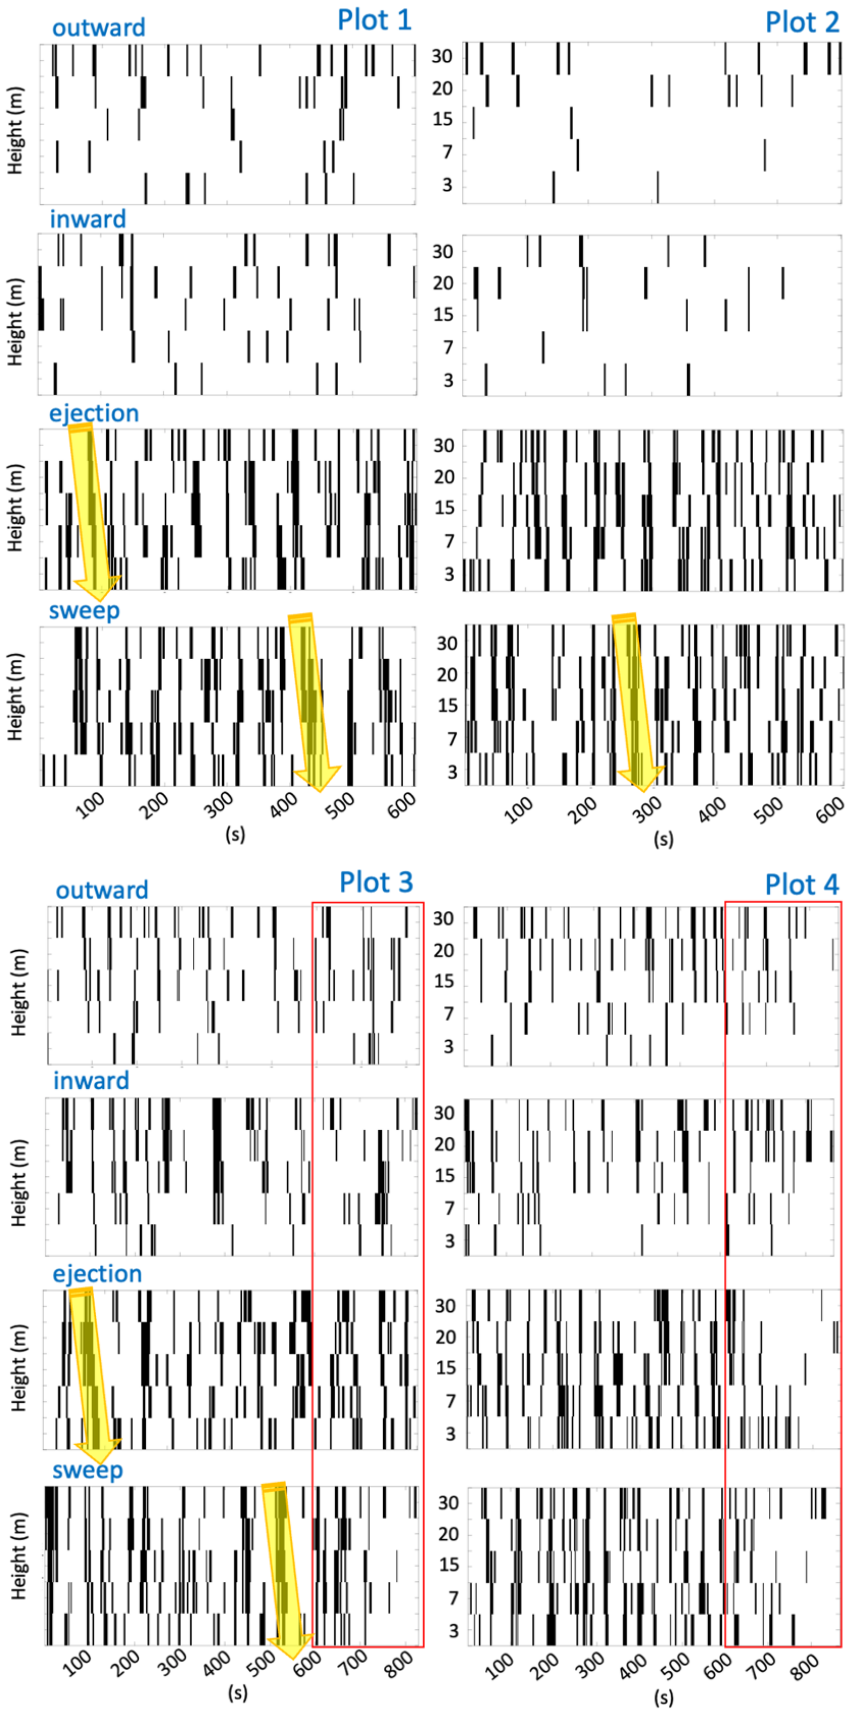

Figure 6- Sweep, ejection, inward and outward events detected at all the 5 height levels of the in-situ tower for plots 1, 2, 3 and 4. The red outlined box shows the period when the fire was progressing through plots 3 and 4. The yellow arrows show examples of downwards propagating structures

3.4. Flaming Zone and Fire Sweep Observations

UAV overhead visible video of the gorse vegetation fire carried out in P2 were selected for this preliminary analysis. Figure 7 highlights the observable flaming zone and some of its main features during the steady-state phase of the fire spread. The flaming zone dynamics was characterized by intermittent "fire bursts" in which clusters of unburned fuel were covered by the fire and ignited. Fire bursts were typically accompanied by strong tilting of the flame front inducing, in most of the cases, direct flame impingement.

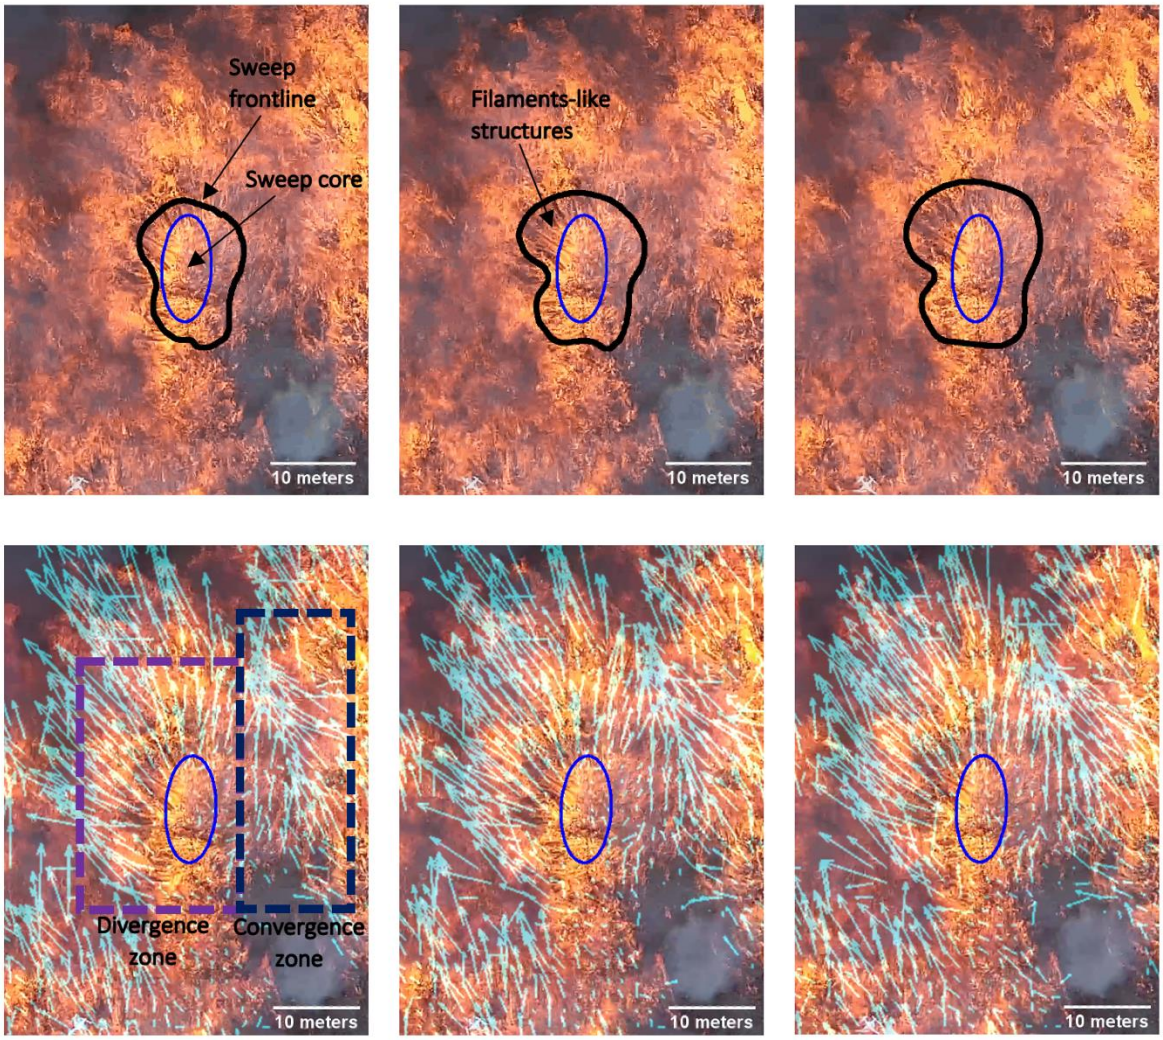

Figure 7- Time sequenced (at 1/30 s interval) frames extracted from the UAV video recorded during the P2 burn and an example of the resulting image velocimetry of identified fire sweep" events"

The structures in Figure 7, are referred to as *fire sweeps*, and are characterized by divergent motion of fire (or *fire sweep frontline*, black line) from a nearly static luminous region (or *fire sweep core*, region inside blue line). Structures with these characteristics were identified sporadically at multiple locations into the flaming zone. Generally, they were found to have a characteristic length of ~ 10 m during the incipient stage up to ~20-30 m during its peak. High luminosity inside the core region of the fire sweeps can last several seconds, and is recurrently accompanied with filament-like fire structures located around the it, which are characterized by divergent motion of the fire with higher spatiotemporal frequency. Inspection of side-view UAV footage (not shown here) suggests that tilted flames from individual bushes located near the core region are at the origin of these structures. Preliminary results from 2D convolution approach was used to track individual fire sweeps and estimate their duration. Two main groups of fire sweeps were identified. The first group is characterized by short-duration structures (< 1 s), generally quickly appearing and disappearing sporadically with short displacement through the flaming zone. Fire sweeps of the second group presented longer durations (up to 4 s) and were observed to move across the flaming zone, some of them from the back to the head of the fire.

4. Conclusion and Ongoing Work

Experimental fire observations included turbulent wind velocity measurements from a 30m tower and UAV-based video in nadir from nearly 200m above the flaming zone. The methods focussed on characterizing the overlying atmospheric turbulence strutcure, Image Velocitmetry (IV) and feature tracking of *fire sweeps*. More IV is planned and will be used to derive and map the displacement of *fire sweeps* and their durations and will be compared with statistical distribution of atmospheric turbulent motions and their durations.

The observations from the gorse aerial imaging of the flaming zone and some of the *fire sweep* processes are similar to the results of the numerical modelling of a spreading fire using FireTec (Cunningham & Linn, 2007). Their simulations included wind speed ranges similar to the conditions of the gorse fire experiment but without atmospheric boundary layer turbulence. The fire produced a series of regular streamwise vortices with flame buoyancy lifting air along the updraft lines and descending between two flaming corridors causing a *fire sweep*. The scale of one of the fire sweep in the Firetec simulations was between 10 and 20m, which is not very dissimilar to the scales we analyzed in this study.

5. Acknowledgements

We would like to give a special thanks to all field support teams including technical and general staff. We also thank landowner for their various contributions leading to the success of the field campaigns. University of Canterbury atmospheric research team would like to acknowledge the very thoughtful, well organized, and proactive support we have received from all the volunteering firefighting crew. The success of our experiments and the safety of our science crew can only be partially attributed to our design but greatly attributed to the safe and well-executed plan from the volunteer crew. A special thanks to the Scion UAV crew: Robin Hartley and Peter Massam. This research was co-funded by Ministry of Business, Innovation and Employment (MBIE), New Zealand, grant number C04X1603 and C04X2103.

Abstract

Go-to strategies to contain advancing wildfires with water as an extinguishing agent can be differentiated in ground- and air-based techniques. Ground-based techniques rely on man-held nozzles connected to a water reservoir such as the water tank on a fire truck. This approach can only be used for fires with intensities below 2000kW/m above which it is deemed unsafe. For higher intensity water is dropped ahead or on top of burning materials. Recent studies have unveiled how inefficient these approaches can be. Studies characterising aerial drops make use of water rigs fitted with nozzles. We propose to scale up such mimicking devices to a novel type of appliance which can be used to contain a fire front of several hundreds of meters length. We show the typical wetting pattern obtained as well as the effective containment of fires reaching intensities above 2500 kW/m.

1. Aerial drop characterisation

Above a certain wildfire intensity, ground-based operations involving personel presence in proximity of the fire front can not be carried out. Aerial support from planes and helicopters are required. The desired effect of aerial water drops is a reduction in the fire intensity to reach levels allowing for ground crews to intervene. The efficiency of such drops on reduction of fire intensity has become the subject of critical review. Indeed, studies show that such operations are effective in only 30% of the cases.[1] Reasons for this inefficiency can be the poor control over the water distribution on the ground and the "shadowing" effect of leaf cover not allowing for the water to reach the ground with the fire progressing in still dry vegetation. A further aspect which has not been fully investigated is the turbulence occurring around an aerial drop, which can fan the wind and thus be enitrely counter-productive.

Setups have been devised to characterise aerial drops. Arrays of cups have been placed on an airstrip to obtain the wetting pattern of a certain aerial mean. This obviously has been carried out at ideal dropping heights in absence of strong wind, which can make the relationship between these idealised wetting patterns and real wetting patterns in proximity of a wildfire difficult. Models have been proposed in order to provide a basis for water distribution in fire management tools.[2] Linking the water distribution to effective containment can be achieved empirically, highlighting the critical aspect of homogeneous water distribution.[3] Indeed patches which receive less than a critical amount of water still allow for fire progression.

The critical amount of water remains surprisingly an elusive parameter. Little research has been carried out on the critical apparent fuel moisture content required to inhibit fire progression. Lab-scale experiments provide hints at certain species requiring a higher exposure to water before reaching pyrolysis temperature.[4]

2. Wetting pattern characterisation in wind tunnel

We take inspiration of such experimental rigs with nozzles to propose a novel containment tool in itself. Such a construction can provide with well-controlled water distribution. With a given flow rate, the running time is the only parameter controlling the amount of water spent on the surrounding vegetation. Knowing the fuel type and density it should be possible to estimate the critical amount of water and thus the required running time of the system.

We carry out similar experiments to the aerial drop characterisation by arranging an array of plastic containers in a wind tunnel. A nozzle is placed laterally to the array and exposed to various wind patterns mimicking real conditions to characterise its wetting pattern on the ground. The nozzle is optimised so as to allow for a homogeneous distribution even in presence of the strongest wind attainable in the facility (3 m/s). Details of the wetting pattern are kept confidential.

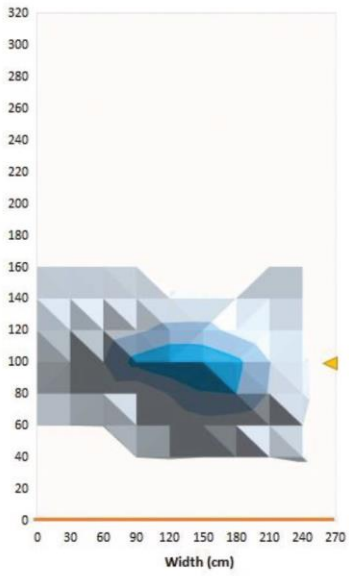

Figure 1: Wetting pattern of nozzle (triangle) over plastic container array in absence of wind.

The droplet dimension distribution is chosen so as to allow for both a wetting of the surrounding vegetation as well as to produce wind-entrained droplets of smaller diameter. This combination will allow the effective wetting of the vegetation, avoiding the "shadowing" effect. Similarly, the entrainment of droplets will allow them to wet vegetation in the general spread direction of the fire and will therefore not be wasted. The effect of increased humidity levels obtained on the extinguishment of flying embers remains to be studied. More detailed PIV analysis in presence of surface-tension modifying agents is also under progress.

3. Effective fire containment in field experiments

A series of selected nozzles is connected by the means of firefighting hoses, forming a closed loop with the single opening being connected to the water reservoir of a fire truck. The hose loop is placed in the top third of a plot of 25meters width and 50 meters length and dubbed Papageno system for the remainder. Water is then pumped at standard operational pressure. After a wetting time of 60 minutes a fire is ignited at the lower section and left to progress towards the system. Infrared images allow for the determination of the rate of spread. Similarly the flame length is recorded. Both indicators (flame lenght of 7 meters and derived fireline intensity of 2500kW/m) place the fire in an intensity regime too high to be safely contained using ground-based approaches. Upon approaching the Papageno system, the fire intensity drops and eventually is contained at the height of the system. The exact dynamics of intensity drop upon approach are still under investigation.

Figure 2: Effective fire containment using the Papageno system

4. Conclusion and outlook

We propose a novel fire containment tool consisting of a hose lenght with bespoke nozzles at regular intervals. The autonomous system allows for the safe retreat of practitioners outside of the danger zone, can operate at night and in presence of strong winds and allows for resource-efficient operations. Further field tests are required to characterise the operating windows of the system. Similarly we strongly recommend to pursue studies allowing for an effective understanding of critical amount of water as a function of fire intensity, which in turn is dictated by fuel type and density.

BRIDGE – a participatory-action research project for community engagement in forest fire risk prevention

Abstract

This brief introduces the BRIDGE research project, its core objectives and the main activities that are being developed in view of stimulating local action for forest fires risk reduction. BRIDGE is a participatory action research project (PCIF/AGT/0072/2019) that aims to develop an integrative approach to different forms of knowledge and action, linking science and local communities, to reduce the vulnerability and enhance strategies for forest fire risk reduction, mainly through collective and preventive action. It was initiated in March 2021 as a consortium coordinated by the Instituto Superior Técnico, Universidade de Lisboa, also including the Laboratório Nacional de Engenharia Civil and the Universidade of Algarve. BRIDGE adopted the Monchique municipality (southern Portugal, Algarve region) as a case study, but aims to develop knowledge, tools and experiences that can be shared with other forest fire risk prone regions in Portugal and elsewhere.

An Innovation Laboratory (InnoLab) is central in BRIDGE as a privileged space aiming to promote dialogue and knowledge sharing between local communities, science and organizations involved in forest fire risk reduction, in this case in the Monchique municipality. The main objective of the InnoLab is to bring together all relevant multiple actors that act, directly or indirectly, in the management of forest territories to promote social learning about forest wildfire risk, strengthening networks and building skills and capacities, both socially and institutionally, to foster participatory processes focused on forest fire risk reduction. A Participatory Mapping method was adopted in InnoLab involving the local community, in particular landowners of Monchique, placing them at the centre of the process of identification, analysis and management of forest fire risks, valuing local knowledge and experiences to reduce vulnerabilities and strengthen adaptive capacities from the perspective of local resilience.

This brief will share achieved outcomes with the participatory mapping involving local landowners of Monchique. It represented an important social practice to foster capacity-building and collaborative actions to forest fire prevention. It also represented an opportunity to promote social learning to better understand forest territories focusing on key issues in forest fire prevention, local vulnerabilities and adaptive capacities, to trigger a Community-based Disaster Risk Reduction (CBDRR) process in Monchique.

1. The BRIDGE Project

This brief introduces the BRIDGE research project, its core objectives and the main activities that are being developed in view of stimulating local action for forest fire prevention. BRIDGE is a participatory action research project (PCIF/AGT/0072/2019) about the development of strategies for forest fire risk reduction, mainly through preventive action. It builds upon scientific and local knowledge and engages local community

action. BRIDGE means linking science and local communities to reduce the vulnerability to forest fires risk. It was initiated in March 2021, with the Instituto Superior Técnico, Universidade de Lisboa coordinating a consortium that includes the Laboratório Nacional de Engenharia Civil and the Universidade of Algarve.

BRIDGE main objective is to integrate different forms of knowledge, explore the nexus society-science-policy to contribute to stimulate forms of local action that build upon communities improved capacities of self-protection and management of local territories and ecologies. BRIDGE builds upon bottom-up approaches but also on top-down approaches, to connect to relevant policies and management orientations that are established at national and European levels. BRIDGE adopted the Monchique municipality (southern Portugal, Algarve region) as a case study, but aims to develop knowledge, tools and experiences that can be shared with other forest fire risk prone regions in Portugal and elsewhere.

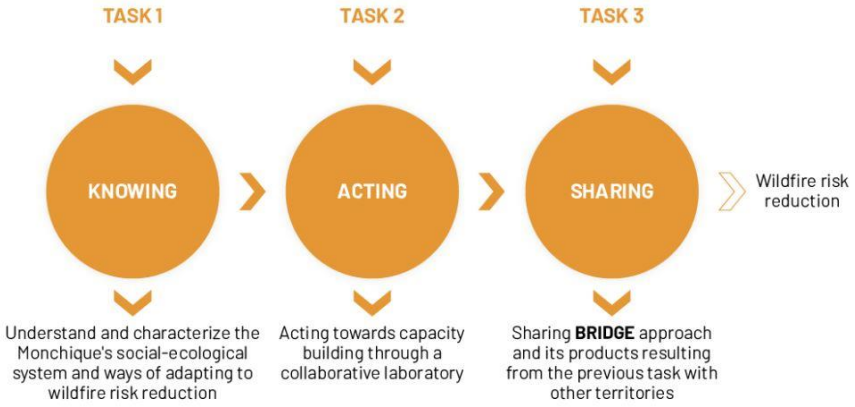

Figure 1. Main tasks of BRIDGE Project (own authors)

BRIDGE is structured in three main tasks (**Figure 1**). The first task is dedicated to improve our project team knowledge on the socio-ecological systems in Monchique and what have been forms of human adaptation to fire risk. The second task is the essence of the participatory action research during which, through the development of a collaborative innovation laboratory (InnoLab), the project aims to improve local capacities and promote dialogues that enable collective learning and sharing of knowledge and experiences on forms of reducing forest fire risks and local vulnerability. The third task aims to share with the outside communities and other territories prone to forest fire risk, what have been learnings and progresses achieved with the local community in Monchique.

In this brief we introduce our conceptualisation of the InnoLab where those collective debates are being and will be further promoted, and also share achieved outcomes from participatory mapping methodology applied in InnoLab meetings involving local landowners of Monchique. These meetings represented an important social practice to foster capacity-building and collaborative actions in view of forest fire prevention and an opportunity to promote social learning on key issues in forest fire prevention and adaptive capacities that can lead to better local resilience.

2. InnoLab: conceptualisation

An Innovation Laboratory (InnoLab) is central in BRIDGE as a privileged space aiming to promote dialogue and knowledge sharing between local communities, science and organizations involved in forest fire risk reduction. The main objective of the InnoLab in Monchique is to bring together all relevant actors that act, directly or indirectly, in the management of forest territories, promoting social learning about forest fire risk, strengthening actors' networks, building skills and capacities, both socially and institutionally, and fostering participatory processes focused on forest fire risk reduction. The ideation of the InnoLab is anchored in the support to create a common purpose of sharing knowledge and experiences and build together multiple forms of collaboration that can stimulate and promote a community-based disaster risk reduction (CBDRR).

Participatory mapping has been widely used in processes of CBDRR (e.g., Gaillard and Maceda, 2009), promoting knowledge exchange among various actors (Rizzi and Porebska, 2020). The use of this methodology

allows visual expressions of the realities perceived by the community, realities expressed through 'filtered' characteristics of the territory (Bartolucci et al., 2022). It contributes to the interpretation of risk areas, local vulnerabilities, allowing the identification of critical issues for a successful disaster risk management and to direct desired and useful risk reduction measures for the community (Cadag and Gaillard, 2012).

In March and April 2022, BRIDGE developed a participatory mapping methodology in InnoLab meetings with local landowners in Monchique, placing them at the centre of the process of identification and analysis of forest fire risk, valuing local knowledge and experiences to strengthen adaptive capacities from the perspective of self-organisation and local resilience (**Figure 2**). In total 30 landowners were involved in the participatory mapping, as members representing one of the followung organisations: Association of Forest Producers of Barlavento Algarvio (Aspaflobal) and/or Agricultural Cooperative of Monchique (Coopachique), A Nossa Terra Environmental Association and Monchique Alerta Association, the last formed by local landowners directly affected by the 2018 forest fire in Monchique.

Figure 2. Participatory Mapping with landowners of Monchique (BRIDGE)

An interesting aspect observed in the participatory mapping involving landowners in Monchique are the different local visions and interests related to forest territories. While some see the forest resources as a source of income based on forest production (in general Portuguese landowners and members of Aspaflobal and/or Coopachique), others focus on the valorisation of forest resources from the perspective of the landscape and local biodiversity (mainly in foreign landowners and members of the associations Nossa Terra and Monchique Alerta). However, even with different interests, visions and expectations, an interesting result of the participatory mapping was the convergent local knowledge of different groups of landowners about the current fire-prone areas, the main factors of forest fire risk and the local vulnerabilities of Monchique's forest territories.

The participatory mapping resulted in an important and valuable georeferenced database (GIS), elaborated on the basis of the perceptions of Monchique's community of landowners and the knowledge of local actors who act directly in the management of Monchique's forest territories. The GIS database resulted in the Integrated Map (Figure 3) containing information such as: location of participants' properties and/or houses, commonly used local access routes, forest areas of relevance and interest to participants, identification of vulnerable residents in the context of forest fires (children, the elderly, people with special needs, etc.), currently fire prone areas, main risk factors and local vulnerabilities in Monchique.

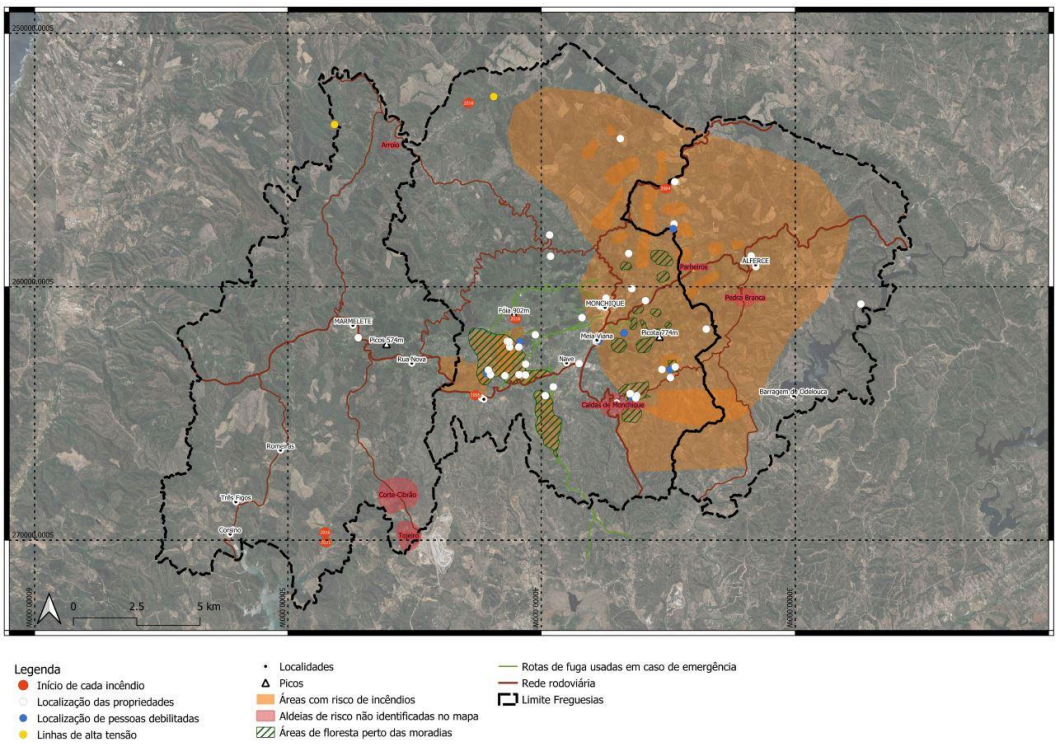

Figure 3. Participatory Map with landowners of Monchique (BRIDGE)

This GIS database, and the respective information that resulted from the debate and collective reflections involving the community of landowners, can contribute to (re)orient strategies for forest fire prevention with a bottom-up perspective, based on local knowledge and expectations. It can also contribute to (re)direct plans, programmes and policies (PPP) tailored to the local reality and specificities of Monchique, for example, the review of the Municipal Forest Defence and Fire Fighting Plan (PMDFCI) and the review of territorial development plans (e.g. Municipal Master Plan, Landscape Management and Recovery Plan, among others).

In line with scholars' suggestions in the literature, the participatory mapping also represent the opportunity for a collective debate on key issues in disaster risk management, promoting a fair and balanced dialogue (Kurastmoko et al., 2017), as well as better understanding of the territory through a social learning process (Kienberger, 2014; Wolf, 2021). In BRIDGE it is emphasized that beyond an important database that integrates diverse views, experiences, and local knowledge, the participatory mapping represents an important social practice to extend adaptive capacities to disasters (Haworth et al., 2016).

The participatory mapping developed in the BRIDGE InnoLab represent, therefore, an opportunity to involve landowners of Monchique in a social learning process on key issues in forest fire risk and prevention. Thus, it contributes to increase the understanding of forest territories, with a potential to reduce vulnerabilities and strengthening adaptive capacities to forest fire risk from the perspective of self-organization and local resilience, as well as to trigger a community-based disaster risk reduction (CBDRR) process in Monchique.

Canopy base height, canopy fuel load, canopy bulk density, airborne laser scanning, fuel maps

Abstract

Canopy fuel characterization is highly relevant for wildfire prevention, especially in the context of extreme events involving crown fires. Airborne laser scanning has been proven very useful to retrieve 3D forest structure at large scales, becoming freely available in many countries in the recent years which provide an opportunity to map fuel parameters that are critical for fire behaviour simulation. Previous studies on canopy fuel modelling predict canopy base height (CBH), fuel load (CFL) and bulk density (CBD) mainly in tree species from temperate conifer forests, with specific models still lacking for the main Mediterranean forest stands and especially deciduous species. This work presents first results of models obtained from low density airborne LiDAR data (1.5 p/m2) for canopy fuel characterization of critical structural variables (CBH, CFL and CBD) in the main Mediterranean forest stands existing in Andalusia region, including Pinus sp, Quercus sp and Eucalyptus sp tree species. The study is part of an ongoing project that include field inventory in 750 plots to characterize canopy fuels in 15 different forest stands representative of Mediterranean tree species, with a samplig design that consider structural heterogeneity in a wide study area (29000 km2). Different modelling techniques (linear regression and random foresst) were tested to assess the best formulation and input LiDAR metrics to be included in the models for each fuel parameter estimation, that will be used to generate high resolution maps of canopy fuels at regional scale. Preliminary models obtained from a set of 170 field plots in pure stands of Quercus ilex, Quercus suber, Pinus halepensis, Pinus pinea and Eucaliptus sp show promising results for canopy fuel characterization from low density airborne LiDAR data in these widely distributed species. However, our results also highlight a significant effect of the different modelling tecniques on the input metrics and accuracy of the models.

1. Introduction

Canopy fuel characterization is highly relevant for wildfire prevention and management, especially regarding potential extreme fire behaviour involving crown fires. Canopy base height (CBH), fuel load (CFL) and bulk density (CBD) are the main canopy structure variables conditioning fire initiation and spread rate in the transition of flames from surface fuels to canopy fuels (Van Wagner, 1977; Cruz et al., 2003; Molina et al., 2014). Fire simulation software can be used to predict fire behaviour but requires high resolution fuel maps of both surface and canopy fuels. Fire managers are increasingly using this kind of simulation programs for operational use, fuel treatment planning and fire severity assessment, demanding updated fuel cartography at regional scales.

LiDAR (Laser Imaging Detection and Ranging) technology has been proven very useful to characterize 3D forest structure, including canopy fuels (Riaño et al. 2003; Andersen 2005; Hudak et al. 2008). Free LiDAR data from airborne platforms are becoming available in more countries in the recent year (e.g. Spain, Finland, Slovenia or France), being a revolution on data gathering for forest monitoring at large scales. For example, the Spanish National Plan for Aerial Orthophotography (PNOA) is providing the second nation-wide coverage of LiDAR data at low pulse density in Spain and already planning the third coverage to start next year. Hence, airborne LiDAR data give an opportunity to get spatially-explicit information to map fuel parameters that are critical for fire behaviour simulation.

Previous studies on canopy fuel modelling with airborne LiDAR include CBH, CFL and CBD models, showing different success depending on the fuel parameter and laser pulse density used. The main tree species assessed include North-American and European conifers, mostly typical of temperate forests (Andersen et al. 2005,

Riaño et al. 2003; González-Olabarria et al, 2012; Gonzalez-Ferreiro et al. 2014, 2017; Alonso-Rego et al., 2021), and some studies for Mediterranean tree species but fitted with field data from small areas with limited transferability (Botequim et al, 2019; Ferrer Palomino y Rodriguez y Silva, 2021). Specific models are needed to get reliable estimation of canopy fuels at regional scale, but information is still lacking for many Mediterranean forest stands, especially deciduous species.

The aim of the present study is to explore different modelling techniques to obtain models for canopy fuel varaibles (CBH, CFL and CBD) from low density airborne LiDAR data for the main Mediterranean forest stands, including *Pinus sp*, *Quercus sp* and *Eucalyptus sp* tree species, and considering the structural heterogeneity from a wide study area. The work is part of a wider project on forest fuel characterization in Andalusia region that is currently ongoing. The best models obtained will be used to generate high resolution maps of canopy fuels at a regional scale.

2. Methods

2.1. Study area and field data

The study area includes the forest stands located in the Andalusia region, in the south of Spain (Figure 1). Most of them are located within the High Wildfire Risk areas ("Zonas de Alto Riesgo de incendio forestal", ZAR) which cover 58% of the whole Andalusian territory, e.i. more than 29000 km^2. The most representative forest stands in terms of area covered and potential fire risk were selected for canopy fuel characterization in the field, resulting in 15 different forest ecosystems (Table 1). Tree species composition was derived from a detailed vegetation map (1:10000 scale) available for Andalusia region. Selected forest ecosystems included pure stands (one dominant tree species) and mixed stands (minimum of 25% of relative canopy cover of the secondary tree species), covering 85% of the forest areas in the region.

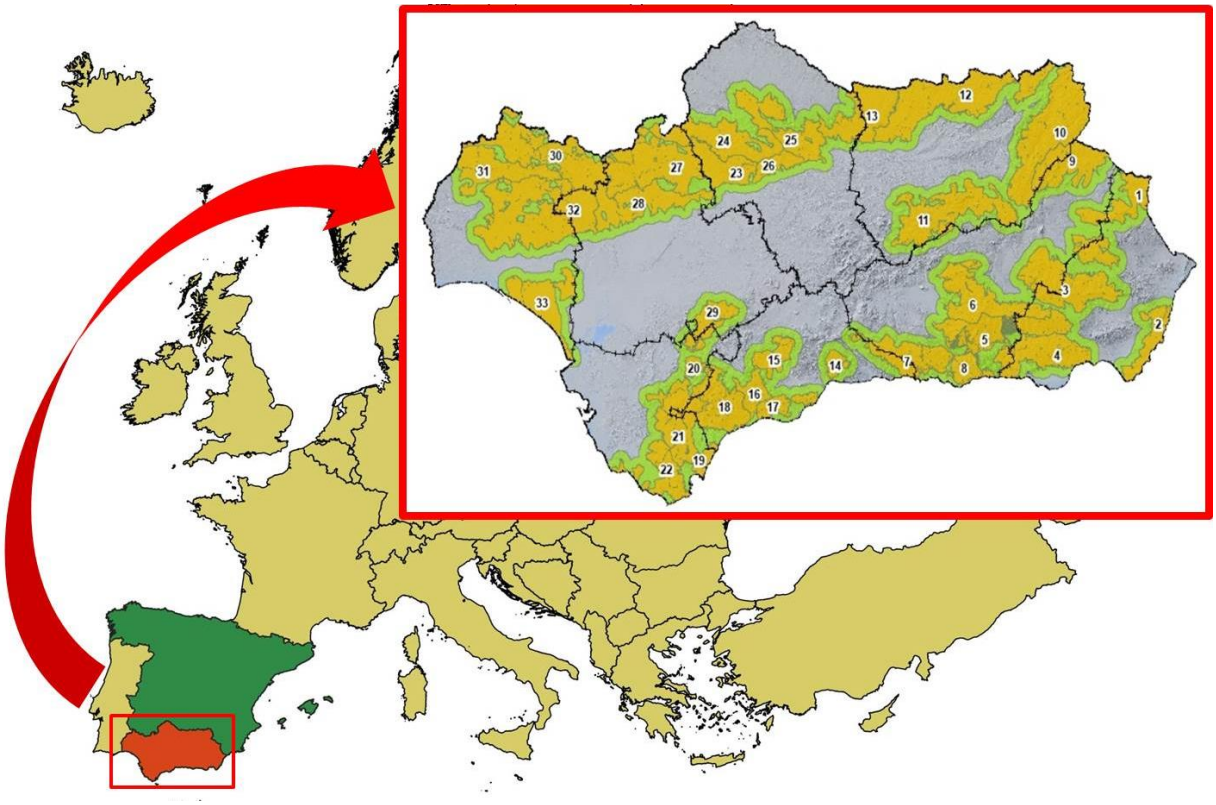

Figure 1- Study area, with detail of the High Wildfire Risk areas (ZAR) in Andalusia (orange) and a 5-km buffer included (green)

A total of 750 field plots will be placed in the selected forest stands including the main Mediterranean tree species. According to the area covered by each forest ecosystem in the study region, between 30 to 90 circular plots will be measured to retrieve canopy fuel data for each forest stand type. Plot locations are chosen in order

to cover the range of structural variability according to the Spanish National Forest Inventory IFN3 (MARM, 2008) and LiDAR data, considering metrics related to fractional canopy cover (FCC), height (H) and canopy relief ratio (CRR) to identify structural heterogeneity in each forest ecosystem (Parker and Russ, 2004).

A GPS providing sub-metre accuracy is used to registered plot centre coordinates for proper LiDAR data comparison in the modelling process. Field measurements are performed in 11.3-m-radius circular plots, equivalent to the 20-m-pixel canopy fuel maps to be generated for the study area. In each plot, diameter at breast height (DBH) of trees thicker than 7.5 cm is measured and used to calculate crown foliar biomass from previous allometric equations developed for each species (Montero et al. 2005). Available canopy fuel load at plot level (CFL) is calculated as the foliar biomass in the stand (kg/m^2).Tree height and crown base height are registered in 4 representative trees per plot, selecting one tree within each quarter section of the circular plot to characterize the mean stand height and canopy base height (CBH). Canopy bulk density (CBD) is calculated from CFL and mean canopy length at plot level, the latter being obtained as H minus CBH.

Table 1- Selected forest stands for canopy fuel modelling at regional scale. *P: pure stands; M: mixed stands; P & M: pure and mixed stands

Forest stand	**Area (ha)**	**Stand type***
Quercus ilex	1218082	P
Pinus halepensis	241798	P
Pinus pinea	206213	P
Quercus suber	190698	P
Eucalyptus sp	138373	P
Olea europaea var. sylvestris	138334	P & M
Pinus pinaster	116117	P

Pinus pinea & Quercus ilex / Quercus suber	19370	M
Quercus suber & other Quercus sp	17460	P & M
Eucalyptus sp & Pinus sp	10510	M
TOTAL	**2480268**	

2.2. LIDAR data

The LiDAR data used in this study correspond to the 2nd regional cover of Spanish PNOA in Andalusia, acquired between 2020 and 2021 at a pulse density of 1.5 p/m^2. Point cloud files were provided in LAZ format and processed using R software (R Development Core Team, 2014) with lidR package (Roussel *et al*. 2020) and QGIS software (QGIS Development Team, 2014). Points classified as soil returns were used to generate a digital terrain model (DTM) at 2m resolution. Points classified as vegetation returns were normalized with DTM to retrieve heights to soil level. LiDAR metrics were extracted from point clouds at plot level to compare with field measurements (Figure 2). Two different thresholds, 2 m and 4 m, were used to get LiDAR metrics from canopy returns in order to considered the heterogeneity of Mediterranean vegetation (Table 2).

Selected LiDAR metrics were also extracted in a 20m grid for the whole study area to characterized the structure of forest stands prior to field measurement (see details in section 2.1), in order to assess FCC (percentage of first returns above 2m), H (percentile 95% of vegetation returns) and CRR (canopy relief ratio). Once the LiDAR models for each canopy fuel variable (CBH, CFL and CBD) and forest type (Table 1) will be fitted and validated with field data, selected input metrics included in the final models will be also obtained as 20m raster files to generate high resolution wall-to-wall canopy fuel maps of the study area.

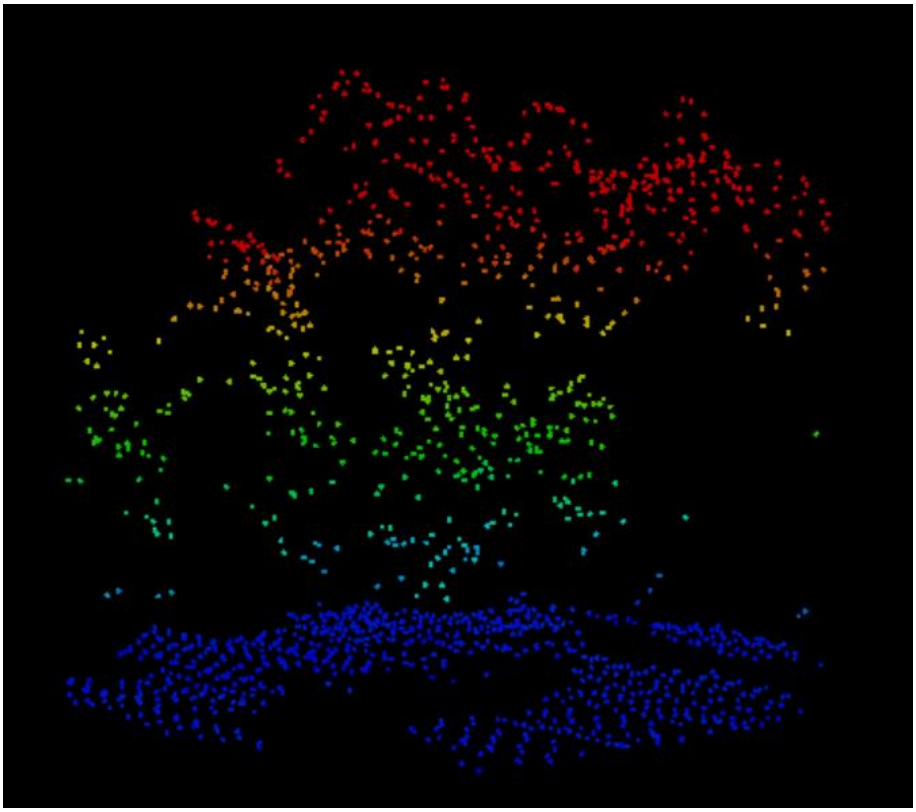

Figure 1- Example of LiDAR point cloud (1.5 p/m2) extracted in a field plot

Table 2- LiDAR metrics used as potential explanatory variables. All metric were extracted and tested at both threshold levels: 2m and 4m

Metric	**Description**
zmax	Maximum return height
zmean	Mean return height
zvar	Variance of return heights
zsd	Standard deviation of return heights
zcv	Coefficient of variation of return heights
ziq	Interquartile range of return heights
zskew	Skewness of return heights
zkurt	Kurtosis of return heights
pzabove	Percentage of first returns above threshold
pzabovezmean	Percentage of first returns above mean height
crr	Canopy relief ratio
p_i	Percentile *i* of return heights (5,10,20,25,30,40,50,60,70,75,80,90,95,99)

2.3. Statistical analysis

Parametric and non-parametric regression methods were used to model canopy fuels with LiDAR data. Different modelling techniques including linear regression and random forests were tested in order to compare the performance of different models. Models were fitted in R software, using crossvalidation for final model selection based on minimum root mean squared error (RMSE) and maximum variability explained.

3. Preliminary results

The field inventory is ongoing, and most of the plots in the main ecosystems are expected to be finished during the summer 2022. At present, there were more than 300 plots available out of 750 planned in the 15 forest types

included in the study. However, here we are presenting preliminary results retrieved from only 170 plots in five pure stands, including *Quercus ilex* (n=41), *Quercus suber* (n=16), *Pinus halepensis* (n=18), *Pinus pinea* (n=44) *and Eucaliptus sp* (n=51), where at the time of writing this communication there were enough field data to perform the statistical analysis. Main statistics describing canopy parameters in each forest stand are summarized in Table 3.

Table 3- Summary of the canopy fuel characteristics of the selected pure forest stands. H = Stand height, CBH = canopy base height, CFL = canopy fuel load, CBD = canopy bulk density, s.d. = = standard deviation

Forest species (field plots)	H (m)		CBH (m)		CFL (kg/m^2)		CBD (kg/m^3)	
	mean (range)	s.d.	mean (range)	s.d.	mean (range)	s.d.	mean (range)	s.d.
Quercus ilex (n=41)	7.27 (3.53-11.48)	1.69	2.08 (0.67-3.7)	0.53	0.20 (0.04-0.76)	0.15	0.04 (0.01-0.14)	0.03
Quercus suber (n=16)	8.60 (5.30-14.65)	2.26	2.58 (2.10-3.7)	0.50	0.04 (0.01-0.08)	0.02	0.01 (0.003-0.01)	0.003
Pinus halepensis (n=18)	9.48 (5.15-17.63)	3.22	3.43 (0.10-9.4)	2.52	0.28 (0.07-0.59)	0.14	0.05 (0.01-0.13)	0.03
Pinus pinea (n=44)	10.71 (5.28-21.30)	3.62	5.85 (1.45-13.0)	3.12	0.61 (0.17-2.19)	0.37	0.14 (0.04-0.59)	0.11
Eucalyptus sp (n=41)	12.56 (5.75-19.98)	3.04	6.17 (2.15-14.2)	2.66	0.66 (0.02-3.02)	0.49	0.12 (0.003-0.88)	0.13

In general, first results showed better models for *Pinus sp* than *Quercus sp* and *Eucalytus sp* stands (Table 4). CBD was the canopy fuel parameter more difficult to estimate, with even unsuccessful model fitting in some cases. Comparing parametric and non-parametric modelling techniques, linear regression generally provided better goodness-of-fit than random forest. In terms of LiDAR metrics, we also observed and effect of the different modelling techniques on the input variables selected as predictors in the models.

When field inventory would be completed, further analysis will be performed to improve these models and to include the rest of selected forest stands. Additional LiDAR metrics (e.g. percentage of returns normalized by height strata) and statistical methods (e.g. non-linear formulations) will be also tested. The final models fitted will allow retrieving predictions of CBH (m), CFL (kg/m^2) and CBD (kg/m^3) based on low-density LiDAR data (1.5 p/m^2) to obtain high spatial resolution canopy fuel maps of the study area adapted to the particularities of the main forest ecosystem in Andalusia. These results could be also applied to get canopy fuel maps from LiDAR data available in other forest stands in the Mediterranean region, as the selected species are very representative not only of the Iberian Peninsula but also of other South-European forest ecosystems, e.g. autochthonous stand composed by the main *Pinus sp* and *Quercus sp* as well as *Eucalyptus sp* plantations (Table 1).

Results from this study are expected to provide relevant information to improve fuel mapping in forest stands for enhance wildfire prevention and management, especially with regard to most conifer and deciduous tree species that are commonly involved in large wildfires in the Mediterranean region but are currently lacking specific LiDAR models for canopy fuel characterization.

Table 4- Statistics of the preliminary models fitted to estimate canopy fuel characteristics in the selected pure forest stands from LiDAR data. CBH = canopy base height, CFL = canopy fuel load, CBD = canopy bulk density, R^2_{adj} = adjusted R^2, R^2_{ps} = pseudo-R^2, RMSE = root mean square error, n.a. = not applicable (unsuccessful model fitting)

Forest species	Lineal regression		Random Forest	
	R^2_{adj}	RMSE (%)	R^2_{ps}	RMSE (%)
Quercus ilex (n=41)				
CBH (m)	0.30	0.432 (20.6 %)	0.19	0.478 (23.0 %)
CFL (kg/m^2)	0.38	0.076 (37.2 %)	0.37	0.121 (59.6 %)
CBD (kg/m^3)	0.34	0.018 (43.1 %)	0.43	0.021 (51.5 %)

Abstract

Wildfires are a common threat to the sustainability of commercial plantations in fire-prone regions. Large losses of plantations from wildfires can lead to the disruption of forest yield, with flow-on impacts to downstream industries, resulting in significant social and economic impacts to local communities. Future climate projections indicate an increase in wildfire activity, including increases in fire extent, severity or frequency in many fire-prone ecosystems. Land and fire management agencies around the world invest significant resources to reduce the likelihood and impact of future fires and increase the capacity for fire suppression. However, we currently know very little about how commercial plantations will be impacted by fire as the climate changes, or if strategic management can mitigate some of these risks into the future.

In this study we sought to 1) quantify fire risks to plantations and nearby community assets under current and changing climates; and 2) evaluate the effectiveness of management options for mitigating some of these risks under changing climates. This research included the customisation of a fire simulation tool (PHOENIX RapidFire) for use in plantation landscapes by developing plantation-specific fuel functions (derived from field-sampling in hardwood and softwood plantations around Australia) that were integrated into fire spread models. To quantify longer-term risks, these advancements were also integrated into a stochastic fire regime simulator (FROST– Fire Regimes and Operation Simulation Tool). Fire risks to both environmental and community assets were evaluated under current and changing climates to support evidence-based management to help guide investment, insurance negotiations, and fire mitigation in the plantation sector. The fire regime simulator (FROST) was also used to evaluate a range of different management options for reducing risk as a basis for efficient allocation of fire prevention and response resources both by plantation growers and by broader fire management agencies.

We found that reducing suppression response times (to 15 minutes or less for all ignitions) and the current approach to management (a construction rate of 2km/h for suppression and 15-minute response times, with 4000ha/year of prescribed burning) were consistently the best management strategies for reducing fire risks to plantations and adjacent communities, regardless of the climate model used. These strategies offer the greatest scope for reducing future wildfire risks to plantation assets and adjacent communities as the climate changes. High pruning in strategic locations may also be worthy of future investment but should be considered in combination with more rapid suppression and prescribed burning. Plantation owners currently have little influence over the amount and location of prescribed burning adjacent to plantations, and fuel reduction burning is not regularly undertaken in Australian plantations. Therefore, rapid suppression response times was found to be the single best investment for minimising impact to plantation assets under a hotter or drier climate.

1. Background & Introduction

Wildfires are a common threat to the sustainability of commercial plantations in fire prone regions. Wildfire is considered one of the main threats to plantations in many countries including Australia, Brazil, Indonesia, Chile and Portugal (Matthews et al. 2012; Booth 2013; Galizia & Rodrigues 2019), with an increased frequency of incidents in recent years (Bartlett 2012). In Australia, vast areas of hardwood and softwood plantations were burnt by the devastating 2019/2020 Black Summer wildfires, with more than a quarter (26%) of commercial plantations burnt in New South Wales alone (Cruz, Alexander & Plucinski 2017). The growth characteristics of plantations can be highly flammable, especially at key stages in their growth cycle. Severe wildfires may result

in high economic losses if burnt trees are not salvageable due to their age profile, or when high-severity fire results in whole-of-stand losses. Wildfires that impact plantations can have flow-on effects for other parts of the wood products industry, potentially resulting in significant negative economic and social impacts to regional communities (Cruz, Alexander & Plucinski 2017). Understanding changes in fire regimes and the associated impacts in plantation landscapes will be key to adequately managing risks to both plantation and community assets in coming decades.

Future climate projections indicate an increase in wildfire activity, including increases in fire extent, severity or frequency in many fire-prone ecosystems (Bowman et al. 2009; Flannigan et al. 2009). Land and fire management agencies around the world invest significant resources to reduce the likelihood and impact of future fires and increase the capacity for fire suppression (Calkin et al. 2005; Berry, Donovan & Hesseln 2006). However, we currently know very little about how commercial plantations will fare as the climate changes, nor how management may be able to mitigate some of these risks into the future. Plantation forestry involves relatively long time scales, with 30-year rotations common. Therefore, improved prediction of fire risk over decade long time-scales is crucial to the industries sustainability.

Fuel management is the primary means for land and fire managers to reduce the occurrence, size and severity of future fires while also having the co-benefit of increasing the capacity for suppression during an active fire (Agee & Skinner 2005; Wilson & Wiitala 2005; Finney, Grenfell & McHugh 2009; Penman et al. 2011). Fuel management in and around plantations is regarded as being important for reducing the likelihood of future impacts from wildfires. Fuel management within plantations primarily focuses on modifying or reducing the amount of fuel in key strata. The modification or removal of surface fuel and increasing the gap between the canopy base height and the ground (through removal of elevated fuels) is known to reduce the overall flammability (Burrows et al. 1989; Agee & Skinner 2005; Johnson & Peterson 2005; Fernandes et al. 2008). However, the effectiveness of different types of management under a changing climate is not yet well understood.

In this study, fire risks to both environmental and community assets were evaluated under current and changing climates to support evidence-based management to help guide investment, insurance negotiations, and fire mitigation in the plantation sector. A fire regime simulator (FROST - Fire Regimes and Operation Simulation Tool) was also used to evaluate a range of different management options for reducing risk as a basis for efficient allocation of fire prevention and response resources both by plantation growers and by fire management agencies.

This research had two key objectives:

1. To quantify fire risks to plantations and nearby community assets under current and changing climates;
2. To evaluate the effectiveness of management options for mitigating fire risks to plantations and nearby community assets under changing climates.

2. Approach

This research included the customisation of a fire simulation tool (PHOENIX RapidFire) for use in plantation landscapes by developing plantation-specific fuel functions (derived from field-sampling in hardwood and softwood plantations around Australia, see Figure 1A) that were integrated into fire spread models. To quantify longer-term risks, these advancements were also integrated into a stochastic fire regime simulator - FROST, that is proposed for future use in operational risk assessments.

2.1. Quantifying fuel accumulation in plantations over time

Prior to this study, plantation fuels were represented in fire-behaviour simulators by Olson fuel accumulation curves based on native vegetation. These curves are characterised by a rapid and steady increase in fuel load in young age classes (~5 to 8 years) followed by a progressive stabilisation to loads of ~16 Mg ha^{-1} in the surface/near-surface stratum and 2 Mg ha^{-1} in the elevated stratum. However, the accuracy of these fuel functions for plantations has not been fully assessed. As a result, fuel hazard has been poorly estimated in plantations, resulting in sub-optimal predictions of fire behaviour and risk in plantation areas.

To address this, we undertook a series of field-based vegetation surveys, to quantify how fuel accumulates over time in hardwood and softwood plantations. The project involved six study landscapes (each roughly 80 km^2) across Australia (Figure 1A). In each study landscape a series of field-based fuel accumulation surveys were conducted. *Sampling of surface, near-surface, elevated and ladder fuels occurred across five different plantation species from immediately post-harvesting (0 years) through to just prior to harvesting (~30 years). These data were used to develop fuel accumulation curves for each species, per region.* Polynomial regression analyses were used to fit functions to the fuel load by age data, using an iterative approach that increased the order of the polynomial to optimise R-squared values.

2.2. Fire regime modelling

The newly developed fuel accumulation curves were integrated into a stochastic fire regime simulator – FROST. FROST is an innovative model that uses available environmental data to spatially and temporally predict current and future trends in fire regimes and can simulate fire regimes over decades and centuries (Penman et al. 2015). It uses PHOENIX RapidFire as the fire behaviour simulator, and uses empirical ignition and fuel models based on biophysical data to allow for realistic estimates of future fire risk. FROST also uses Bayesian Networks to capture uncertainties in risk estimates and produces reliable simulations by integrating dynamic relationships associated with past fires (Penman et al. 2015).

The major components of FROST are termed 'machines'. The primary machines include a weather machine, an ignition machine and a fuel machine. These machines provide the input data for the fire behaviour simulator (in this case PHOENIX RapidFire) to run fires for each day. FROST also includes a fuel treatment manager, a disruption machine and a suppression machine. These machines allow the user to test various operational scenarios and can be used to simulate management strategies and their impact on fire behaviour. These machines were used to evaluate management options for mitigating fire risks to plantations and nearby community assets under changing climates.

2.3. Scenario modelling

The FROST simulation modelling tested the effects of climate change on the fire regime across the six study landscapes. We selected two global climate models:

1. ECHAM5 (*hotter*), submodel 1 – characterised by a relatively large increase in annual temperature over south-eastern Australia (of about 2.5 ^oC) with little change in annual precipitation (0%), and,
2. CSIRO Mk3 (*drier*), submodel 1 – characterised by an increase in average annual temperatures over south-eastern Australia (of about 1.6 ^oC) and a decrease in average annual precipitation (-7%).

We ran simulations for current (1990-2009) and far-future (2060-2079) climate epochs. Planning for a changing climate with associated higher future fire risk will enable plantation owners to assess and undertake management options that will have the greatest reduction in risk under a changing climate. The 20 years of climate data were looped five times to allow the fire regime to play out over 100 years. Each scenario was replicated 25 times to cover variation in the runs given that many of the conditions are probabilistic.

2.4. Management strategies

In consultation with plantation owners from the six study landscapes, a series of potential management strategies were identified. Management strategies were designed around the themes of fire preparedness, fire response or fire prevention. A set of four potential management scenarios were defined for each region. These scenarios were compared to a 'current management' option and a 'no-management' option. Current management reflected a construction rate of 2 km/h and response time of between 15-45 mins for all ignitions, depending on the region, with prescribed burning (outside of plantations) set at a 5-year interval within Strategic Fire Advantage Zones and at minimum tolerable fire intervals based on the native vegetation in landscape burning areas. Each of these scenarios were explored for current (1990-2009) and far-future (2060-2079) epochs, and using the two global climate models (ECHAM5 and CSIRO Mk3).

3. Key findings & recommendations

3.1. Fuel curves for plantations

3.1.1. Softwood plantations (Pinus radiata)

We found that fuel curves derived from field data collected in plantations around Australia (hereafter termed 'new plantation' fuels) were much more nuanced than the 'traditional' fuel curves. Surface/near-surface fuel loads were consistently higher in the new plantation fuel curves (particularly in the first year or two of a rotation) suggesting that traditional fuel curves used in Phoenix may be under-predicting fuel accumulation, and therefore fire risk in plantations.

New plantation fuels for softwood plantations indicated that combined surface/near-surface fuel loads peak at age 0 at around 25 Mg ha^{-1}. This was followed by a sharp decrease to a low point of 5 Mg ha^{-1} at 5 years, followed by a near-linear growth until 14 years (to 15 Mg ha^{-1}) and a decrease in load until 24 years (12 Mg ha^{-1}). When compared to the traditional fuel function currently implemented in PHOENIX this translates to an increase in surface/near-surface fuels load under 5 years, and lower or similar loads from 5-30 years.

Elevated fuel loads for *P. radiata* peaked at 2.5 Mg ha^{-1} at around 8 years in the new plantation curve, followed by a steady decrease to approximately 0.5 Mg ha^{-1} at 20 years. While fuel loads are in the same range as the traditional fuel curve, the new plantation fuels were found to predict higher elevated fuel loads at younger ages than the traditional fuels, which predict a maximum of 1.8t/ha at approximately 15 years.

3.1.2. Hardwood plantations (Eucalyptus globulus)

Similar to the softwood plantation fuel curves, we found that fuel accumulation curves in hardwood plantations also differed from the traditional fuel curves, indicating more variability in the curves than previously suggested. For hardwood plantations, the new plantation fuel curves demonstrated that the combined surface/near-surface fuels started at ~6 Mg ha^{-1} and remained relatively stable until 10 years, before reaching a peak of 16 Mg ha^{-1} at 18 years. These values were higher than the traditional fuel curve which starts at 1.7 Mg ha^{-1} before reaching a maximum of 13.9 Mg ha^{-1} at 15 years.

Elevated fuels in the new plantation curves for *E. globulus* were found to be very low immediately post-harvest before reaching a peak of ~2.5 Mg ha^{-1} at 3 years. This was followed by a decrease to almost 0 Mg ha^{-1} from 7 years from which point fuel loads remained largely stable at less than 1 Mg ha^{-1}.

The new field-derived plantation fuel accumulation curves demonstrated that fuel loads in hardwood plantations were considerably higher than previously indicated by traditional Olson curves, especially in the surface/near-surface stratum between 0-7 years from planting.

Information about when fuel loads are at their highest will be important for plantation owners. This knowledge may help guide fuel management within plantations in an attempt to reduce future fire risk to their assets.

3.2. Fire risk profiles

Overall, impacts were greatest under the hotter (ECHAM5) climate prediction. Annual area burnt, annual area burnt by high intensity fire, and burn frequency were consistently higher under this model, and these effects were more pronounced in the northern study landscapes. This indicates that future climate predictions that are characterised by a larger increase in temperatures (i.e. >2.5 ^{o}C) with little change in annual precipitation, are likely to result in higher future fire risks for both plantation and other human assets.

In terms of the best management scenarios for reducing risks to plantation assets and adjacent communities, our results were largely consistent across the study landscapes. Increased suppression effectiveness (characterised by early detection and a response time of <15 minutes for all ignitions) and the current approach to management (a construction rate of 2km/h for suppression and 15-minute response times, with 4000ha/year of prescribed burning) were consistently the best management strategies (Figure 1B). Our results indicate that improving suppression response times and continuing the current rate of fuel management outside of plantations will offer the greatest scope for reducing future wildfire risks to plantation assets and adjacent communities. High pruning in strategic locations may also be worthy of future investment but should be considered in combination with more rapid suppression and prescribed burning.

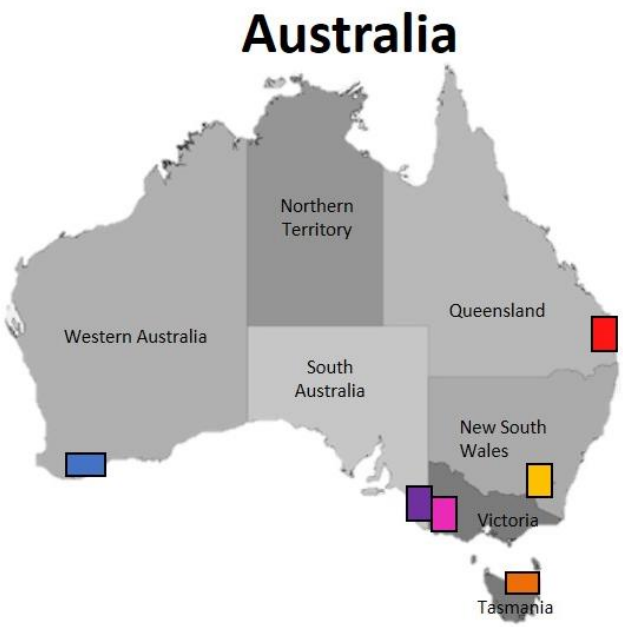
4. Conclusions

In this study we found that fuel curves derived from field data collected in plantations around Australia were much more nuanced than traditional fuel curves. Surface/near-surface fuel loads were consistently higher in the new plantation fuel curves (particularly in the first few years of a rotation) indicating that traditional fuel curves used in PHOENIX may be under-predicting fuel accumulation, and therefore fire risk in plantations. We therefore recommend that the traditional Olson curves be replaced with the new plantation fuel curves for future fire risk modelling where plantations are present in the landscape of interest.

We found that future climate predictions characterised by larger increases in annual average temperatures with little change in annual precipitation were more likely to result in increased fire risks for both plantation and other human assets. This knowledge, combined with a new understanding of how fuel accumulates in plantations over time will help guide strategic fuel management in plantations.

Regarding the best use of resources for reducing fire risk to plantations under a changing climate, we found that increasing suppression response times and continuing the current approach to fuel management outside of plantations were the best strategies for reducing future impacts to plantations, regardless of the climate model used. Therefore, additional suppression resources and strategic positioning of these resources throughout the landscape (i.e. based on burn frequency maps and areas of high-risk plantations) will be an important area for future investment. Focusing on increasing early detection may also help reduce the risk of future losses. Plantation owners currently have little influence over the amount and location of prescribed burning adjacent to plantations, and fuel reduction burning is not regularly undertaken in Australian plantations. Therefore, rapid suppression response times is the single best investment for minimising impact to plantation assets under a hotter or drier climate.

A)



B)

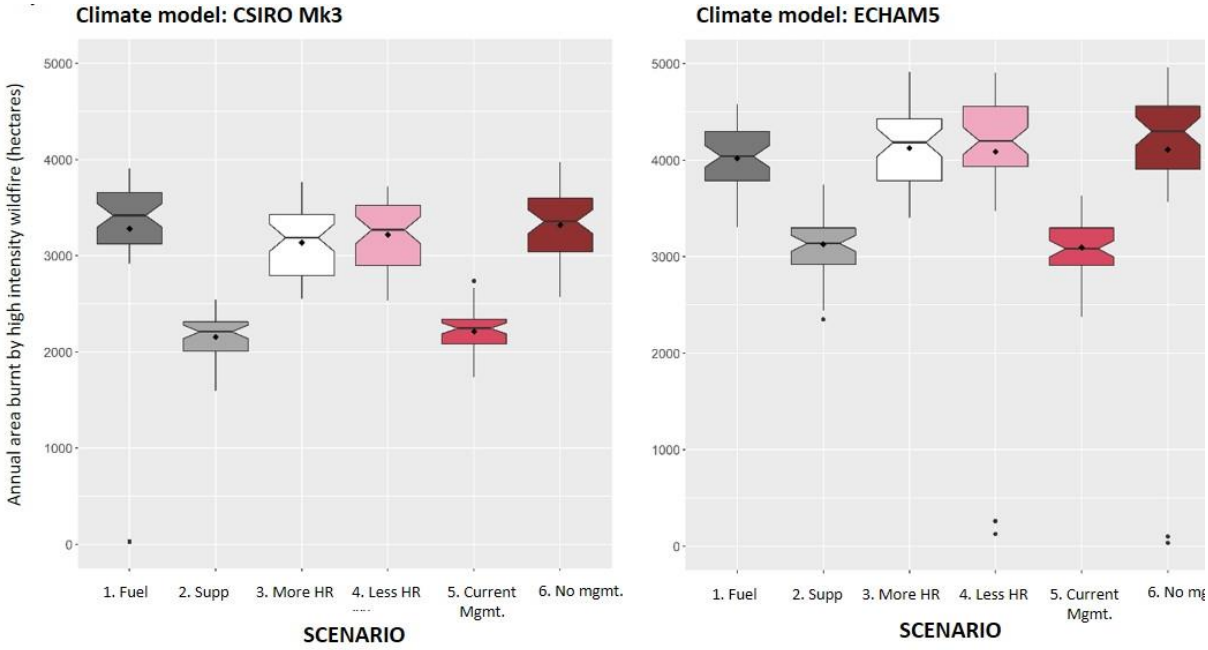


Figure 1- A) Map of Australia with the six study regions indicated by coloured boxes. B) Simulated future annual area burnt by high-intensity wildfire by management scenario and under two climate models (CSIRO Mk3 left; ECHAM5 right). Values are based on 25 replications over a 100-year simulation period and are presented as notched box plots with the mid-line indicating the median and non-overlapping notches indicating significant differences. Modelled scenarios were: 1. Fuel – surface/near-surface fuel loads reduced to 10t/ha throughout rotation and elevated fuels reduced within 1km of towns to reflect high pruning practices. 2. Reducing suppression response time (to an average of 10 minutes throughout each plantation region). 3. Increasing the amount of annual area burnt by prescribed fire outside of plantations (from 4000ha/year to 6000ha/year). 4. Reducing the amount of annual area burnt by prescribed burning outside of plantations (from 4000ha/year to 2000ha/year). 5. Current management approach (suppression resources set to reflect a construction rate of 2km/h and response time of 15 minutes for all ignitions, and prescribed fire outside of plantations at 4000ha/year). 6. No management – a 'do-nothing' approach (no fuel management within or outside of plantations).

Forest fuel, TGA-FTIR, Heating rate, Combustion indices, Kinetic analysis

Abstract

This article presents a first attempt of implementation of a lab-scale methodology proposed to describe the thermal decomposition behavior, and evolved volatile analysis of vegetative fuels using the TG-FTIR technique. Experiments within this method include testing the usual grinded form of samples compared to the intact form, which can render reliable and useful information to improve the understanding of the ignitability and combustibility of forest fuels. Moreover, slow (20 and 40 °C/min) and quasi-fast (60, 80 and 100 °C/min) heating rates were chosen to get close from the actual conditions of wildland fires (preheating/smoldering and flame region, respectively). In this work, we report the thermal decomposition behavior under inert (N2) and oxidative (air) atmospheres of Genista Salzmannii Needles (GSN) involved in high-intensity fires of Mediterranean forests. The results showed that the intact GSN were characterized by a higher mass loss rate compared to the grinded GSN. Furthermore, TG analyses were performed to assess thermal reactivity and combustion indices (ignition, devolatilization, combustion and burnout indices) of grinded and cut GSN samples at fives heating rates. The used set of the thermal indices are important properties to be determined when talking about efficient wildland fire management. As the heating rate increases, reactivity and combustion indices increase linearly. At low heating rates (20 and 40 °C/min), these parameters were quite similar for both samples, while the gap becomes more and more significant at elevated heating rates (60, 80 and 100 °C/min). High correlation coefficients (R2 > 0.96) were obtained, which indicate a good degree of fitting reliability between combustion characteristics and the tested heating rates. The determined slope can be used to compare and classify ignitability and combustibility of vegetative fuels related to fire risk potential. Based on the 3D-FTIR spectra, the dominant gases released during pyrolysis were CO2, C=O bond, C-H and C-O bond and H2O, while during combustion, CO2 and H2O were the major products. For kinetic investigations, activation energy (Ea) was calculated by means of two iso-conversional methods. The variation of Ea with the conversion rate has exhibited a quite similar behavior during the whole pyrolysis and combustion process. Char formation, at the end of an intense devolatilization, was the most complex process. The oxidation of the remaining char was characterized by a significant decrease of Ea and thus it was not considered as a major event in the combustion process.

1. Introduction

Due to the worrying climatic conditions and the high sensitivity of Mediterranean forests to fires, the evaluation of fuel hazard and fire risk gets more and more attention. The thermal decomposition of forest fuels is considered as the initial step of the forest fire process. Moreover, the determination of kinetic parameters of thermal degradation provides the necessary data for the development of realistic models *(Cancellieri et al. 2013)*. In studying forest fires, thermogravimetric analysis (TGA) was commonly used to investigate the thermal behavior and kinetics data of the decomposition process of vegetative fuels *(Leroy et al. 2006, 2010)*. Moreover, *Shu et al. (2021)* analyzed the combustibility and pyrolysis kinetics of forest combustibles and demonstrated their importance for fuels managing and forest fires prediction. However, few reliable experimental and modelling studies have examined the effect of different heating rate and sample sizes on the pyrolytic and combustion behavior and kinetics of forest fuels using TG-FTIR.

Genista Salzmannii is considered as an important vegetative fuel involved in fires of Mediterranean forests. This species is characterized by a very strong homogeneity and a 90% cover (Leroy-Cancellieri, 2014). Moreover, in a recent paper focus on an experimental and numerical investigation of prescribed fire on *Genista*

salzmannii, Fayad et al. (2022) highlight the high-intensity of wildland fire generate by this vegetation specie. As it has been demonstrated that only small fuel particles with diameter less than 6 mm, were supposed to contribute actively to fire spread *(Burrows, 2001)*, this study is focused on *Genista Salzmannii* Needles (GSN) which constitute the most of this plant.

So far, to authors knowledge, there has been no detailed investigation on the solid-phase thermal degradation behavior and kinetic analysis of GSN to support wildland fire research. This work is in this purpose. It was first focused on the investigation of thermal decomposition behavior and the evolved gas component during pyrolysis and combustion by TG-FTIR. Both grinded and cut GSN were investigated, and the effect of heating rate on thermal reactivity and combustion indices (ignition, devolatilization, combustion and burnout indices) was studied. Then, kinetic analyses were performed using two model-free methods at five heating rates of 20, 40, 60, 80 and 100 °C/min. Finally, the followed methodology and the obtained data were used to establish a database of forest fuels and will provide basic information for forest fuels management and fire modellings.

1.1. Test sample

The plant material under study, representing *Genista salzmannii*, was collected from the mountain forest in Letia region, France. The raw *Genista Salzmannii Needles* (GSN) were prepared (cut and grinded samples, see Figure 1) and dried in a forced air convection oven with a temperature of 60 °C to remove the external moisture part before the thermogravimetric tests. The grinded sample (< 600 µm) was selected for proximate analysis. Moisture (M), volatile matter (VM) and ash (A) content were determined according to EN14774-3:2009: E, EN15148:2009: E and EN14775:2009: E standards, respectively. The fixed carbon content was calculated by difference: FC (%) = 100% - (M+A+VM). The moisture content was 1.28 and 5.7% for grinded and cut sample, respectively. The result of proximate analysis, on a dry basis, was volatile (77.95%), fixed carbon (20.11) and ash (1.94%). The GSN has lower moisture and higher content of VM. The flaming zone could be the major step during combustion process. In addition, the ash content of GSN was very low. Ash in vegetative fuels retards flaming combustion and reduces the rate of VM release, which result in poor combustion performance and enhanced fire resistance *(Cai et al. 2017)*.

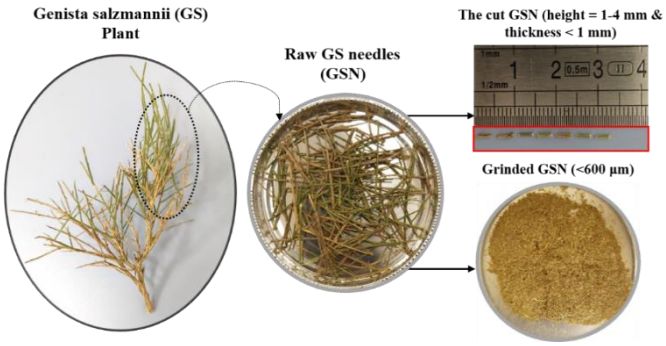

Figure 1- Grinded and cut GSN samples.

1.2. TG-FTIR analysis

Thermal decomposition behavior of grinded (< 600 µm) and cut (3-4 mm) samples of GSN was investigated by using a Perkin Elmer TGA 8000 analyzer. Air and N_2 atmospheres were used as the carrier gas with a flow rate of 30 ml/min. The gases evolved during pyrolysis and combustion were qualitatively monitored in real-time by coupling the TG instruments with a Fourier Transform Infrared (FTIR) spectrometer (Frontier, PerkinElmer, USA). The non-isothermal TG experiments with mass of about 15 ± 0.5 mg, placed in a ceramic crucible, were conducted from 35 to 1200 °C at different heating rates of 20, 40, 60, 80, 100 °C/min. During wildland fires, slow pyrolysis exists during preheating and/or smoldering combustion of vegetative fuels, while fast pyrolysis occurs in the flame zone. The selected heating rates conform to those adopted in the slow (20 and 40 °/min) and fast (60, 80 and 100 °C/min) pyrolysis *(Safdari et al. 2019)*.

1.3. Combustion characteristic indices

On the basis of TG-DTG data, characteristic parameters of thermal decomposition of vegetative fuel including the initial decomposition temperature (T_{id}), the ignition temperature (T_{ig}), the maximum mass loss rate temperature ($T_{DTG-max}$), the burnout temperature (T_b), their corresponding time (t_{id}, t_{ig}, $t_{DTG-max}$ and t_b,

respectively), the maximum and average mass loss rate (DTG_{max} and DTG_{mean}), and temperature and time interval at the half value of DTG_{max} in the descending and the rising part of the peak (ΔT and Δt, respectively) were determined. These parameters can be used to quantitatively evaluate the thermal reactivity (R) and combustion indices namely ignition characteristic index (ICI), devolatilization index (DI), combustion characteristic index (CCI) and burnout characteristic index (BCI) *(Xie et al. 2020; Liu et al. 2021; Wnorowska et al. 2021)*. The used equations were listed in Table. 1.

Table. 1-Thermal reactivity and combustion indices formulas.

$R = 100 * \sum \frac{\|DTG_{max}\|}{T_{DTG_{max}}}$	$ICI = \frac{\|DTG_{max}\|}{t_{peak} * t_{DTG_{max}}}$	$DI = \frac{\|DTG_{max}\| * \|DTG_{mean}\|}{T_{DTG_{max}} * T_i * \Delta T_{1/2}}$
$CCI = \frac{\|DTG_{max}\| * \|DTG_{mean}\|}{T_i^{\,2} * T_b}$	$BCI = \frac{\|DTG_{max}\|}{\Delta t_{1/2} * t_{DTG_{max}} * t_b}$	

1.4. Kinetic theory

The kinetic parameters provide required information to better understand the mechanisms controlling the thermal decomposition of vegetative fuels and for fire risk assessment. The kinetic analysis of GSN was carried out by using non-isothermal iso-conversional methods *(Álvarez et al. 2016)*. According to Arrhenius theory, the rate equation in terms of conversion (α) was represented as:

$$\frac{d\alpha}{dt} = Ae^{\frac{-E_a}{R.T}} f(\alpha)$$

where, α is the conversion degree ($\alpha = (m_0 - m_t)/(m_0 - m_f)$), A is the pre-exponential factor, E_a is the activation energy and f(α) is the reaction model. The model-free method as Flynn-Wall-Ozawa (FWO) was used to estimate the activation energy as follows:

$$\ln(\beta) = \ln\left(\frac{A.E_a}{R.G(\alpha)}\right) - 5.331 - 1.052\left(\frac{E_a}{R.T}\right)$$

A straight line was obtained by plotting log(β) versus 1/T and E_a can be estimated from the slope for each conversion $\left(slope = -1.052\left(\frac{E_a}{R.T}\right)\right)$. Another iso-conversional integral model-free method is Kissinger-Akahira-Sunose (KAS), which gives more accuracy or gives exact values of activation energy as compared with FWO. It was represented as follows.

$$\ln\left(\frac{\beta}{T^2}\right) = \ln\left(\frac{A.R}{E_a.G(\alpha)}\right) - \left(\frac{E_a}{R.T}\right)$$

Here, E_a can be estimated by plotting $\log(\beta/T^2)$ versus 1/T.

2. Results and discussion

2.1. Thermal decomposition of GSN

Figure 2 and 3 shows the TG-DTG profiles and a typical 3D-FTIR spectra of gas products from pyrolysis and combustion of grinded (a, b) and cut (c, d) GSN at different heating rates. It can be seen that pyrolysis process of both sizes can be divided into three stages constituting two peaks and one flat line. The first stage (< 180°C), corresponds to GSN self-rehydration and the release of light volatiles. The second stage (major mass loss) include the next peak (200-600 °C) was dominated by the degradation of hemicellulose, cellulose and partly by that of lignin (rapid pyrolysis). The last stage (> 600 °C) indicates the carbonization, where a small quantity of char (unreacted fixed carbon and ash particles) was remaining. Based on the different peaks wavenumbers, the prominent pyrolytic products were CO_2, carbonyl groups (C=O), aromatic rings (C=C), H_2O, CH_4, and C-H or C-O bond contained organics. The evolved gases were principally emitted between 200 and 600 °C, which was in agreement with TG data. In case of combustion, it was observed that after residual moisture removal the mass loss takes place in two steps: the first one corresponds to the devolatilization (oxidative pyrolysis), and the second one relates to the oxidation of char. The dominant gases released during oxidative pyrolysis zone (100-

400 °C) were CO_2, C=O, H_2O and C=C. The peak of aliphatic C-H was very low. At higher temperature (above 550 °C), char oxidation produces a large amount of CO_2 while the absorbance bands of C=O and C=C decreased. In addition, the absorbance peak of CH_4 appeared at 500 °C while the saturated C-H declined gradually. Overall, the char combustion process produces CO_2, H_2O, CH_4 and a small amount of CO.

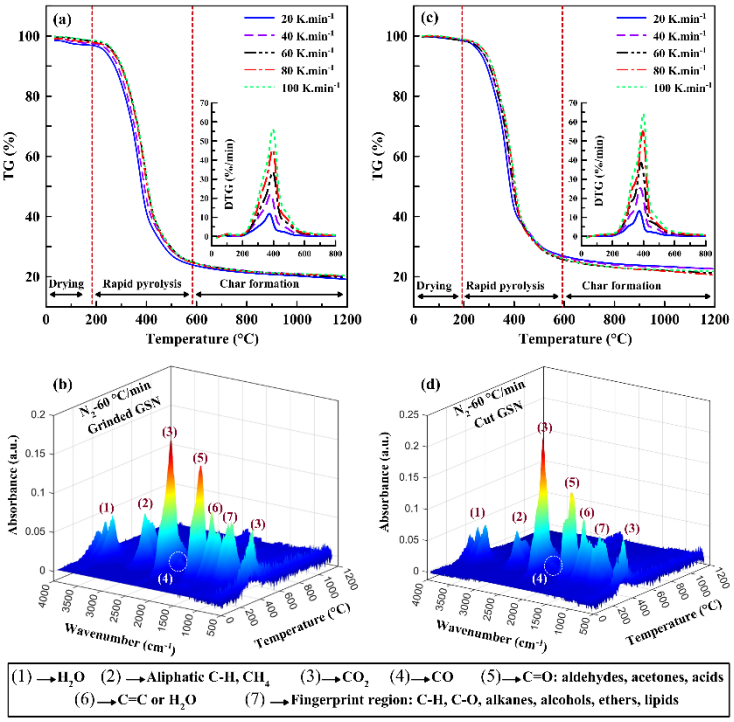

Figure 2-TG-DTG profiles and typical 3D-FTIR spectrum of the evolved volatile products from the pyrolysis of grinded (a, b) and cut (c, d) GSN.

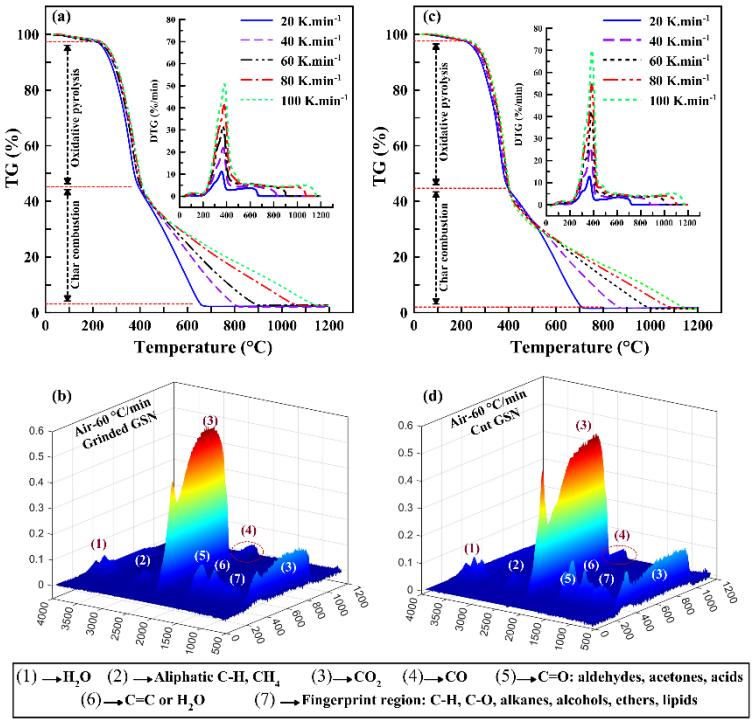

Figure 3- TG-DTG profiles and typical 3D-FTIR spectrum of the evolved volatile products from the combustion of grinded (a, b) and cut (c, d) GSN.

When the heating rate increased, the TG curves move towards high temperature region because of the limited heat transfer throughout and between particles *(Parthasarathy et al. 2021)*. Moreover, it can be observed from

the DTG curves that the width and the height of peaks were increasing with increasing heating rate. On the other hand, the observed thermal behavior of grinded and cut samples of GSN was compared. The difference of DTG peaks between grinded and cut samples was increasing with increasing heating rate. This can be explained by the control of heat and mass transfer limitations, which leads to improving the weight loss rate of cut samples. Moreover, the residence time of combustion at high heating rate was short, which often leads to ineffective heat and mass transfer within and among particles. Furthermore, the rapid pyrolysis zone of both samples become more homogenous at height heating rates (80 and 100 °C/min) because of the simultaneous degradation of some components, which effecting an overlapping of peaks/shoulders.

Figure 4 demonstrates the evolution of thermal reactivity (R) and the four combustion parameters (ICI, DI, CCI and BCI) as a function of heating rates. Correlation coefficients (R^2) were all greater than 0.96, indicating a high degree of fitting reliability between combustion parameters and the tested heating rates for grinded and cut samples of GSN. As the heating rate increases, all the calculated parameters increase linearly. At low heating rates (20 and 40 °C/min), the combustion indices values for grinded and cut GSN were quite similar. The gap becomes more and more significant at high heating rates (60, 80 and 100 °C/min). This can be explained by the fact that during the heating of the cut GSN (at higher heating rate), the limitations of heat transfer leads to inefficient heat flux transmission within the sample, and thus their accumulation on the open surfaces of the sample. This leads in turns to a very short ignition and combustion times, which improves ignition and combustion indices compared to grinded GSN.

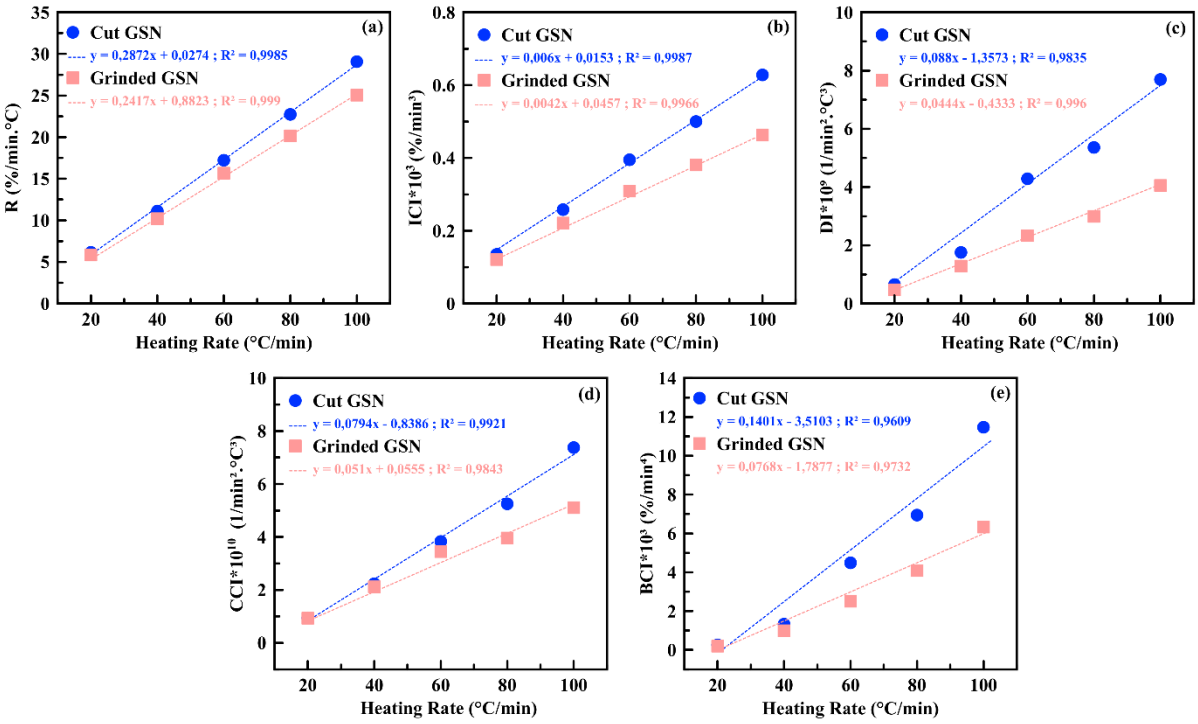

Figure 4- The relationship between R (a) ICI (b), DI (c), CCI (d) and BCI (e) and heating rates.

2.2. Kinetic analysis by model free methods

Understanding the thermal behavior and kinetics of vegetative fuels is very important for managing these resource materials and predicting forest fires. In the present study, the FWO and KAS models were used to evaluate the apparent activation energy (E_a) during pyrolysis and combustion of grinded and cut GSN samples at five heating rates. Figure 5 exhibits the E_a values for pyrolysis (a, b) and combustion (c, d) at different conversion degree. During pyrolysis (Figure 5a-b), it was observed that the E_a values for the cut GSN samples were higher as compared with grinded samples. The increased E_a in the conversion range of 0.05-0.35 was mainly caused by the hemicellulose decomposition. At $\alpha = 0.35$, the E_a values show a slight change until $\alpha = 0.75$ and represent the degradation of active cellulose. It is likely that pyrolysis reaction at $0.35<\alpha<0.75$ follow the same mechanism. Thereafter, a significant increase in the E_a values (especially for cut sample) was observed at the high conversion rate (0.8-0.9), followed by a rapid decrease at $\alpha = 0.95$. This can be explained by the fact that after the rapid pyrolysis reaction, solid char was formed gradually. A further volatilization of this material

(with low reaction activity) resulted in a remarkable activation energy increase (Chen et al. 2013). Moreover, the differences in the inherent structures of the produced char of grinded and cut GSN possibly account for the different pyrolysis behaviors at high conversion rates ($\alpha > 0.8$). Figure 5c shows the same behavior of E_a values at $0.05 < \alpha < 0.65$ during combustion of the grinded sample. A significant decrease of E_a at $\alpha > 0.65$ was due to the oxidation of remaining char, which was not considered as a major event (Rahib et al. 2020). Combustion of the cut sample (Figure 5d) at $0.55 < \alpha < 0.75$ displays a complex mechanism with negative E_a values, which indicates that devolatilization process was completed and the char was formed (Bhattacharyya et al. 2021). The reason behind this fact was probably due to the slow rate of degradation taking place at this juncture as indicated by the change of the TG curves slope in Figure 5d (see also Figure 3c). Moreover, the calculated correlation coefficients (R^2) at this region were very low, which means that the obtained E_a values were not reliable.

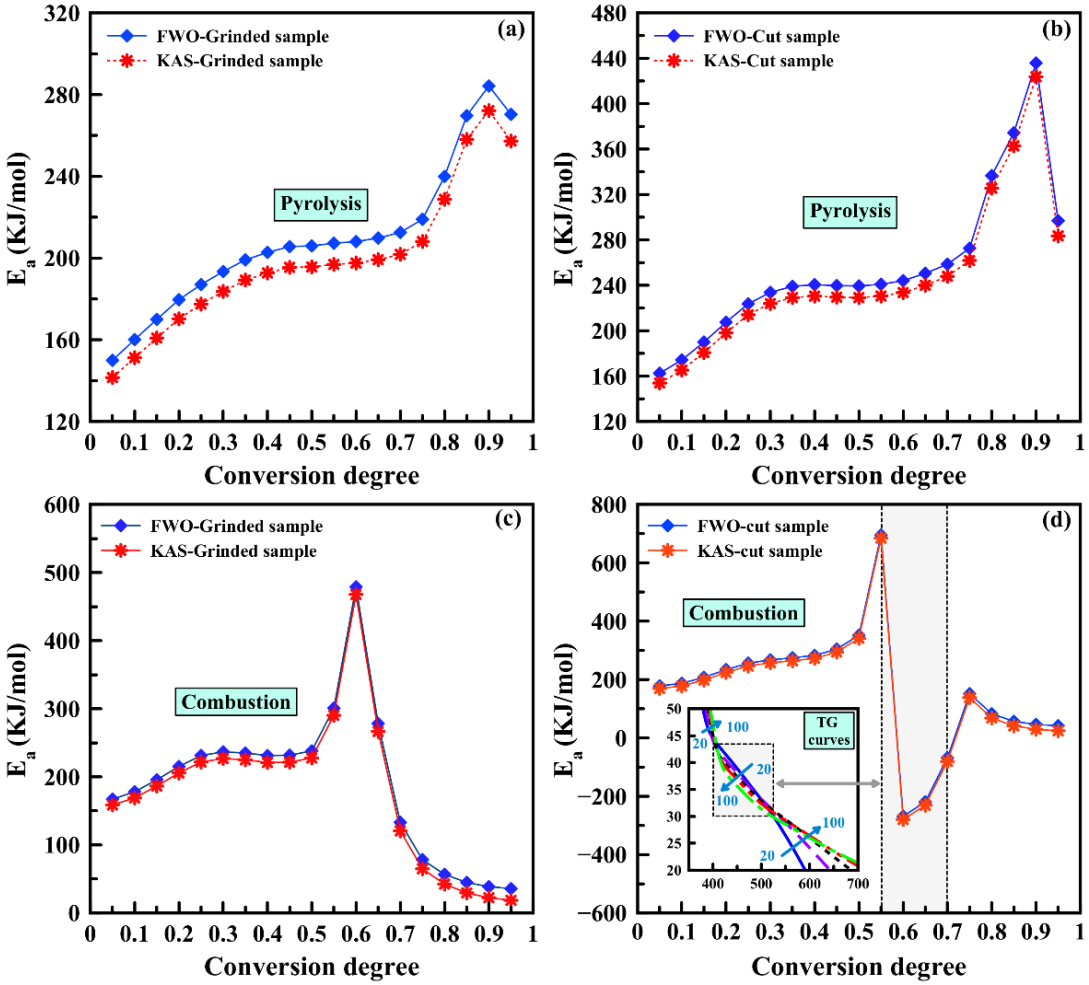

Figure 5- Estimation of E_a values according to FWO and KAS methods.

Generally, the verification of the whole chemical kinetics, controlling the thermal decomposition of forest fuel, is critical to ensure that the obtained parameters can be used in modelling the wildfire behavior. In perspective, the activation energy boundary obtained in this study by FWO and KAS methods will be compared with that obtained by model-fitting method to predict the most probable reaction mechanism. To go further into the improvement of kinetics analysis, a numerical optimization procedure will be applied in order to determine the adequate kinetic triplet.

Rural fires, risk communication, traditional burning practices, mental models

Abstract

Climate change increases the average temperature and reduces precipitation, leading to an increased risk of rural fires around the world, but mainly in regions with a Mediterranean climate, such as Portugal. Despite the high risk of rural fires, fire is still a traditional land management practice. Beyond fire misused risk, the accumulation of fuel loads, due to the high population dispersion and lower interaction of communities with the land, also drives rural fires risks. Thus, researchers have sought to understand the key features of communication practices to achieve the most desired natural risk management results in relation to rural fires. According to the Committee on Risk Perception and Communication, in 1989, risk communication is defined as "an interactive process of exchanging information and opinions between individuals, groups, and institutions". However, there is a need for dialogue between the responsible for communication and relevant stakeholders. The Carnegie Mellon mental-models approach encompasses participatory processes to translate the nature and magnitude of the risk, allowing for a deeper understanding of what can be done to mitigate social and environmental impacts in the future.

Considering rural fires risks and risk communication challenges, this study aims to design an effective risk communication plan oriented to the rural population, in the context of rural fires. For this objective to be achieved, the mental models approach was developed, exploring the underlying reasons for resistance to behavioral change and defining guidelines to support the design of new risk communication strategies, including the dissemination of new behaviors and practices that mitigate the ignition of rural fires.

This systemic approach has been applied and tested in the rePLANT project, whose purpose is the development of research activities, innovation and transfer of knowledge and technology, to increase sustainable forest management, the competitiveness of the Portuguese forestry sector and reduce the impact of rural fires. Preliminary findings show what must be communicated about rural fires risk, how must be communicated, target audiences' profiles, the role of actors for effective risk communication on rural fires, attributes of good risk communication on rural fires, evaluation of the risk communication results.

Finally, it is expected that this research provides guidelines to help decision-makers and stakeholders to design an effective risk communication plan oriented to prevent traditional burning practices, as well as to mitigate socioeconomic and environmental impacts in the future. This approach also highlights the importance of exploring the underlying reasons for resistance to behavioral change and defining guidelines to support the design of new risk communication strategies.

1. Introduction

Climate change has been affecting society and nature in an intense and progressive way over the last few years (Shukla et al. 2019). The increase in the average temperature and the significant reduction in precipitation led to an increased risk of rural fires around the world, but mainly in regions with a Mediterranean climate, such as Portugal (Nunes et al. 2021). Despite the high risk of rural fires, fire is still a traditional land management tool,

used for the elimination of residual materials from agricultural and forestry activities, and cleaning method to eliminate of excess biomass in the control of invasive species (Nunes et al. 2021; Meira Castro et al. 2020; Pereira et al. 2013). Beyond the risk of fire misuse, the accumulation of fuel loads, due to the high population dispersion and lower interaction of communities with the land, also contribute to increase the rural fires risks.

These challenges motivated the launch of a set of legislative measures that seek to promote the management, cleaning, and control of these species (Nunes et al. 2021), such as Decree-Law 14/2019 which make burning prior communication and authorization mandatory. Although the efforts, the risk of rural fires stems in part from the absence of effective management policies aimed at rural areas (Coelho et al., 2020). Still, implementing risk-based long-term planning improve fire management efforts (Turco et al., 2019).

Thus, researchers have sought to understand the key features of best communication practices to achieve the most desired natural risk management results in relation to wildfires (Steelman and McCaffrey, 2013). In the past, the term "risk communication" was considered a one-way process of disclosing messages in which experts assumed the role of transmitters and, in turn, laypeople assumed the role of recipients of messages. However, this unidirectional character of messages within the scope of risk communication began to be understood as too limiting. According to this perspective, the Committee on Risk Perception and Communication, in 1989, presents a distinction between the terms "risk messages" and "risk communication", exposing this the latter as "an interactive process of exchanging information and opinions between individuals, groups and institutions" (Committee on Risk Perception and Communication, 1989, p. 2).

Morgan et al. (2002) retrieve Fischhoff (1990), Gibson (1985), Gow and Orway (1990) to define the concept of risk communication, considering it as the communication whose purpose is to provide lay individuals with the information necessary for them to be capable of making independent and informed decisions about risks in the field of health, safety and the environment. However, there is a need for dialogue between the responsible for communication and the set of stakeholders (Palenchar, 2005). Stakeholder participation in the risk assessment and management process can enable not only improve the quality of decision-making, but it can also avoid harmful confrontations between the entities and the community (Renn, 2010). Mental models approach encompasses participatory processes to translate the nature and magnitude of the risk, allowing for a deeper understanding of what can be done (Morgan et al. 2002) to mitigate social and environmental impacts in the future.

Considering the rural fires risks and risk communication challenges, this study aims to design an effective risk communication plan oriented to the rural population, in the context of rural fires. For the objective to be achieved, a systemic approach was developed, exploring the underlying reasons for resistance to behavioral change and defining guidelines to support the design of new risk communication strategies, including the dissemination of new behaviors and practices that mitigate the ignition of rural fires.

2. Method

According to Fraser and Gondim (2004) "in the qualitative approach, what is intended, in addition to knowing the people's opinions on a given topic, is to understand the motivations, meanings and values that support opinions and worldviews. In other words, it is giving voice to the other and understanding from what perspective does he speak". In this sense, the qualitative research approach is predominantly present in this study, combining participatory processes (such as interviews, dynamic interactions to build mental models, focus groups) and ethnographic (such as on-site visits and observations) to design an effective risk communication plan oriented to prevent rural fires in Portugal. Additionally, the quantitative approach was employed in the mapping and definition of lay sampling zones, through the application of Non-Parametric Multi-Criteria Analysis (Vego et al. 2008).

This systemic approach is divided into three main stages: understanding the expert perspective, understanding the context, and designing the solution, and six milestones, as shown in Figure 1. The research design involved mapping and defining the sample, identifying potential participants to be interviewed (including actors from industries, public entities, academics, the third sector, and society), developing the data collection instrument (semi-structured interview scripts), systematizing data collection with different actors (mental models development in a digital visual collaboration platform) on the risk of rural fires.

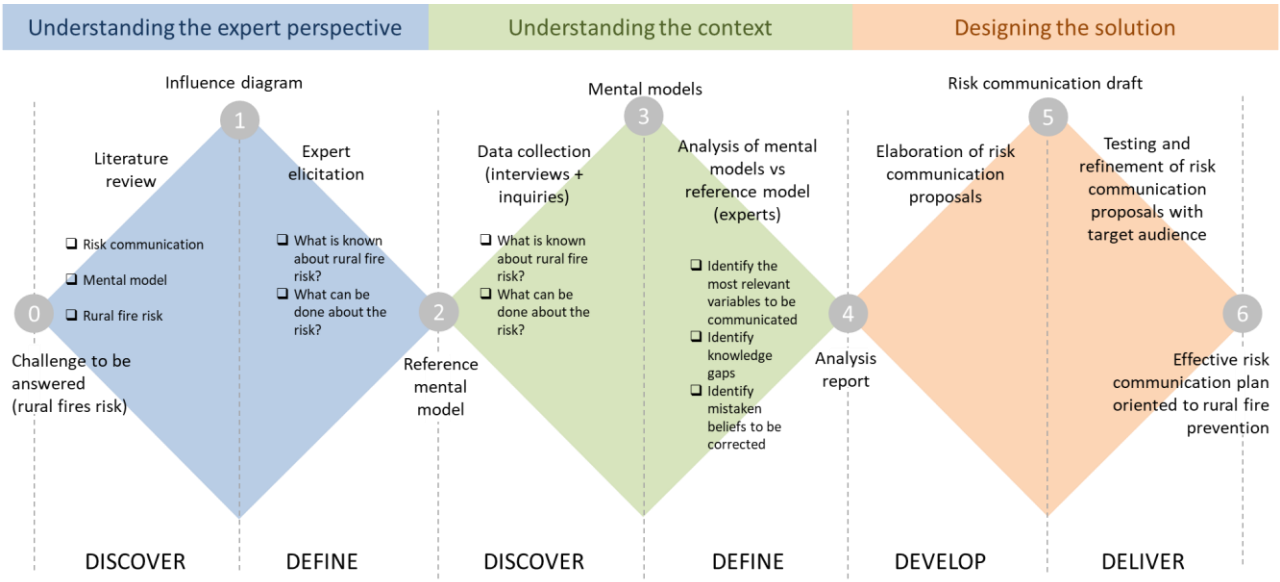

Figure 1- Systemic approach to design an effective risk communication plan oriented to mitigate the impact of traditional burning practices in rural fires

Overall, understanding the expert perspective stage included the literature review and expert elicitation to build the reference mental model. Literature review encompasses topics on risk communication, mental models and rural fires that enable in-deep understanding of the topics, especially regarding the best practices of risk communication, crucial tasks to develop an effective mental model and associated factors of rural fires risk, including risky behaviors and practices. Additionally, the bibliographic review established methodological premises to study development, being the first one is the mental model's elaboration, commonly represented by an influence diagram (Morgan et al. 2002).

Part of the expert elicitation consists of experts giving their contributions and comments regarding the mental model under construction. The experts' contributions are periodically validated by the research team and incremented in the reference mental model to translate the aggregated knowledge of the expert community regarding rural fires risk, behaviors, and practices to mitigate the ignition of rural fires.

Once concluded the reference mental model, Non-Parametric Multi-Criteria Analysis (Vego et al. 2008) was employed to map and define the lay sampling zones, as previously said. In this mapping, criteria were used, such as: Municipalities Council involved in the Forest Intervention Zones of Vale do Sousa; respective municipalities, districts, codes, terrain typologies and demographic data; analysis of occurrences associated with burning - last 3 to 5 years; construction of indicators for sample selection.

The understanding of the context stage begins with the data collection in the field through interviews with rural residents to understand their beliefs and perception about the impact of traditional burning practices in rural fires hazard, expressed in their own terms. Interview protocol was shaped by the expert mental model, so it allows for the expression of correct and incorrect beliefs (Morgan et al. 2002). However, to enrich the research at the beginning of this stage, participatory components such as focus groups and on-site visits and observations were added to compose the original Carnegie Mellon mental-models approach that we have been followed.

The data collected was transcribed, coded, and analyzed following a thematic analysis approach. We use software to support this process, NVivo. Once the results are summarized, the responses from interviews with rural residents will be analyzed in term of how well these mental models correspond to the expert model captured in the influence diagram (identify the most relevant variables to be communicated, identify knowledge gaps, identify mistaken beliefs to be corrected).

In addition, it will be applied inquiries to groups sampled from the intended audience to validate the mental model final analyses. This confirmatory questionnaire includes items captured about the beliefs expressed in the open-ended interviews and experts' model. The main purpose of this step is to estimate the population prevalence of these beliefs (Morgan et al. 2002).

Finally, the design solution stage encompasses three steps: elaboration of risk communication proposals which are presented as a risk communication draft, after the testing and refinement of risk communication proposals with the target audience, an effective risk communication plan oriented to rural fire prevention is concluded.

3. **Preliminary findings and work in progress**

We sought to present the systemic approach designed to build an effective risk communication plan to prevent traditional burning practices in Portugal. This systemic approach has been applied and tested in the first major project of initiative and operationalization of the ForestWISE Collaborative Laboratory – Collaborative Laboratory for Integrated Forest and Fire Management, called rePLANT, whose purpose is the development of research activities, innovation and transfer of knowledge and technology, to increase sustainable forest management, the competitiveness of the Portuguese forestry sector and reduce the impact of rural fires.

However, it is important to emphasize the original Carnegie Mellon mental-models approach have been amplified in this study, with the employment of participatory components (focus groups and on-site visits and observations), and quantitative elements (Non-Parametric Multi-Criteria Analysis), which supported deepening the knowledge of underlying reasons for resistance to behavioral change and defining guidelines to support the design of new risk communication strategies.

Preliminary findings show some themes resulted from the data analysis, between them: what must be communicated about rural fires risk, how must be communicated and attributes of good risk communication on rural fires, target audiences' profiles, the role of actors for effective risk communication on rural fires, evaluation of the risk communication results. Table 1 shows these themes and some respective quotes.

Table 1 - Preliminary findings (themes resulted from the data analysis and quotes)

What must be communicated about rural fires risk	*(…) "if I'm going to communicate, I have to tell people what depends on them so that things go well. They cannot change the day, they cannot change the temperature of the day, they cannot change humidity, they cannot stop the wind. But they can make strips, they can put little vegetation so they don't burn too hard. That's why I would say that here in a communication strategy, the person has to be responsible for what he has control over and he has to pay attention to what he has no control over. And in risk communication, I think this is very important, making people realize that they have to act on the factors over which they have control".* (Regional Coordinator at a public institute that seeks to increase the protection of people, their property and reduce the impact of rural fires)
How to communicate and attributes of good risk communication on rural fires	*" I think proximity, because this works better if it is done locally, by local people, with local bodies, because obviously a massive campaign, as Portugal now calls it, obviously affects a part of the population that does these practices, it touches in some points, but I think it doesn't reach everyone, it's not like that, so accurate for this type of... or rather, a solution for this type of target audiences. I think this has to be much more worked on locally, with the action of local producers, with the association of farmers, with the parish councils, with the councils, it has more to be with this type of local solutions".* (Wood Regulation & Sustainability Manager at one of the main producers of wood-based panels in the world)
Target audience profiles	*"There are several target audiences, not everything is the same, the message should not be the same for everyone".* (Lieutenant Colonel at a security force of a military nature from Portugal) *"Communication must not only respond to this aging process, but at a later stage, it must respond to those who will succeed them".* (Executive Director at Forestry Association of Portugal)
The role of actors for effective risk communication on rural fires	*"We contribute to, we are not the entity that generates awareness-raising actions, but we contribute to. AGIF does it in terms of general communication, in strategic terms, it gives the guidelines, because in the past it was the ICNF that was the responsible entity. All entities carry out awareness-raising actions at their various levels. We also do it,*

	and this is important because we reach the population, the municipality, the parish and explain to the elderly, how it should be done, the risks they have, the impact they may have on these burnings". (Lieutenant Colonel at a security force of a military nature from Portugal) *"The presidents of the Municipality Council, in regions like ours, have a preponderant role in the transmission of this type of messages, even the priest, so it ends up being.... Then obviously, as the message passes, the more informal spaces such as cafes and communities turn out to be good places to spread the word, and people pass on this message of responsibility for the use of fire and the need to communicate its use".* (Forestry Technician at a consulting and technical support company, investment management and the execution of agroforestry work) *"And that's another issue that we're really bad at, and that's alignment. it's like saying "Okay, there is all this, and we have to give all this to people so they can understand in 360 degrees the problem. And how do I have to do it?" And that too fails. And then each authority, each technician who is responsible for a given matter, always thinks that his or her own will definitely contribute to the solution of the problem, and is unable to bridge the gap with the other. I make a parenthesis again, that I think this is changing, but it is changing very slowly, that should have changed a long time ago".* (Executive Director at Forestry Association of Portugal)
Evaluation of the risk communication results	*"You have to listen the person on the other side, he has to say what he perceived from the message and what he really understands from this message, if he agrees, if he does not agree, if he thinks it should be different, if there was another way to do it".* (Head Forestry Innovation and Development at a Portuguese pulp and paper company) *"(...) very little has been done to evaluate the results of the many information campaigns that have been carried out. And one thing is done, which in my view is profoundly wrong, and that is to measure the success of a campaign by counting how many tens of thousands of pamphlets have been distributed. And that's the effort made, and how much money was spent. This is the effort made, this is the cost. What was the benefit? What has been gained? To what extent have behaviors changed? Very little is known. And this is a fundamental aspect".* (Full Professor and Ph.D. Natural Resources) *"The truth is that the number of fires in Portugal has decreased a lot, the number of ignitions has decreased. I mean, today it's a third of what it was 20 years ago. Now... as there are no studies on this, we don't know if this is behavior change, per se, that is, more care, more prevention, more awareness-raising results, or prevention results, or campaigns, we don't know if that's it. , or if it's simply changes in, say, lifestyle".* (Associate Professor and Ph.D. Forest Sciences)

We are currently in the context understanding phase, which we have already been carried out two focus groups sessions and also on-site visits and observations. These activities are the firsts steps to start collecting data in the field, that precede the interviews with rural residents to understand their beliefs about the impact of traditional burning practices on rural fire risk, expressed in their own terms.

Finally, it is expected with this research to provide guidelines of a systemic approach to help decision-makers and stakeholders to design an effective risk communication plans oriented to prevent burning practices, as well as socioeconomic and environmental impacts in the future. This approach also highlights the importance of exploring the underlying reasons for resistance to behavioral change and defining guidelines to support the design of new risk communication strategies, including the dissemination of new behaviors and practices that mitigate human caused rural fires.

Abstract

The increasing importance of prescribed fire use has led to an increased focus on the development of modelling tools suited to conditions typical of prescribed fire scenarios. An improved understanding of flame spread through porous surface fuels represents an important part of these efforts. In the lower wind speed conditions typical of many prescribed burns, the role of fuel structure may be of greater importance than in highly wind-aided flame spread scenarios. The porous nature of wildland fuel beds complicates efforts to apply existing, solid surface theories for flame spread in low or quiescent wind conditions as radiation, convection and conduction may all occur within the porous fuel in addition to flame heating. An important first step in the development of any flame spread theory is the identification of the dominant heat transfer mechanisms but for wildland fuels the effect of fuel structure on the relative importance of different heating mechanisms must be considered. To investigate the role of fuel structure we therefore present a series of laboratory-based flame spread experiments conducted in pine needle fuel beds with various structural properties. The fuel loading and bulk density were independently varied by controlling fuel bed height with water-cooled heat flux gauges used to measure the (radiant and total) heat flux from both the above-bed flame and the in-bed combustion region. A single dimensionless parameter ($\alpha\sigma\delta$), incorporating the fuel bed porosity (α), fuel element surface-to-volume ratio (σ), and fuel bed height (δ), was used to describe the overall fuel bed structure. The heat flux measurements highlighted the dominant role of in-bed heating across all of the studied fuel conditions although the magnitude of above-bed flame heating increased with increasing fuel loading. Heat fluxes from the in-bed combustion region exceeded those from the above-bed flame region with the magnitude of the peak (radiant and total) heat flux at each measurement location generally increasing with increasing $\alpha\sigma\delta$ across the studied range ($\alpha\sigma\delta = 49\ to\ 399$). However, the effect of fuel loading was also apparent with a positive relationship also observed between fuel loading and flame height. The experimentally observed effective heating distances also varied with bulk density and fuel loading and were used to evaluate the use of a thermal modelling approach incorporating the bulk structural properties of the porous fuel bed. Comparison with experimental observations of spread rate indicated a maximum variation in predicted spread rate of 29 % where only radiative transfer from the in-bed combustion region was considered, with closer agreement at lower ασδ values. Where the contributions of both the in-bed and above-bed heat transfer mechanisms were considered, the need to incorporate additional heat loss terms into this thermal model were apparent. This study therefore emphasises the important role of porous fuel structure on the in-bed heat transfer and assesses suitable, physically meaningful structural descriptors. The experiments presented in this study will also provide a valuable dataset for future model development efforts incorporating measurements of fire behaviour and underlying physical phenomena across a wide range of structural conditions.

1. Introduction

Flame spread dynamics in quiescent/low-wind conditions typical of many prescribed fire scenarios differ compared to wind-driven wildfires particularly as the dominant heat transfer modes may change, altering the pre-heating of fuels ahead of the flame front. Differences in fire behaviour challenge existing model tools (Hiers *et al.*, 2020) and have motivated recent physics-based model development efforts (Gallagher *et al.*, 2021). However, semi-empirical models (e.g. Rothermel's model) underpin many simulation models (Andrews, 2018).

Rothermel's model (Rothermel, 1972) involves application of the energy conservation principle to a unit volume of fuel ahead of the flame front. This results in an expression for the rate of spread equal to the ratio between the propagating heat flux and the net heat required for ignition of the fuel. In the development of the Rothermel model, an analytical solution of this energy balance could not be made as the heat transfer mechanisms associated with these heat flux terms was unknown therefore the development of empirical terms was required for model closure.

Identification of the dominant heat transfer mechanism(s) is an important first step in the development of any flame spread theory (Williams, 1977). The porous structure of wildland fuels allows radiative and convective heat transfer to occur within the fuel bed. Appropriate descriptors of porous fuel bed structure which can be related to variations in both above-bed and in-bed heat transfer processes are therefore required. Several studies have measured heat fluxes in/near wildland fuels however analysis of the relative importance of heat transfer mechanisms and the effect of fuel structure is restricted by the wide variety of measurement types and locations limiting inter-study comparisons (Frankman *et al.*, 2010).

In the present study, heat transfer in pine needle fuel beds (heat fluxes from both from the trailing combustion region and the overhead flame) were investigated experimentally. Fuel loading and bulk density were independently varied by controlling the fuel bed height with fuel bed structure also described by the dimensionless parameter $\alpha\sigma\delta$ which incorporates porosity (α), surface-to-volume ratio (σ), and fuel height (δ) (Campbell-Lochrie *et al*, 2021). A simple thermal modelling approach, incorporating the experimentally measured heat fluxes and heating distances, is used to explore the relative importance of different heating sources.

2. Methods

Experiments involved a flame spread table (1.5 m by 0.67 m) with vermiculite substrate and insulated sidewalls (extending 0.03 m above fuel height). Gas phase temperature measurements (0.25 mm dia. K-Type thermocouples) and video analysis enabled characterisation of fire behaviour (spread rate, flame height). Heat Release Rate (HRR) was calculated using oxygen consumption calorimetry. 10 ml of acetone, distributed equally over a 0.67 m length of alumina-silica fibre, provided a line ignition source.

Heat fluxes from the flame and the in-bed combustion region were measured using water-cooled heat flux gauges (calibrated up to 100 kW/m^2). Windowed (sapphire lens with spectral transmission range of 0.2 – 5.5 µm) and exposed gauges were co-located to measure radiant and total heat flux respectively. Two different experimental setups were employed (as shown in Figure 1) allowing measurement of both horizontal heat flux through the fuel bed and vertical heat fluxes to/through the fuel bed.

The first series involved four heat flux gauges (two pairs of co-located windowed and exposed gauges) positioned vertically (sensor face parallel to fuel bed surfaces) at a horizontal distance of 1.3 m from the ignition line (0.2 m from the end of the fuel bed). One pair was positioned flush to the table surface (exposed to above-bed flame heating) while the second pair was positioned flush with the fuel bed surface (exposed to both above-bed and in-bed heating). In-bed thermocouples were positioned at a distance of 0.3 m, 0.6 m and 0.9 m from the ignition line.

In the second series, two heat flux gauges (windowed and exposed pair) were used. Gauges were positioned to measure the horizontal heat flux (sensor face perpendicular to fuel bed surfaces) and located within the fuel bed (midpoint of the gauge at a height of 12.7 mm above the table surface). Gauges primarily measured heat fluxes from the in-bed combustion region transferred horizontally through the fuel bed. Gauges were located at a horizontal distance of 0.9 m from the ignition line (0.6 m from the end of the fuel bed). Above-bed thermocouples were positioned at distances of 0.6 m, 0.8 m, 0.85 m and 0.9 m from the ignition line.

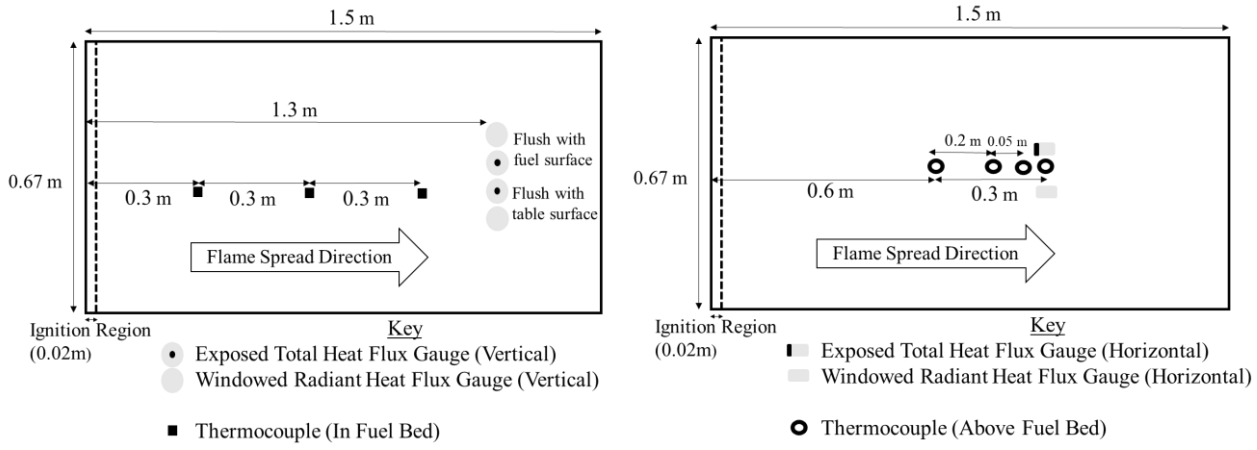

Figure 1. (left) 1st experimental setup involving four vertical heat flux gauges [sensor faces parallel to fuel bed surfaces] (right) 2nd experimental setup involving two horizontally-oriented heat flux gauges [sensor faces perpendicular to fuel bed surfaces]

Fuel beds (1.5 m by 0.67 m) were composed of pitch pine *(Pinus rigida* Mill.) needles (density = 706 ± 71 kg/m^3, surface-to-volume ratio = 5063 ± 640 m^{-1}) collected in the New Jersey Pinelands National Reserve. The dead needles had an average Fuel Moisture Content (FMC) of 13.2 % ± 4.6 %. Fuel bed structure was varied by altering fuel loading (0.2 to 1.6 kg/m^2), bulk density (10 to 40 kg/m^3), and fuel height (10 to 80 mm).

3. Results & Discussion

3.1. Overall Observations

A positive correlation between spread rate and fuel loading, and a negative correlation between spread rate and bulk density were observed, as shown in Table 1. Positive relationships between spread rate and $\alpha\sigma\delta$ ($R^2 = 0.91$) and between flame height and spread rate ($R^2 = 0.86$) were also observed.

Table 1. Summary of fire behaviour observations

Fuel Loading [kg/m^2]	**Bulk Density** [kg/m^3]	α	δ [mm]	$\alpha\sigma\delta$	**N**	**Flame Spread Rate** [mm/min ± Max/Min]	**Flame Height** [m ± 0.05 m]	**Peak HRR** [kW ± Max/Min]
0.2	20	0.972	10	49	2	82 ± 17	0.05	4.5 ± 2.4

1.6	20	0.972	80	394	4	206 ± 67	0.74	120.3 ± 12.3

3.2. Heat Fluxes

As shown in Figure 2, except where negligible heat flux was measured, heat flux profiles typically consisted of an initial steady growth period followed by a sharp rate of increase prior to a period of peak-decay behaviour.

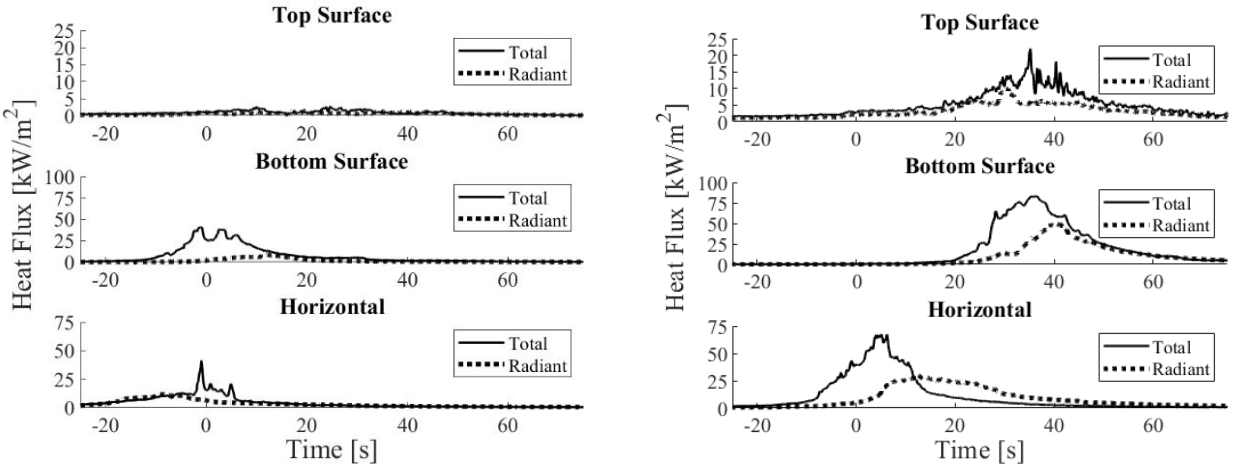

Figure 2. Characteristic total heat flux profiles at each gauge location for fuel beds of (left) $\alpha\sigma\delta = 98$ and (right) $\alpha\sigma\delta = 197$

Across all fuel conditions, heat transfer from the in-bed combustion region was the dominant heat transfer path in this flame spread scenario (compare top surface with bottom surface and horizontal measurements in Figure 2). In the first experimental series, the ratio of peak total heat flux measured at the bottom surface to that measured at the top fuel bed surface, ranged from 2.2 to 14 across the studied conditions. In-bed heating as measured by the horizontal gauges (heat transferred horizontally through the fuel bed from the combustion region) exceeded flame heating from the above-bed flame (measured at the top surface of the fuel bed), as shown in Figure 3.

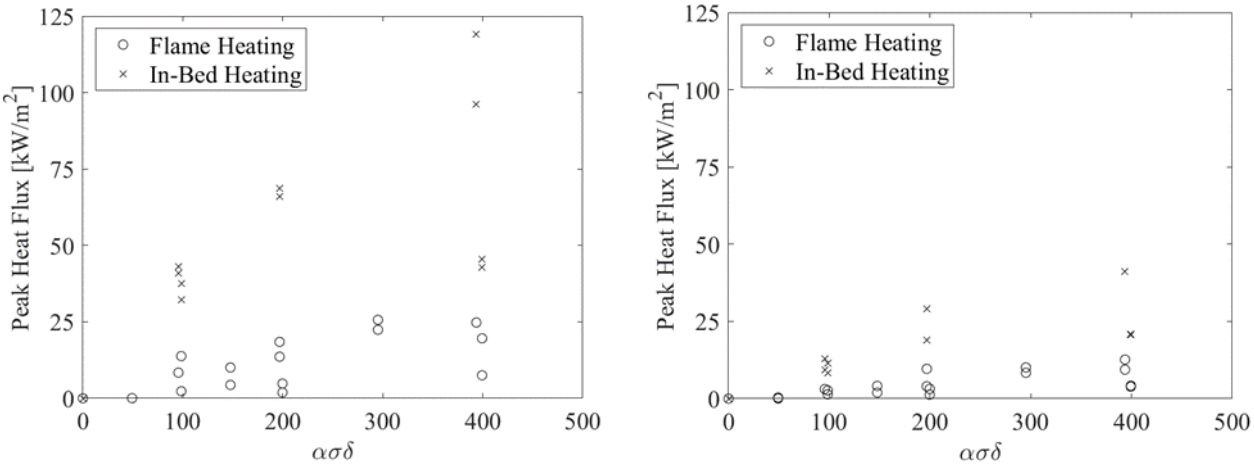

Figure 3. Comparison of peak (left) total and (right) radiant heat flux from the above-bed flame (flame heating) with horizontal heat flux through fuel beds (in-bed heating) of various structures

As shown in Figure 3, heat fluxes varied between fuel beds of different fuel structure ($\alpha\sigma\delta$). Generally, higher peak fluxes (radiant and total) occurred in fuel beds of higher $\alpha\sigma\delta$ values. However, the importance of fuel loading at similar ασδ values is observed in the two highest ασδ cases (ασδ=394 and ασδ=399), with significant variation in heat flux magnitudes occurring between these cases. The heat flux from the overhead flame increased with fuel loading which is in line with the positive relationship observed between fuel loading and flame height. Effective heating distance through the fuel bed is dependent upon porosity and attenuation characteristics of the fuel bed and varied with fuel loading and bulk density.

3.3. Thermal Model

A thermal model was constructed based on assumed bulk fuel bed properties, following an energy conservation approach similar to those previously described for porous fuel beds (Frandsen, 1971) and thermally thin solids (Quintiere, 2006). A control volume was defined within the fuel bed and fixed to the pyrolysis front position (x_p) as shown in Figure 4 with the flame spread rate described by:

$$v_p = \frac{\int_{x_p}^{\infty} \dot{q}_p^{"}(x)\,dx + \int_{x_p}^{\infty} \dot{q}_f^{"}(x)\,dx}{\rho c_p \delta (T_{ig} - T_s)}$$

where $\dot{q}_p^{"}$ is the heat flux into the control volume from the combustion region (integrated across the effective heating length), $\dot{q}_f^{"}$ is the heat flux from the above-bed flame, T_{ig} and T_s are the ignition and initial fuel temperatures respectively, and δ is the fuel height. Bulk fuel bed properties were based upon volume-averaged air and needle properties (density (ρ) and specific heat capacity (c_p)). Both $\dot{q}_p^{"}$ and $\dot{q}_f^{"}$ were integrated across their respective effective heating distances which were determined experimentally based upon the time between onset of heating at the heat flux gauge (0.5 kW/m^2 threshold) and the time of peak heat flux. Similarly, heat flux magnitude is based on experimental values, with 1 s moving average applied.

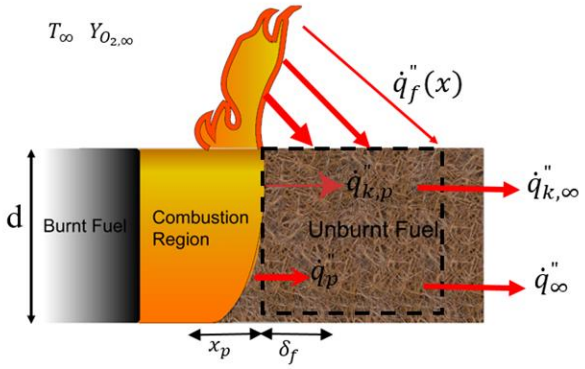

Figure 4. Schematic of control volume for flame spread model

Considering only radiative heat flux from the combustion region results in similar predicted Rate of Spread (ROS) values to those observed experimentally. A maximum variation between the predicted ROS and the experimentally measured ROS of 29 % was observed, with closer agreement for fuel beds of lower ασδ values, as shown in Figure 5. Given the greater HRR values in fuel beds of higher ασδ values, it may be that greater entrainment increases the convective cooling, with these heat losses not accounted for in this model.

Considering instead heat transfer only from the flame results in an underestimation of the ROS, particularly in fuel beds of lower ασδ values. This suggests that the dominance of the heat transfer from the combustion region increases at lower ασδ values. The predicted ROS is also shown where both the combustion region and flame heat transfer are included in the thermal model. This tends to overestimate the ROS, compared to experimental observations, however the effect of convective cooling (or radiative losses) is not considered and therefore this over-estimate is not unexpected and is in line with previous studies (De Mestre *et al.*, 1989).

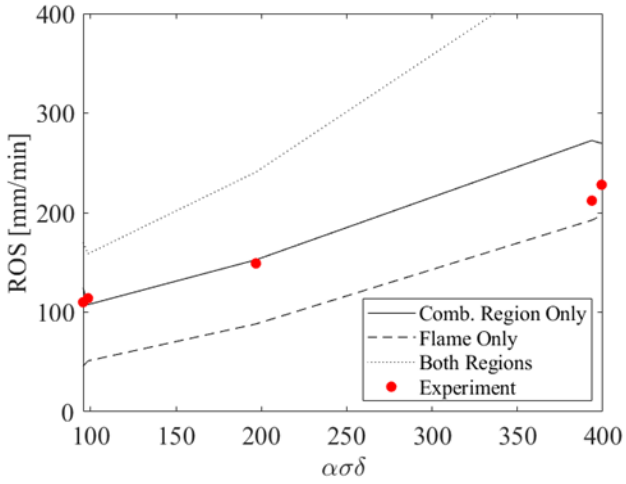

Figure 5. Comparison of avg. experimental Rate of Spread (ROS) values and thermal model ROS predictions for cases considering radiant heat flux from combustion Region only, flame region only, and both regions

4. Conclusions

By varying the structure of porous fuel beds (fuel loading, bulk density, fuel bed height), fuel loading and bulk density were observed to independently influence flame spread rate and fire behaviour (flame height, heat release rate). The effect of fuel structure on flame spread rate was well-described by the parameter $\alpha\sigma\delta$. Examining further the underlying physical mechanisms controlling the flame spread process highlighted the dominant role of in-bed heat transfer (from the combustion region in the fuel bed) across the range of fuel beds studied ($\alpha\sigma\delta$ = 49 to $\alpha\sigma\delta$ = 399). The significance of heat transfer contributions from the overhead flame generally increased with increasing $\alpha\sigma\delta$ value of the fuel bed, in contrast with some past predictions regarding heat transfer mechanisms in shallow fuel beds. Direct measurement of heat flux and effective heating distance, allowed development of a simple thermal model considering only radiative heating contributions. Comparison with experimental observations of spread rate indicated a maximum variation in predicted ROS of 29 % where only radiative transfer from the in-bed combustion region was considered, with closer agreement at lower $\alpha\sigma\delta$ values. Where the contributions of both the in-bed and above-bed heat transfer mechanisms were considered, the need to incorporate appropriate heat loss terms into this thermal model was apparent.

Fuel moisture content, Prescribed burns, Turbulence statistics, WFDS

Abstract

Prescribed burns are valuable tools utilized for land management. They serve the purpose of reducing the risk of wildfires by lowering the build-up of dry fuels, improving forest health, and controlling the growth of plants and insects. One of the crucial components that affects the execution of prescribed burns and controls the fire behaviour and smoke dispersal thereafter is the fuel moisture content, which needs to be considered when planning prescribed burns. The fuel moisture content variation is dependent on the meteorological variables, fuel properties, and the local turbulent fire dynamics, and so varies spatially and temporally over the land area before and during the fire advancement. In previous studies, the fuel moisture content was treated based on average properties, independent of the effect of local turbulence. In this study, the spatiotemporally varying fuel moisture content is obtained by a physics-based model that considers the coupled energy and moisture balance dynamics inside the fuel layers. This moisture model is implemented into the Wildland-urban Interface Fire Dynamics Simulator (WFDS) by means of a two-way coupling. Along with the local fuel properties, the model uses the instantaneous solar radiation and relative humidity, together with the instantaneous turbulent wind velocity and ambient air temperature at the boundary of each fuel sub-surface (grid) in the simulation domain. The coupled model is employed to study the effect of the dynamic variations of the fuel moisture on the turbulent evolution of the fire plume during a line fire propagation over a flat grassland. The findings of the study will provide insights into the effect of the fuel moisture content on the plume dynamics and smoke dispersal during prescribed burns and will assist in planning these burns.

1. Introduction

Prescribed fires, also known as controlled burns, are planned and controlled applications of moderate to low intensity fires under specific atmospheric conditions. In addition to mitigating wildfires, prescribed fires are essential for maintaining the health of fire-dependent ecosystems. In fire-dependent ecosystems, prescribed fires serve the purpose of: (1) regulating the buildup of dry fuel, (2) controlling the growth of plant species, insects, and parasites, and (3) improving the health of the soil (Heinselman and Wright, 1973). In addition, prescribed fires help with training firefighters and prepare them for the required actions during wildfires. The smoke from prescribed fires, however, may be troublesome for the neighboring communities. It may substantially impact the air quality and increase the risk of road accidents. When the plumes from prescribed fires penetrate the troposphere, they add smoke aloft, which impacts regional as well as global scale climate for instance by reducing insolation and altering the cloud microphysics (Lareau and Clements, 2017). Contradictory to this, when the plumes remain restricted to the atmospheric boundary layer, they affect the local population by posing health hazards in the nearby communities. These near-field plumes bring about persistent temperature inversions, unanticipated patterns of smoke transport, and could pose a travel risk by reducing visibility.

An important factor that influences the fire plume dynamics, as well as the fuel flammability, fire propagation behavior, and the burn plan is the fuel moisture content (FMC). FMC is influenced by the vegetation characteristics, the background atmospheric conditions, and the local fire-induced turbulent airflow and temperature during the fire. Therefore, as a result of the instantaneous variations in solar radiation, relative humidity, and the local turbulent wind velocity and air temperature the FMC varies both spatially and temporally at the fuel boundary. While there are studies that investigate temporal variations of the FMC using empirical models (Alves, 2009; Slijepcevic, 2013) and physics-based models (Wittich, 2005; Matthews, 2006), an

understanding of the spatiotemporal turbulent variations of the FMC at the fuel boundary during fire events is missing. In this study, we aim to examine the effects of the dynamically varying FMC on the turbulence statistics of the flow and plume dynamics during a line fire using a coupled fire-atmospheric interaction model that considers the spatiotemporal variations of the fuel moisture content.

2. Model Description and Simulation Setup

The change in the FMC is modelled by utilizing a physics-based FMC variation model (Matthews, 2006). The model represents the transfer of energy and water and their two-way interactions in a fuel bed, which is bounded between the atmosphere and soil surface. The fuel bed is comprised of multiple layers of fuel and each layer is made up of three components of the fuel solid, air, and free liquid water. The model is controlled by precipitation, diurnal solar radiation, the local wind speed and ambient air temperature, relative humidity, and the physical properties of the fuel (e.g., the surface to volume ratio, packing ratio, and height of the fuel bed). The energy and moisture balance equations (Eq. 1 and 2, respectively) are solved inside each layer in a coupled way to obtain the FMC (m).

$$C_{h,m}\frac{\partial T_m}{\partial t} = \frac{1}{V_m}\left(\frac{\partial R_{net}}{\partial z} + \frac{\partial H_C}{\partial z}\right) - \mu_{m,a}H_{ma} - \mu_{m,a}\lambda E_{ma} - \mu_{m,l}H_{ml} \quad (1)$$

$$\rho_{air}\frac{\partial m}{\partial t} = -\mu_{m,a}E_{ma} - \mu_{m,l}E_{ml} \quad (2)$$

Here, the energy budget equation (Eq. 1) models the variations of the fuel temperature (T_m) with time. In these equations, $C_{h,m}(Jm^{-3}K^{-1})$ and $V_m(m^3m^{-3})$ are the volumetric heat capacity and volume fraction of the fuel solid. $\mu_{m,a}(m^{-1})$ and $\mu_{m,l}$ (m^{-1}) are, respectively, the surface area-to-volume ratio at the interface between the fuel solid and air and at the interface between the fuel solid and the intercepted liquid water. λ (Jkg^{-1}) and ρ_{air} (kgm^{-3}) are the latent heat of vaporization of water and density of air. R_{net} (Wm^{-2}) is the net radiative heat flux, H_C (Wm^{-2}) is the heat flux due to conduction, H_{ma} (Wm^{-2}) is the sensible heat flux at the fuel boundary, E_{ma} $(kgm^{-2}s^{-1})$ is the moisture flux between the litter solid and air, H_{ml} (Wm^{-2}) is the heat flux between the fuel solid and the intercepted liquid water, and E_{ml} $(kgm^{-2}s^{-1})$ is the moisture flux between the fuel solid and the intercepted liquid water.

The FMC model is coupled with the Wildland-urban interface Fire Dynamics Simulator (WFDS) in a two-way manner to allow for the investigation of the FMC variation effects on the fire and plume dynamics. WFDS is a large-eddy simulation (LES)-based model that simulates the fire-atmospher interactions. In the two-way coupling, the FMC model utilizes the instantaneous information of the meteorological conditions and the fire-induced flow from WFDS and provides the instantaneous fuel moisture content to WFDS at each timestep.

In this study, the coupled model is used to investigate how the instantaneous changes of the fuel moisture due to the turbulent interactions at the fuel boundary affect the fire and plume behavior in a case of a line fire in a flat grassland. The domain size and grid resolutions are found through sensitivity analyses and the first and second-order turbulence characteristics of the flow and plume dynamics, as well as the fire propagation behaviour under the effect of dynamic FMC change is investigated. The results are also compared against cases with constant FMC and with no fuel moisture. Findings of this study provides a better understanding of the role of fuel moisture in fire behavior and near-field plume structure and dynamics.

Emergency Alerting Technologies Relevant to Forest Fires

Frank W. Bell

Kybernetix LLC, Clifton NJ, USA, {fbell@kynx.us}

Keywords

Fire fatalities, Mobile, WEA, SMS Broadcast, Broadcast digital radio, Broadcast television, Alerting

Abstract

California wild and forest fires in 2017 resulted in over 100 fatalities. While WEA alerts were transmitted to mobiles in selected areas, the power and network outages limited their delivery. WEA is similar to the SMS Broadcast system used elsewhere. It does not require subscription, and can be geotargeted, usually by map polygon. There are already available and in development other alerting technologies. The Emergency Alert System on radio and TV in the U.S. has been in use for many years. It is a broadcast break-in system the overrides program content. This was used in one location for the wildfires, but not elsewhere as geotargeting is not possible with this system. It is and analog broadcast technology architecture. AM and FM Broadcast in the U.S. now has HD Radio that is mixed analog and digital. A limited data message can be carried and used for selective delivery of messages. DAB, DAB+ and DRM also can carry a message payload, which can be used for a selective delivery mechanism when the receiver has location position. This may be in a vehicle radio/navigation system. The current digital television system in the U.S. and some other countries is now being replaced by ATSC 3.0. This provided a superior modulation format, Layered Division Multiplexing (LDM) for delivery of program content and alerts to suitable mobiles. An IC for UHF reception and prototype mobiles have been developed. No external antenna is required. Bothe of these new technologies are tested as delivering alerts independently of the mobile network. Within the limitations of radio and TV propagation, such capabilities would provide technology redundancy. The television signal propagation may be limited in rural areas, but ATSC 3.0 is capable of having on frequency repeaters to make a single frequency network for improved coverage of program content and alerting. Multilingual alerts based on the CAP Event Terms list with Message Formats are being provided for.

1. The Lifesaving Value of Alerting

Some comparisons are made between disasters that are unalerted and others which have alerts beforehand.

1.1. Samoa and American Samoa Tsunami 2009

1.1.1. Fatalities comparison

In the 2009 earthquake and subsequent tsunami, there were 22 confirmed fatalities in American Samoa and 147 in Samoa. While the tsunami in American Samoa was 4.6 to 6 m high the Samoan landing was 6.1 to 9 m high. This explains in part the difference in fatalities

1.1.2. Benefit of Alerting Comparison

The fatality ratio is 22 to 147. The height ratio is 6 to 9. Compensating for the height, the ratio is 1 to 4.45. In American Samoa the radio station operator, DJ Ms Lupe Lohman, initiated a tsunami alert. http://news.bbc.co.uk/2/hi/asia-pacific/8282741.stm. This was relayed by criers, church bells and other means. In Samoa, no alerting was recorded, and the radio station had no Emergency Alert System. At the NAB Trade show in 2017, I spoke with the representatives of Triveni (a Viavi division) who stated that it was one of their products that was used. Samoa at that time was a protectorate of New Zealand. Such equipment is not in use in New Zealand, but SMS Broadcast is now in use to mobiles.

1.2. Indian Ocean 2004 and Tohoku, Japan 2011

1.2.1. Fatalities Comparison

In the 2004 Indian Ocean earthquake and tsunami, there were an estimated 227 898 fatalities and in Japan there were 22 303 fatalities and missing. While the tsunami height in Indonesia was 30 m for a 9.3 magnitude quake, the 2011 earthquake and tsunami in Tohoku had a 40.5 m height for 9.1 magnitude.

1.2.2. Benefit of Alerting Comparison

The fatality ratio is 22 303 to 227 898. Whie the height and earthquake magnitude differ; they somewhat cancel each other at a 40.5 m and 9.1 magnitude in Japan versus 30 m and 9.3 in Indonesia. Compensating for the differences the benefit ratio is 1 to 13.5. This is much higher than for Samoa, however in Japan there were many more mitigation measures implemented beyond alerting. The cost of the alerting system has not been obtained in writing. It is worth noting that this system was installed in 2009 and is considered to have delivered sufficient benefit to pay for that investment in two years.

While this analysis of only two examples is unsatisfactory for assessing a standard deviation of results or of differences with control examples, the problem is the lack of comparable examples. As an illustration, compare the Haiti earthquake 2010 magnitude 7.0 with 300,000 fatalities and Christchurch New Zealand 2010 magnitude 7.1, or 2011 magnitude 6.1 or 2016 magnitude 5.7 with considerable damage in the latter but with two noted fatalities and 100 injuries in 2010, 185 deaths in 2011. None of the events included alerting the public. It may be possible to use factor analysis to extract some factors relevant to the alerting question, but that requires a large amount of related set data. Such a set of data does not appear to be available. One would hope that future researchers are able to improve on this with future data after some more implementation of alerting in the future.

1.3. Evaluation of Wild and Forest Fire Fatalities in the U.S.

1.3.1. Los Angeles Times 2018-12-03

This is a newspaper report copied and is in the appendix as an attachment. In one of the fires there were 88 fatalities in Butte County. The headline noted that more than one third of the cellular recipients did not receive alerts. A subscription alerting service was used.

1.3.2. Cellular at risk of wildfires

This is an engineering evaluation of cellular or mobile base stations and the risk of fires at their locations, which may be on high land. It is in the appendix. No discussion of fatalities is included.

1.3.3. Gatlinburg 2016 Nov 28 firestorm

This report is applying to Gatlinburg, Tennessee and is in the appendix as an attachment. While there were a limited number of fatalities, being 14, this is included because the Emergency Management Office lost its communications and was unable to initiate an Emergency Alert to mobiles or broadcasters. While satellite or amateur radio hypothetically could have been technologies to use in such a situation, the lack of landline and internet phone were also rendered inoperative. This highlights the importance of redundant technologies.

1.3.4. NBNCBC Telecommunications Outage Report 2017 Firestorm

This report applies to wild and forest fires in California in 2017 and is in the appendix as an attachment. Napa, Sonoma and Mendicino Counties were affected with 44 lives lost.

2. The Importance of Redundancy for Emergency Alerting, Including Technologies

2.1. The Fatalities noted in 1.3 total 132.

This is a situation where one single or few technologies were used. The Emergency Alert System using broadcast radio and television was only used in one alert, and no fatalities in that area were noted. It is also worth noting that broadcast coverage areas are normally much larger than forest fire areas. This technology at that time would have alerted large numbers of recipients for whom the alert was irrelevant. The lack of selection of alert delivery as a polygon on a map is highly desirable. Alerting delivery presently has the potential to give rise to large numbers of people evacuating, with a potential for traffic congestion that could have been a serious hindrance to firefighting, police and ambulance crews. There is no suggestion that this is an advisable course of action for alerting should such problems arise.

If an appropriate area could be selected, given the conservative benefit of alerting noted in 1.1.2 as being 4.7, the fatalities could have been reduced to 28, saving 105 lives compared with using a single technology. The results for Japan in 2011 suggest that more technologies produce better results.

3. An Outline of Broadcast Alerting Developments.

3.1. HD Radio, DAB, DAB+ and DRM.

In the U.S. there is AM and FM digital broadcasting added to the analog carrier. It is possible to replace the analog carrier with digital only. On FM there is a 200 kHz station spacing and this allows for digital carriers alongside the analog signal. There is a limited data rate available for alerting messages, which may include a map polygon, jurisdiction or receiver type for selectivity. A receiver may obtain the current location from the navigation system or via Bluetooth from a mobile. AM HD Radio has very limited alert data capacity, but this has potential. Selectivity may be implemented by selecting between the alert audio and the program audio. On FM there are up to 3 digital programs, of which one is replicating the analog signal. In a region, one may be a news, alert and weather program with lower data rate. This may be possible on DRM, but research is needed.

DAB and DAB+ are multi-station and digital only. It may be possible to designate one as a news, alert and weather program with lower data rate. The alert message data would provide the selection criteria for program or alert audio selection. This would only require software added to the consumer receiver and a means of determining the location, e.g., vehicle navigation or Bluetooth to a mobile.

3.2. ATSC 3.0 “nextgenTV” and DVB.

The ATSC 3.0 or nextgenTV system included alerting audio+data (as A/331) and video as separate from the TV program, which may be 4K or UHD with High Dynamic Range and Wide Colour Gamut. It is a transport technology that may be used for new technologies in the future as a complement to the present internet. The audio may be immersive. Other HD or SD TV channels may be included, or UHD when a 7 or 8 MHz bandwidth is available. The video is HTML5, not an inflexible format. The modulation is Layered Division Multiplexing (LDM). There is a QPSK high power and low data rate layer, and a selectable constellation lower power high data rate component. The alerting and a Standard Definition video with stereo plus the alerting data is in the QPSK. This UHF band signal may be received by a little antenna in a suitable mobile. Protypes have been demonstrated. While this expands the potential audience to such mobiles, the importance here is the delivery of alerts. This system is broadcast in South Korea and USA currently. India, Brazil, Jamaica have announced, and Canada and Japan are expected to replace their digital TV system with ATSC 3.0. It can carry European SD and HD video. It addition to cinema quality video and audio, it is also IP based. Enabling delivery via the air, satellite, or cable as well as the internet. China is participating also. The importance here is the better delivery of alerts than possible with DVB to mobiles. In order to reach more remote areas, it is possible to replace TV translators with Single Frequency Networks (SFN) for wider coverage without additional spectrum required. U.S. broadcasters have released considerable spectrum to the mobile providers.

3.3. Cable, fibre and telco TV.

The various systems all have low bandwidth data delivery possible. When the Set Top Box has its location data by one of various means, the selective alert delivery can be implemented. This is anticipated development work. The distribution of these fixed line systems in rural areas is not expected to be high, but they are important for urban areas.

3.4. Satellite TV and radio.

In the U.S. this is DirecTV, Dish Network and SiriusXM. These all provide alerting currently, but with better alerting technology, these distributions can be improved. Other countries have various systems which are likely to be amenable to better alert delivery. Satellite delivery for Earthquake Early warning has an added delay that becomes significant.

3.5. Internet alerting.

There are many forms of internet alerting. A distribution to broadcasters is via the internet. Then there is Federation of Internet Alerts, Google Alerts and more including subscription services.

3.6. Message content.

The OASIS-Open Emergency Management Technical Committee has developed an Event Terms list which is now a committee note for the Common Alert Protocol standard x.1303 of itu.int. This standard is adopted by over 70% of the world, including much of Europe. Each term may have a detailed spectra which is not defined. Based on this Committee Note, a collection of historical alerts, various lists from many sources and other

research a list of Message Formats {currently 427} these include many for fire alerts and fire risk messages. A tab for wildfire messaging is in the spreadsheet. The Message Formats have been translated into a first draft for many languages. The intent is to enable multilingual alert generation by Emergency Managers who only know one language. Also, using this message added data and the codes, alerts in neighbouring countries for emergencies that are cross-border can reasonably easily be made. Information from previous work has been incorporated. The intent is to have a level playing field for consumer electronics manufacturers to be able to implement one version of software to be able to process alerts in any country. English, Spanish, French and Portuguese are some of the languages translated.

3.7. WEA and SMS Broadcast to Mobiles.

Currently many mobiles receive alerts from WEA (in the U.S.) or SMS Broadcast (many countries) and other SMS or subscription services. In the U.S., authorized Emergency Managers using Alert Origination Software may send alerts to the FEMA IPAWS system to various recipients including mobile service providers and broadcasters. With the anticipated implementation of ATSC 3 or nextgenTV to mobiles, there is the likelihood of the mobile receiving multiple alerts from one origination message. Identification of this to reduce alert fatigue by the public is designed into the complete system. Between the various sources, the technology redundancy should provide much improved reliability of distribution. Intelligent Highway Signs, loudspeaker systems and other technologies may also be incorporated.

3.8. Systems Interoperability Standards and some applications.

Alerting Protocols; Common Alert Protocol (CAP) with Event Terms list expanded as core protocol. This may be translated to Emergency Alert System (EAS) based on FCC Part 11 rules for analog and legacy television and analog radio. Improved EAS adapted for HD Radio, DAB, DAB+ and perhaps DRM. DVB Alerting distribution where applicable. CAP based messages on ATSC 3 in HTML5 which can be translated to CAP if needed. Others may be adapted e.g., for Japan.

Earthquake Early Warning using an appropriate version of CAP with delivery optimized for speed. If possible, within 3 seconds of detection.

Healthcare; EDXL-HAVE, HL7 and others

Other Emergency Management; EDXL-DE, EDXL-RM. EDXL-TEP, EDXL-TEC, EDXL-SITREP, XchangeCore. Google Earth, Esri, NAVTEX, https://www.g2.com/categories/emergency-management atsc3advocate.com. https://onemediallc.com/resources/

4. Conclusions.

4.1. Audience Relevance.

This is always important with any media content distribution. The audience of an alert should as much as is reasonably practicable, be those for whom the alert is intended. That audience of this paper is gathered to address Forest Fires. Consequently, while much more could be stated on these subjects, those things are considered not as relevant. A public opinion survey regarding alerting is attached as Research_Study. Questions are welcome to fbell@kynx.us

4.2. Anticipated Costs and Benefits.

The major expense for such improvements is for improved software for the consumer receivers where that is practicable. Vehicle digital or satellite radio receivers may have their software upgraded as part of the dealer maintenance. Older vehicles may be replaced with newer ones which may already have the software from the factory. Some devices can have software downloaded to a USB for vehicle upgrade or directly to the device. Once developed, the cost is the time and effort including informing the users. Other consumer electronics like radios have new replacements in time. The cost of the infrastructure for alerting delivery is significant, and the cost of developing that is also significant. The benefit of lives saved is considerably more significant. In “Risk and Reason” by Cass Sunstein, the value of a life for public policy purposes in the U.S. when written was in the range of $US 1 M to $10 M. Other countries may have such assessments made. An honest assessment of this aspect is helpful for making economic decisions. Disasters and wars may be made lesser problems by such considerations.

A desirable capability is that of delivering alerts to mobiles. ATSC 3.0 or nextgenTV has this capability designed in and is also designed to be significantly better to deliver such alerts to mobiles than previous digital TV systems. Much of the world is using DVB or ISDB which have been improved. DVB-H was a commercial failure, and probably a poorer performer with a limited range. DVB-NGH has been developed as a successor, but the implementation commercially has been limited by the range. That is primarily arising from the type of modulation ATSC 3.0 uses LDH which has a high power low data rate component for inherently greater range. Future mobiles providing for this and DVB-NGH would require development. A Mark One nextgenTV evaluation model has been produced but is not yet publicly available. While there is much progress, this particular aspect has remaining significant work to be done, and the benefit is not at present apparent to the public if this cost is to be recouped by a full increase in product price.

Experimental and numerical characterisation of the smouldering combustion of peat

Smouldering; peat; pyrolysis; char oxidation; burning rate

Abstract

Smouldering peat fires are a major source of greenhouse gas emissions. As the climate warms, the frequency and severity of peat fires will continue to increase, with a single large fire event contributing as much CO2 to the atmosphere per day as an industrialized country. Estimates of the amount of CO2 released by peat fires contain large uncertainties, driven by overwhelming uncertainty in the mass of peat consumed in these fires. The present work addresses uncertainties in peat fire dynamics and smouldering through an iterative experimental and modelling process. Presented here is a first step towards predicting greenhouse gas emissions. Experiments focus on capturing the mass burnt in a smouldering peat fire and describing the smouldering—pyrolysis and oxidation—process. Mass loss rate is found to vary as a sample is tested in lateral spread vs downward spread configurations. A one-dimensional model of peat smouldering is implemented, with initial qualitative results presented here, showing the drying of wet peat and the pyrolysis front. These results represent the current work in progress on this effort. Further work will compare experimental and simulation results for additional parameters of interest, and simulations will be used to inform which soil parameters to explore experimentally.

1. Introduction

The smouldering of organic soils is a key wildfire hazard across the globe with peat fires burning primarily in boreal regions in the northern hemisphere (e.g., Siberia, Canada, Alaska) and tropical regions (e.g., Southeast Asia). Boreal peat (at northern latitudes from Europe to the Arctic) stores over 400 Gt of carbon (Beaulne *et al.* 2021), which can be released to the atmosphere if the peat is ignited. As the climate warms, the frequency and severity of peat fires will continue to increase. The timescales of this release (days) compared to the timescales for the formation of peat (millennia) mean it has a significant potential to drive climate change. Estimates of the amount of greenhouse gases (GHGs) released by peat fires contain large uncertainties, driven by overwhelming uncertainty in the mass of peat consumed in these fires (Rodríguez Vásquez *et al.* 2021).

Sustained smouldering is dominated by two processes: pyrolysis and oxidation. The pyrolysis process is controlled by heat transfer through the soil and is therefore influenced by its moisture content (MC), the composition of the peat (specifically the quantity of inert material/inorganic content (IC)), and the heat losses to the environment. The oxidation process is governed by the diffusion of oxygen through pyrolyzed soil regions. These two processes produce different carbon-based emissions. Therefore, to elucidate the contribution of peat fires to GHG emissions, we must (1) be able to predict the mass of peat consumed, and (2) have detailed knowledge of the processes and dynamics of the smouldering combustion.

[1] Sandia National Laboratories is a multimission laboratory managed and operated by National Technology and Engineering Solutions of Sandia, LLC., a wholly owned subsidiary of Honeywell International, Inc., for the U.S. Department of Energy National Nuclear Security Administration under contract DE-NA0003525. SAND2022-3524 C.

Recent efforts have been made to understand the process of smouldering combustion to better understand the hazards posed by this wildfire process. Previous work on peat fires has used commercial peat to analyze gas emissions (Hu *et al.* 2020) and the chemical reactions involved in the ignition and spread of smoulder (Hadden *et al.* 2013) in the laboratory. The influences of MC (Amin *et al.* 2020; Huang and Rein 2017; Lin *et al.* 2020), wind and slope (Christensen *et al.* 2020), density (Krieger Filho *et al.* 2020), and depth of peat (Lin *et al.* 2021) on spread rate have been studied. A one-dimensional (1-D) model has been developed (Huang and Rein 2015; Huang and Rein 2019; Huang *et al.* 2015) and used to understand the relationship between depth of smouldering and MC. This model has been used to explore the effects of MC, IC, and peat properties on critical ignition conditions (Huang and Rein 2015; Huang *et al.* 2015). Limited work has been done in the laboratory using natural peat as the medium under investigation, though work has been done with peat from near Edinburgh, Scotland (Rein *et al.* 2009).

Here, we present initial steps towards providing more accurate estimates of GHG emissions from peat fires. The experiments explore key 3-D effects, such as specimen size and orientation. Initial results are presented from quasi-1D simulations, based on the model created by Huang and Rein. As part of an iterative experimental and modelling process, the experiments will be used to validate the model and expand it to 2-D and 3-D, while the model will be used for physics elucidation and to explore the experimental parameter space to inform which experiments to perform.

2. Experimental set up

To explore the competing effects of heat transfer and oxygen diffusion on peat smouldering, a series of one-dimensional opposed flow smouldering experiments were undertaken in the laboratory. Two cuboidal peat sample sizes of cross-sectional area 625 and 2,500 mm^2 (25- and 50-mm side lengths) and total length of 300 mm were studied in the vertical downward and lateral orientations, as shown in Figure 1 below. An open boundary condition was used in all cases to allow the free flow of oxidiser into the reaction zone by constructing sample holders from woven stainless-steel mesh with hole size of 0.96 mm (~46% open area). An electrical nichrome coil was used for ignition, supplying a power of 50 W for 5 min. Commercially harvested sphagnum moss peat was used as the feedstock. Prior to testing, the peat was dried in batches for at least 48 hours at 80°C. The bulk density of peat was fixed at 350-400 kg/m^3. The approximate mass of peat for the three sample sizes tested is 50 and 200 g.

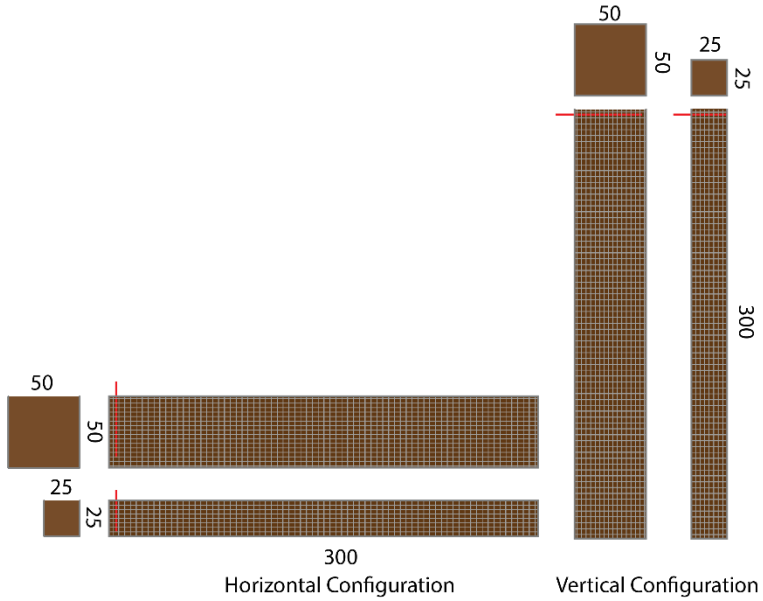

Figure 1- Schematic of experimental setup for lateral (horizontal configuration) and downward (vertical configuration) spread experiments for both sample sizes. All dimensions are in mm. The red line represents the ignition location.

Real time mass measurements were made during the experiment and the mass loss rate (MLR) was calculated and smoothed using a 51-point Savitsky-Golay filter with a second order polynomial. Temperature

measurements were made at the centreline of the sample using 0.25 mm diameter K-type thermocouples. These are used to track the position of the pyrolysis and smouldering fronts as a function of time. The propagation rate was recorded using time-lapse imagery which was processed computationally.

3. Experimental results and analysis

The smouldering process is characterised using the mass and MLR data, which can capture the effects of both pyrolysis and oxidation. Propagation rate data and temperature data will be included subsequently to elucidate the smouldering front characteristics.

3.1. Experimental mass and mass loss rate data

The mass of the sample as a function of time is presented in Figure 2a. As the sample dimension increases, so does the duration of the smouldering, as the mass of peat has also increased. Orientation of the specimen impacts the duration of the smouldering process for a given propagation direction. The smouldering propagation direction also appears to change the smouldering dynamics. Vertical downwards smouldering is characterised by a period of relatedly high MLR per unit cross section (Figure 2b) after ignition (25-100 minutes) and then a period of lower MLR (100-150 minutes), which is anticipated to represent the transition from primarily pyrolysis to long-time oxidation. The longitudinal smouldering, on the other hand, is characterised by a quasi-steady MLR, suggesting that steady state propagation has been achieved.

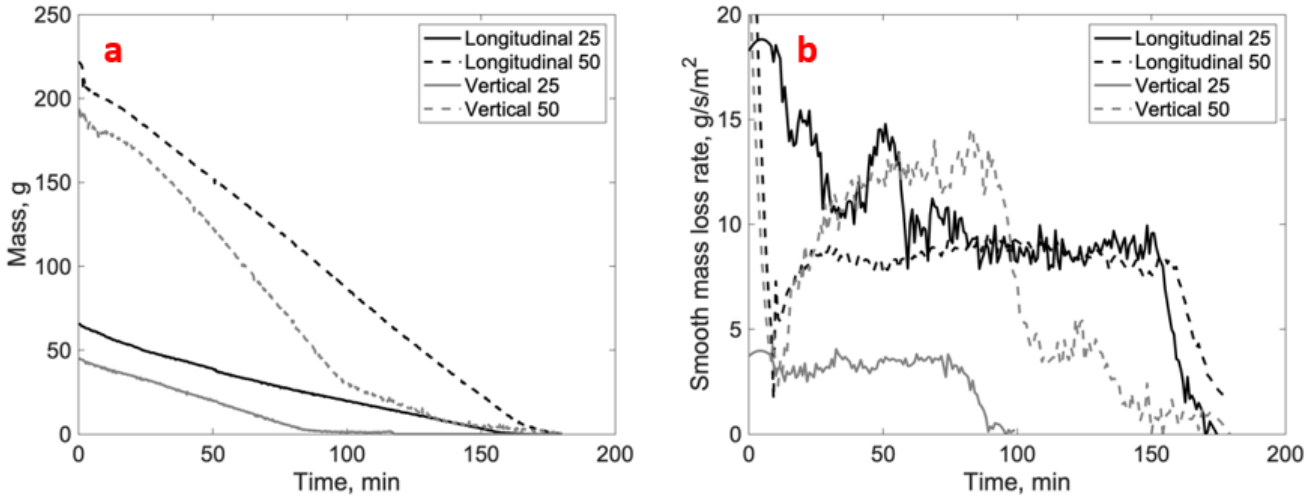

Figure 2- Sample mass (left) and mass loss rates (right) as a function of time for cuboidal samples with 25- and 50-mm sides.

4. Computational modelling

The quasi-1-D model used here is based on the work of Huang *et al.* (2015) and Huang and Rein (2015), in which a 1-D model of peat smouldering was developed in GPyro. A version of their model has been implemented in Sierra Thermal/Fluids: Aria, a generalized Galerkin finite element method code (Notz *et al.* 2016). The governing equations are solved both in the solid phase and in the gas phase for continuity, continuity of species, and enthalpy. We use Darcy's law for flow through a porous media to calculate the gas phase velocity. The ignition source is modelled as a constant 800°C temperature on the top end of the peat column. Boundary conditions on the cool end assume convective and radiative heating to an ambient environment. Material properties of the solid phase species were taken from Huang and Rein (2015). A 5-step reaction mechanism, developed in Huang and Rein (2014), is used to describe the peat smouldering process, with kinetic parameters for each reaction taken from Huang and Rein (2015). To account for the experimentally observed collapse when a peat column burns, the model solves the quasi-static conservation of momentum.

The model is run for 30,000 s on a lateral column of peat 400 mm long and 100 mm x 100 mm square. A 1-D problem is approximated in Aria by creating a mesh with elements in only one direction (i.e., a stack of blocks).

The element edge length along the column of the peat is 2 mm. Time is advanced implicitly using adaptive time stepping based on problem difficulty and error control, with a minimum of 1^{-9} s and a maximum of 1 s.

Initial modelling results, presented in Figure 3, show notional agreement with lateral spread experiments. A snapshot of one of the experiments shows black char and ash behind the smouldering front. Modelling results show the drying front (in red) and leading edge of the pyrolysis front (in blue). Experiments and simulations are compared at an arbitrary time. While further work is required to verify and validate the model, initial results are promising.

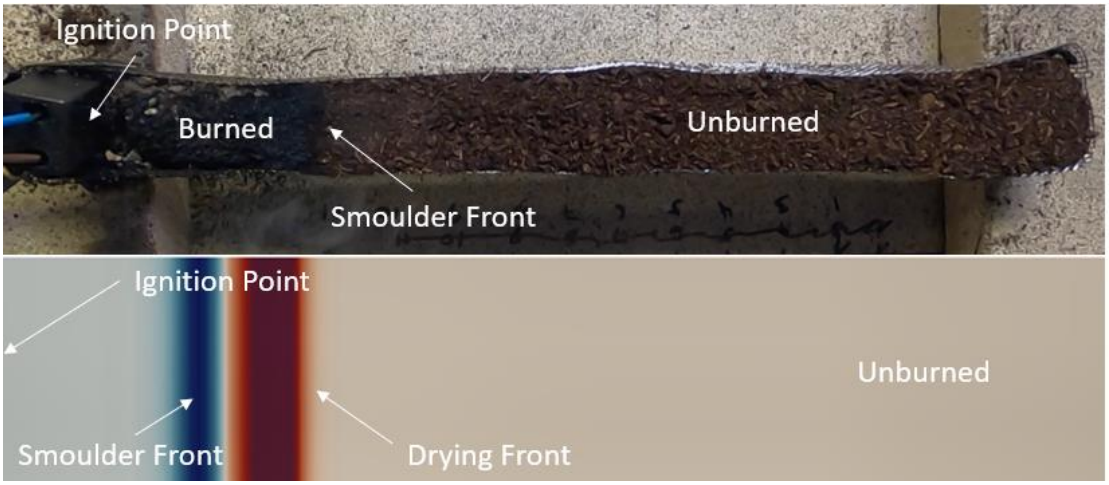

Figure 3- Top: Lateral peat spread experiment, smouldering direction left to right; Bottom: simulated peat smouldering, where red represents the drying front and blue represents the pyrolyzing front

5. Conclusions and application

The present work shows the first steps of an iterative modelling and experimental process aimed at ultimately predicting GHG emissions from smouldering peat fires. The experimental MLR results show areas of pyrolysis versus oxidation, correlating with expected carbon emissions. More detailed modelling results will be presented after verification with literature and validations with the experiments has been completed. A limitation of this model is the 1-D assumption as peat smouldering, particularly in field environments, is spatially heterogeneous. While the current computational model is 1-D, the code base is fully 3-D, allowing for easy expansion to higher dimensions in future work. Further work will include the iterative experimental/computational design process described.

6. Acknowledgements

Keywords

Gorse, oxygen consumption, TGA/DSC, heat release rate, burning behaviour

Abstract

Wildfires have been causing considerable damage worldwide, and improving the ability to predict wildfire behaviour will ensure effective emergency response and keep ecosystems and communities safe. Increasing the understanding of factors affecting vegetation flammability is necessary for improving fire behaviour prediction models. This work investigates the influence of moisture content on the flammability of live and dead needles (0-3mm), twigs (3.1-6mm) and stems (6.1-10mm) of gorse (Ulex europaeus L.). Gorse is a shrub invasive in New Zealand, Chile and Western United States. In these countries, gorse poses a fire risk to nearby communities, as it contains flammable volatile resins, accumulates a substantial amount of elevated dead material, and grows in large masses, all of which promote fire ignition and growth. Gorse flammability was quantified with a bench-scale oxygen consumption calorimeter (cone calorimeter) with a focus on heat release rate. Supporting tests were performed on small sub-samples using simultaneous thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC) to assess material-scale pyrolysis dynamics, providing fine scale information on the thermal degradation of each tissue type at the particle level.

The experimental methodology included investigation of the maximum moisture content at which each tissue type can ignite at 50 kW/m2, which is a reasonable approximation of the heat flux at the vegetation surface during fire front arrival in a shrub fire. Six moisture content levels from zero to the highest ignitable moisture content were then selected, and samples were conditioned in a climate chamber until the desired moisture content was reached. Three replicates of each tissue type were tested in a cone calorimeter at each moisture content. Flammability was assessed based on the heat release rate, total heat release, effective heat of combustion, residual mass fraction, time to ignition and combustion duration. Additionally, a small sub-sample of fresh live and dead needles, twigs and stems was analysed in the TGA/DSC apparatus. TGA/DSC results showed a different thermal degradation mechanism between live and dead fuel, with live tissue undergoing pyrolysis at a lower temperature than dead. However, the pyrolysis dynamics were not substantially different between needles, twigs, and stems, suggesting that the differences in their flammability attributes measured in the cone calorimeter are likely driven by physical characteristics such as surface-area-to-volume ratio rather than chemical composition. The results of this work contribute to the understanding of gorse flammability and the effect of moisture content and fuel structure on fire behaviour.

1. Introduction

In recent years, wildfires around the world have been increasing in frequency, intensity and duration (Jolly et al., 2015), leading to the loss of lives and property, and the destruction of ecologically important areas. Simultaneously with changes to the wildfire regime, a growing number of people are living in the wildland-urban interface (WUI) – the interface between the urban setting and the rural landscape such as lifestyle blocks (Andrew & Dymond, 2013), significantly increasing the potential damage from wildfires due to the proximity

of people and property to large vegetated areas. More wildfires are entering the urban environment from the natural surroundings, such as the 2018 Carr Fire in Northern California (Lareau et al., 2018) and the 2017 Port Hills Fire in Christchurch, New Zealand (Pearce, 2018). In order to protect the growing WUI and make communities more resilient to future wildfire events, it is vital to understand fire behaviour and the complex interactions between fire, fuel (vegetation), weather and terrain in these environments. The current knowledge of how vegetation characteristics such as species, size, chemical composition and physiological properties affect wildfire behaviour (e.g. heat production, rate of spread, thermal radiation, etc.) is limited, and there is a need to increase our understanding of the physical and chemical dynamics of vegetative fuels commonly found in the WUI.

Gorse (*Ulex europaeus* L.) is a shrub native to Western Europe that has been introduced to other parts of the world (Kariyawasam and Ratnayake 2019), and is a prolific invasive species in some places such as New Zealand, Chile, and Western United States. Gorse poses a serious problem not only from a land management perspective, but also for wildfire management, as it occupies vast areas, often near populated centres (Figure 1), and burns readily. The flammability attributes of gorse and how they are affected by plant characteristics have not been extensively studied in the literature. Previous studies show that moisture content and surface-area-to-volume ratio are among the most important variables dictating plant flammability (White & Zipperer, 2010, Fares et al., 2017, Etlinger & Beall, 2004), and both of these characteristics vary spatially and temporally.

Figure 1 – Gorse shrubland on a hillside overlooking Christchurch, New Zealand

The flammability of vegetation is a complex phenomenon that encompasses attributes of the fuel's ability to initiate and propagate combustion. There are four main components of vegetation flammability: ignitibility, or the ease with which the fuel ignites; combustibility, or the rate at which combustion occurs; consumability, or the proportion of biomass that gets consumed; and sustainability, or the ability of the fuel to maintain combustion and produce energy (Anderson, 1970; Martin, 1994; White & Zipperer, 2010).

On one hand, oxygen consumption calorimetry is a relatively direct method for quantifying heat release rate (HRR) by measuring the amount of oxygen consumed per unit mass of fuel during the combustion of the sample. A cone calorimeter (Huggett 1980, Janssens 2002) is a bench-scale oxygen consumption calorimeter that creates a nearly uniform heat flux at the surface of a 10×10 cm^2 sample with a conical heating coil. A cone calorimeter measures all four flammability components: ignitibility as the time to sustained ignition, combustibility as the averaged and maximum heat release rate, consumability as the mass loss rate, and sustainability as the duration of heat release. Although all these components are considered in this study, emphasis was placed on the heat release rate, as it is considered to be the main attribute for describing fuel flammability (Babrauskas & Peacock, 1992; Madrigal et al., 2012), and can be used to indicate the extent of damage caused to the environment as well as the amount of energy available for igniting subsequent fuel and propagating the fire.

On the other hand, simultaneous thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC) is a method that can give insight into the small-scale flammability dynamics of a solid fuel, tracking the mass loss rate of a small (~15 mg) sample in pure nitrogen while the temperature is increased at a consistent rate. Unlike with the cone calorimeter, measurements at this small scale provide insights into flammability characteristics that fundamentally affect fire behaviour. More specifically, variables such as particle size and moisture content are explicitly disregarded in the context of TGA/DSC measurements, so the results can be

directly tied to other attributes such as live/dead condition of the sample. This technique is used in this study to complement and reinforce the analysis emerging from the cone calorimetry results.

The objectives of this research are to evaluate the effect of moisture content on gorse flammability, and to investigate the effect of condition (live and dead) and tissue diameter (needles, twigs and stems) of gorse on its flammability. These objectives are achieved by quantifying the heat release rate, effective heat of combustion, residual mass fraction, time to ignition and combustion duration of live and dead needles, twigs and stems at a range of moisture contents. Because of word-limit constraints, we only report cone calorimeter test results for a single moisture content of 7%, and results from TGA/DSC for a single heating rate of 20°C/min.

2. Materials and methods

2.1. Sample collection and classification

The flammability of six gorse tissue types was investigated, namely dead and live needles, twigs and stems using the cone calorimeter and the TGA/DSC apparatus. The samples were collected from a research site (43.461°S, 172.353°E) along the Waimakariri river, north of West Melton, New Zealand. The predominant vegetation at the site is gorse, with plant heights ranging from 40 to 200 cm. Plant material up to one centimetre in diameter was collected and separated into needles, twigs and stems based on diameter, with particles up to 3 mm classified as needles, material from 3.1 to 6 mm classified as twigs, and material from 6.1 to 10 mm classified as stems. The groups were further separated into live and dead condition based on the colour and general appearance of the material (Figure 3).

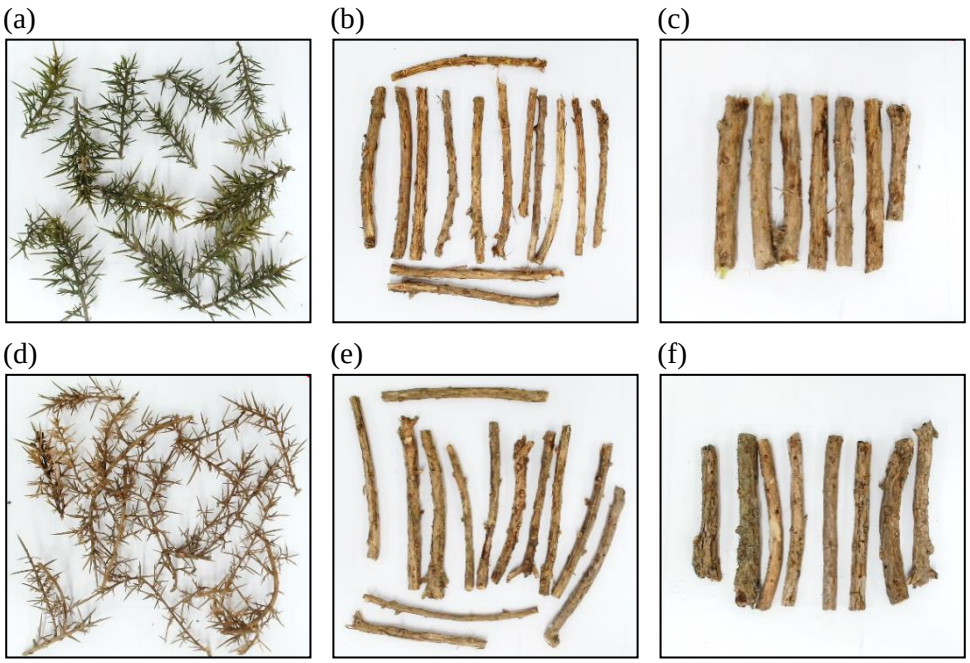

Figure 2 – Examples of six tissue types tested in the cone calorimeter and the TGA/DSC apparatus: live needles (a), live twigs (b), live stems (c), dead needles (d), dead twigs (e), and dead stems (f). The samples shown were prepared for testing in the cone calorimeter, and all have the apparent surface area of 70 cm^2.

2.2. Cone calorimetry

The collected plant material was trimmed to 10 cm lengths to fit into the 10×10 cm^2 sample holder of the cone calorimeter. Some material of each tissue type was placed into an environmental chamber to obtain a range of moisture contents, and ignition tests were performed on each tissue type to determine the maximum moisture content at which piloted ignition can occur at 50 kW/m^2. The heat flux of 50 kW/m^2 was chosen for ignition testing and cone calorimetry experiments because it is representative of the radiative heat flux at the vegetation surface at the time of fire front arrival in a shrub fire (Morandini & Silvani, 2010). Following the ignition tests, six moisture content treatment levels were selected to span the range from 0% up to the maximum ignitable moisture content, and three replicates of each tissue type at each moisture content were prepared for testing in

the cone calorimeter, ensuring that the apparent surface area (the surface area of the sample exposed to the radiative heat flux from the cone heater) is consistent between samples.

Table 1 – Experimental design for the cone calorimetry tests and TGA/DSC tests, with 7% tissue moisture content for cone colometry samples, and variable moisture content representative of field conditions for TGA/DSC samples

3 tissue sizes		2 conditions		2 experiments		1 or 3 replicates
Needles Twigs Stems	×	Live Dead	×	Cone calorimetry	×	Rep 1 Rep 2 Rep 3
				TGA/DSC	×	Rep 1

The samples were tested in the cone calorimeter at 50 kW/m^2 in accordance with the ISO 5660-1 standard (ISO 5660-1, 2002), with the exception that a porous 10×10×2 cm^2 wire frame sample holder (Barboni et al. 2017) was used to ensure that testing conditions are representative of field conditions. The surface area exposed to the cone heater element was kept at 70 cm^{-2} for all tissue types to ensure similar heating and ignition conditions. Because of word-limit constraints, we only report results from cone calorimeter test for a moisture content of 7%. Mass of the samples varied between the experiments as follows: 3.05 to 4.5g for needles, 12.9 to 15.7g for twigs, and 25.2 to 31g for stems.

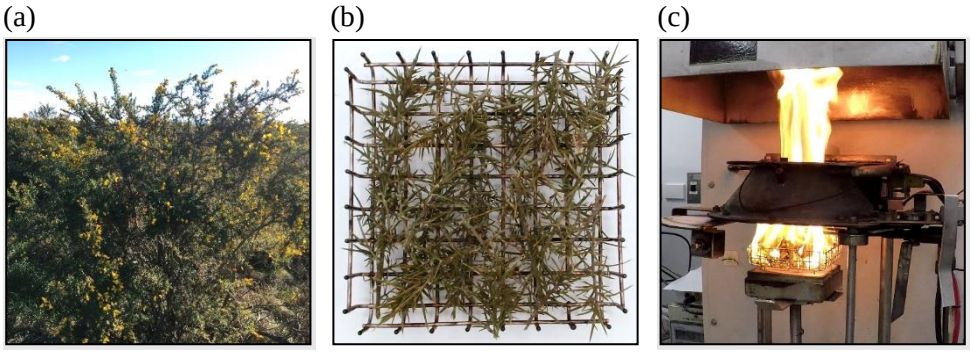

Figure 3 – Gorse plant at the field site (a), gorse needles in a sample holder prepared for the test in the cone calorimeter (b), and gorse needles during the test (c)

2.3. Simultaneous differential scanning calorimetry and thermogravimetry

SDT Q600 manufactured by TA Instruments was used to investigate the thermal decomposition behaviour of gorse needles under nitrogen environment. The equipment was calibrated following manufacturer's instructions for weight, temperature and heat flow at the tested heating rate. Fresh gorse samples were ground using a sample grinder and sealed in air-tight plastic containers for testing within 24 hours. Approximately 15 mg of ground sample was placed inside a 90 µL alumina cup, applying a dynamic heating mechanism from 20 to 1200°C at 20°C/min. The relative sample weight was calculated by dividing the raw weight by the weight of the sample at 185°C once all the cellular water evaporated and the mass loss rate stabilized.

3. Results

The heat release rate curves measured with the cone calorimeter for the six tissue types at 7% moisture content are presented in Figure 4. The pattern of heat release rate varies between tissue types, providing a good basis for comparing their overall flammability. Tissues of smaller diameter ignited faster and burned more vigorously, reaching their peak heat release rate faster than larger size classes, while larger particle sizes were associated with delayed ignition, longer burning and decay stages of combustion, and greater total energy production.

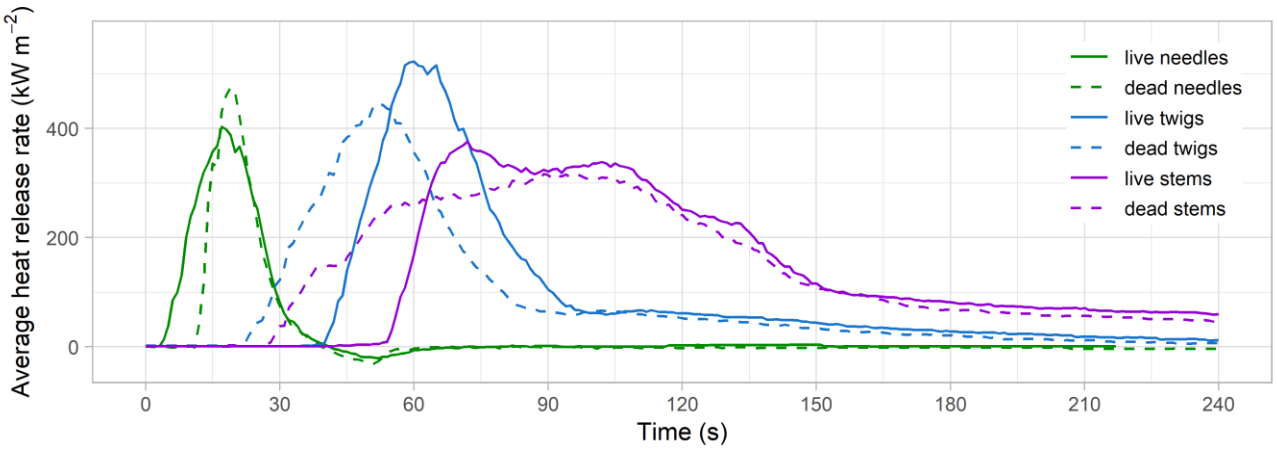

Figure 4 – Heat release rate for gorse needles with 7% moisture content as a function of time since the start of exposure to the radiative heat flux of 50 kW m^{-2}. Three replicates of each tissue type were tested, and their results were averaged into one curve for readability.

Flammability attributes derived from the heat release rate data are summarised in the top row of Figure 5, and attributes manually measured in the lab during testing are shown in the bottom row of the figure. Total heat release ranged from 50.6 kJ to 502 kJ for all tissue types at the studied moisture content. The effective heat of combustion ranged from 13.7 to 18.1 kJ g^{-1}, which is similar to the 12 to 17 kJ g^{-1} range observed for Douglas fir (*Pseudotsuga menziesii* (Mirb.) Franco) trees with 5 to 15% moisture content (Babrauskas, 2006). Peak heat release rate, a measure of combustibility, increased with decreasing particle size, and ranged from 318 to 613 kW m^{-2} across tissue types. This is similar to values found in literature for different species such as 400 kW m^{-2} for dead litter of *Pinus pinaster* (Madrigal et al., 2011) obtained using mass loss calorimetry, and 550 to 1050 kW m^{-2} for dead leaves and twigs of *Cistus monspeliensis* 0.75 to 3mm in diameter (Barboni et al., 2017) obtained with a cone calorimeter. Time to ignition, a measure of ignitibility, and combustion duration, a measure of sustainability, increased with increasing particle size. Time to ignition ranged from 8 to 59 seconds, while combustion duration ranged from 10 to161 seconds respectively. Time to ignition for individual tissue types was comparable to values found in literature. For instance, time to ignition for live and dead twigs measured in this study was between 23 and 51 seconds, while the time to ignition for oven-dried leaves and twigs of Montpellier cistus (*Cistus Monspeliensis* L) from existing literature was 35.7 ± 5.8 seconds. Residual mass fraction ranged from 0.0236 to 0.077 g g^{-1}, and was considerably higher for dead tissue compared to live tissue. Further experiments are required to gain insights into this trend.

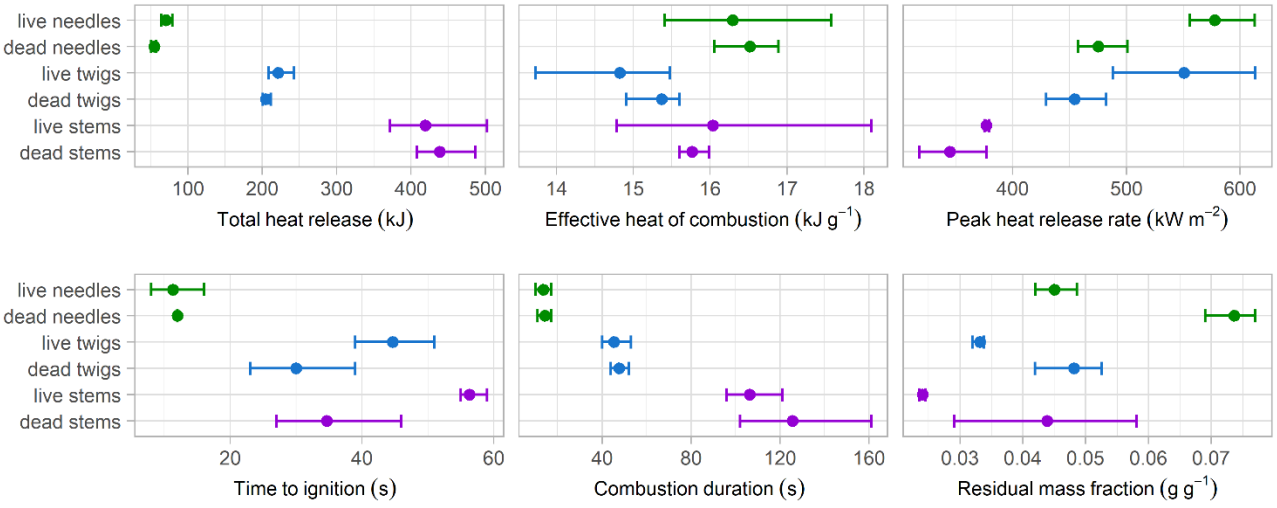

Figure 4 – The mean and range of flammability attributes measured with the cone calorimeter. The whiskers indicate the minimum and maximum values measured for the three replicates, and the point indicates the mean

The mass loss rate of small (~15 mg) ground samples of the six tissue types measured in the TGA/DSC apparatus is presented in Figure 6. The peak mass loss was greater for the live needles, twigs and stems (1.14, 1.02 and

0.904 % °C^{-1} respectively) compared to the dead needles, twigs and stems (0.61, 0.78 and 0.74 % °C^{-1} respectively). The peak mass loss also generally occurred at a lower temperature for the live needles, twigs and stems (93, 356 and 350 °C respectively) than for the dead needles, twigs and stems (366, 371 and 348 °C respectively). The varying slope before the decomposition peak and the subsequent plateau and perturbations after the decomposition peak for all tissue types indicate that gorse tissues consist of multiple material components, which thermally decompose across overlapping temperature range.

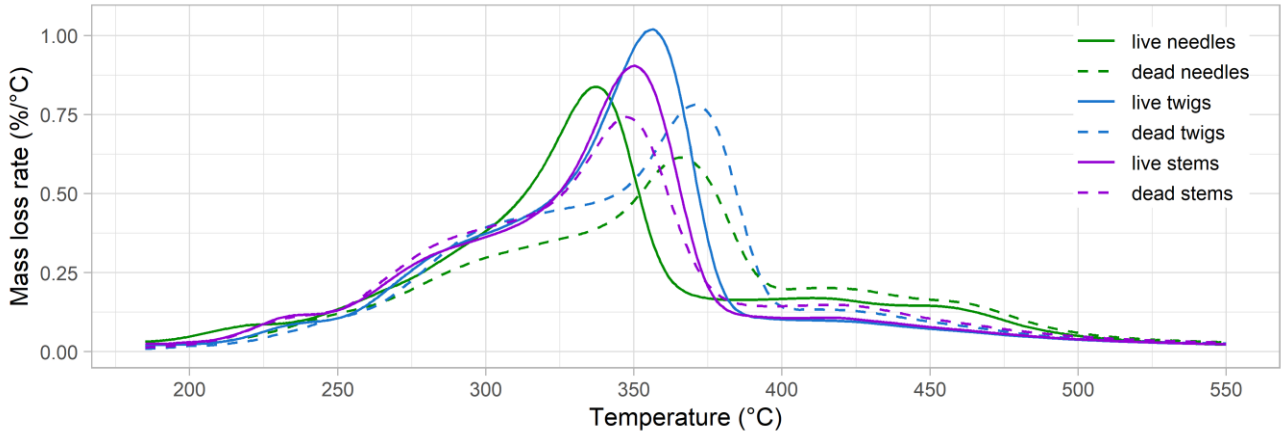

Figure 6 – TGA/DSC results: mass loss rate as a function of temperature at the heating rate of 20 °C/min

The pyrolysis dynamics were not substantially affected by particle size for live material, as the degradation rate and temperature peaks were around 350°C, suggesting that the differences in flammability attributes measured in the cone calorimeter are likely driven by physical characteristics such as surface-area-to-volume ratio rather than chemical composition. Generally, dead material showed higher peak temperature, suggesting lower flammability potential, which can be associated with the differences in the volatiles content.

Flame spread, combustion dynamics, prescribed fire, field experiment, pine litter

Abstract

Understanding flame spread and combustion dynamics in surface fuels is important for both planning and evaluating the impact of prescribed fires. However, prescribed fires tend to be conducted under light and unsteady wind conditions as compared with those which have been well studied for wildfire scenarios. To improve this understanding and provide data for next-generation fire models, it is necessary to collect detailed time-resolved observations of these processes. To accomplish this, a series of small-scale field experiments was conducted in pine needle litter. 10 m x 10 m plots were constructed with fuel loads of either 0.5 kg/m2, 1.0 kg/m2, or 1.5 kg/m2. Wind was measured with an array of 17 anemometers and flame spread and combustion mode were monitored with an overhead infrared camera and thermocouple arrays. The light and gusty wind conditions resulted in unsteady fire behavior and a single relationship between wind speed and spread rate is unable to capture the range of behavior observed. A novel technique is introduced for identifying regions of flaming versus smoldering combustion in the infrared imagery. This approach indicates that flaming and smoldering times can be related directly to fuel loads, rather than wind conditions, though more work is required to link these times to burning rates. The implication is that dynamic flame spread in these conditions is difficult to predict without models that account for fire-atmosphere interactions. However, fuel consumption, and therefore prescribed fire effects, may be more straightforward to predict. This work has also resulted in a uniquely detailed dataset for testing fire models.

1. Introduction

Understanding and predicting fire behavior in relatively light and unsteady wind conditions is important in the context of prescribed fire. A quantitative approach to both planning these activities and evaluating their effectiveness relies on such an understanding (Hiers et al., 2020). For example, modelling the spread rate of fires can help practitioners plan specific burns to optimize desired objectives. However, unlike fires under strong wind conditions (typical of wildfires) and steady or zero wind conditions (typical of laboratory studies), realistic burning conditions during prescribed fires often involve light, dynamic winds where fire-induced buoyant flows may become dominant. In order to investigate the effect of these conditions, and to provide detailed data for modeling efforts, a series of field experiments was conducted in pine needle litter. The aim of this work is to analyze highly-resolved measurements of flame spread and combustion to determine the relative roles of fuel structure and wind at fine scale, under conditions relevant to prescribed burning.

2. Methods

Experiments were carried out on a 10 m x 10 m plot (see Figure 1) within a pitch pine/loblolly pine plantation in the Pinelands National Reserve of New Jersey. A total of 35 experiments were conducted under various fuel and weather conditions; however, this analysis focuses on a subset of 19 of these for which fire spread

successfully across the plot and the measurements made were consistent. The fuel beds consisted of pitch pine (*Pinus rigida* Mill.) needles or an equal mix of pitch pine needles and oak (predominantly *Quercus montana Willd.*) leaves from local sources. The beds were manufactured to achieve average loadings of nominally 0.5 kg/m^2, 1.0 kg/m^2, or 1.5 kg/m^2, in order to represent different prescribed fire return intervals. Burns were carried out in ambient temperatures between 17 °C and 31 °C, relative humidity between 22 % and 66 %, and fuel moisture contents between 5.9 % and 14.4 %.

2.1. Wind measurement

Wind was measured with an array of 17 3D sonic anemometers (Figure 1). One of these was located at the plot center at a height of 10 m Above Ground Level (AGL), while the remaining 16 were in a 4x4 grid at nominally 3.0 m AGL. All anemometers were sampled at a frequency of 10 Hz.

For this analysis, a characteristic time-dependent horizontal wind vector was determined for each experiment. All anemometers were used for this calculation, to give an indication of the average wind across the experimental area. Previous measurements of ambient wind in the plantation indicated low sensitivity to height between the 2.5 m and 10 m levels (both are in the open sub-canopy space). Measurements of *u* and *v* velocity components were averaged independently, using 10-second moving average. Readings where the anemometer recorded a temperature in excess of 50 °C were rejected from this process, as they were within the fire plume and outside the operating range of the anemometer.

The spatial averaging procedure removes any localized features of the wind field, over the plot area, but allows for the fact that at any given moment, individual sensors may be impacted by the fire and not produce reliable data. The temporal averaging procedure removes some high frequency components of the signal in order to focus on the dominant behavior. The choice of a 10-second window was guided by the fact that mean winds were on the order of 1 m/s and the plot length was 10 m.

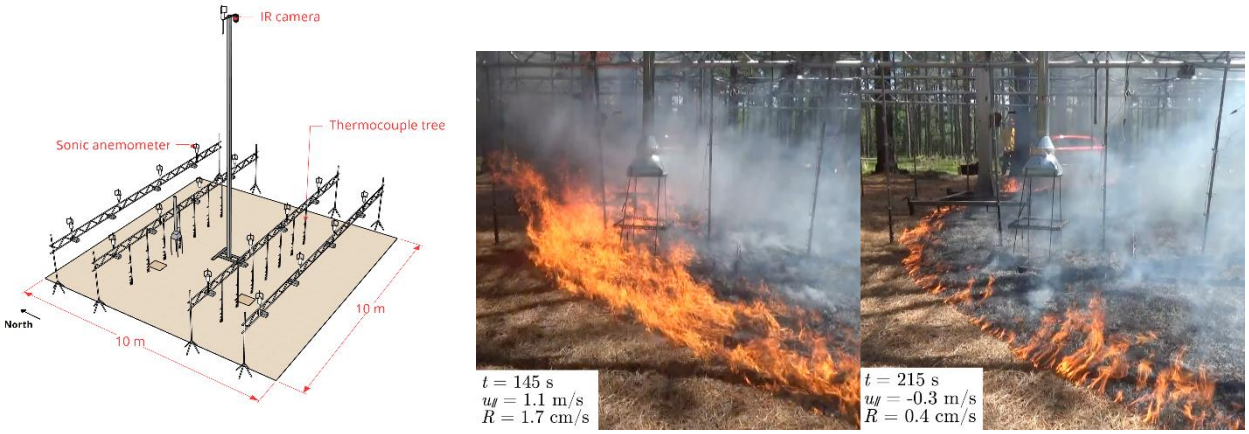

Figure 1- (left) Schematic of experimental plots; (right) example of fire spread during heading and backing conditions in a single experiment.

2.2. Flame spread

Infrared (IR) images were captured from a downward-facing IR camera placed at the center of the plot (Figure 1). The camera had a frame rate of nominally 25 Hz and provided a resolution of ~5 cm^2/pixel. True temperature measurement of the fuel bed is complicated by several factors (including unknown emissivity and possible emission and absorption by combustion products). However, the data are still valuable in a comparative sense, as described below, and temperatures are referred to as 'pixel' temperature rather than solid or gas phase.

The IR data were used to determine the progression of the leading edge of the flame front as a function of time. For each pixel, the arrival time of the flame front was determined by the corresponding temperature first exceeding 200 °C for a continuous period at least 1 second. The exact location of the flame front is sensitive to these criteria, but the advancement of the front is much less so.

Masks were applied to remove regions of spurious data where objects (e.g., camera support tower, instrumentation trusses, trees) obscure the view of the camera. Images were post processed and projected onto a Cartesian coordinate system. The spread rate, *R*, was calculated by taking the inverse of the gradient of the

arrival time matrix using and applying filtering and spatial averaging techniques to create a continuous spread map over the entire plot area (including masked regions).

Spread vectors with relevant corresponding arrival times were averaged to create a plot-average magnitude and direction of spread, excluding 1 meter of data on either flanking edge of the fire (dependent on the ignition edge). This approach allows the wind to be decomposed into the component in the direction of spread at a given moment, $u_{/\!/}$, and the component perpendicular, $u_{\perp}$, and the influence of wind could be analyzed independent of the compass direction at a given moment.

2.3. Combustion mode

An assessment of the combustion dynamics was conducted by estimating the duration of flaming and smoldering combustion for a given experiment. Separating these different combustion modes can prove quite difficult, particularly in the field. Visual assessment can be complicated by the obscuring presence of smoke and by the fact that the occurrence of smoldering combustion can be difficult to observe.

The IR imagery offers a solution to both problems; however, there is still a challenge in identifying the different regimes in the temperature signal for a given pixel. Both flaming and smoldering combustion may be associated with high temperatures in overlapping ranges, so it is not enough to simply apply thresholds. Further, the long-wave spectral range of the IR camera used here is poorly suited to observing emission from the flames.

Despite these challenges, visual inspection of the IR imagery shows that some presence of the flaming region can be detected. Because the flaming combustion zone is strongly affected by turbulence, we hypothesize that the ability to observe this region in the IR footage is a function of the rapid fluctuation in the temperature signal, rather than its absolute value. Therefore, we classified the combustion modes by analyzing these fluctuations.

A short-time Fast Fourier Transform was computed on the pixel noise, taken as the difference between the 25 Hz signal and a 1 Hz moving average. The average power at high frequency (> 4 Hz) was then computed. The maximum power was identified for each pixel, and the point at which the transient power falls below 5% of this value was taken as the threshold between flaming and smoldering. The onset of flaming was taken as the first point the 1-second moving average of temperature exceeds 200 °C, and the end of smoldering was taken as the final point above 200 °C. The resulting image of combustion times was then subjected to the same projection and spatial averaging as the spread rate map. This approach relies on user-selected thresholds for both the magnitude of the temperature and the magnitude of the signal noise. However, the calculation of flaming time was consistent with measurements made with thermocouples positioned at the top of the fuel bed (see Figure 1).

3. Results and discussion

3.1. Flame spread

Mean wind speeds were in the range of 0.5 m/s to 1.5 m/s, with relative standard deviations between 0.17 and 0.61. This gives an indication of the light and unsteady conditions; however, it does not account for shifts in wind direction which contribute to the dynamic fire behavior. Mean spread rates were in the range of 0.2 cm/s to 5.0 cm/s, with relative standard deviations between 0.26 and 1.73. To demonstrate the dynamic nature of individual burns, an example of the flame spread and wind calculation is shown in Figure 2. When the spread vector and the horizontal wind are not aligned there is necessarily a reduction in the magnitude of wind speed in the direction of spread ($u_{/\!/} \leq U$). An evaluation of the correlation between mean wind and spread, using Spearman's rank coefficient, yields a value of 0.22 (probability, p = 0.37) when using overall magnitude (U) and 0.53 (p = 0.02) when using magnitude in the direction of spread ($u_{/\!/}$). This points to the importance of capturing the dynamic wind in gusty conditions, rather than an average horizontal magnitude.

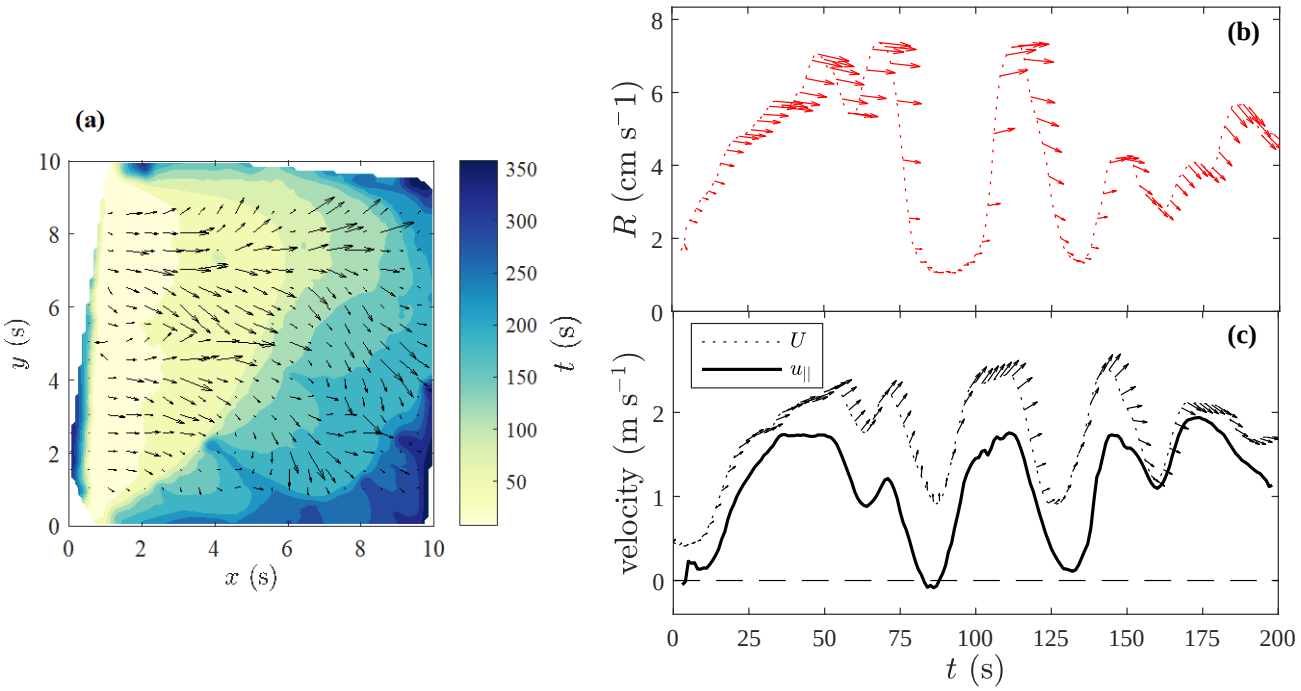

Figure 2- Example of fire spread analysis for one burn, ignited from the west (x = 0 m) with a fuel load of 0.5 kg/m². (a) The computed vectors of spread rate, overlaid on a contour plot of arrival time. (b) The time history of plot-average spread vectors. (c) The average wind vectors with the total magnitude (U), and wind magnitude in the direction of average spread ($u_{\parallel}$).

The analysis of spread rate and wind speed for all burns indicates a large scatter which cannot be accounted for with other environmental variables (fuel load, fuel moisture, relative humidity, ambient temperature). This is demonstrated by normalizing the spread by its value with no-wind, as shown in Figure 3. Large deviations occur when fitting to possible simple models for wind speed dependence. In fact, a hysteresis was observed in temporally resolved relationships of spread rate and wind. An assessment of Byram's convective number (Nelson, 1993) indicates the significant feedback between wind speed and spread rate is linked to the marginal conditions – fires are neither consistently plume dominated nor wind driven.

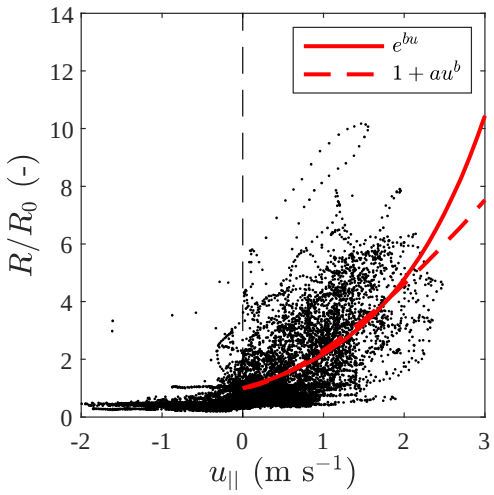

Figure 3- Relationship between instantaneous wind and spread rate. Spread rate is normalized against the average no-wind ($|u_{\parallel}|$<0.2 m/s) value for a given burn. Red lines are fits to common functions (Sullivan, 2009).

3.2. Combustion mode

An example of the analysis of flaming versus smoldering time is shown in Figure 4. The thermocouple and IR pixel temperature increase dramatically at the same time, indicating arrival of the fire front. Both maintain an elevated temperature for roughly 40 s, at which point the thermocouple temperature drops rapidly while the pixel temperature remains elevated. The power in the high-frequency noise in pixel temperature drops dramatically at the same time the flaming period ends, thus all remaining time at elevated temperature can be classified as smoldering.

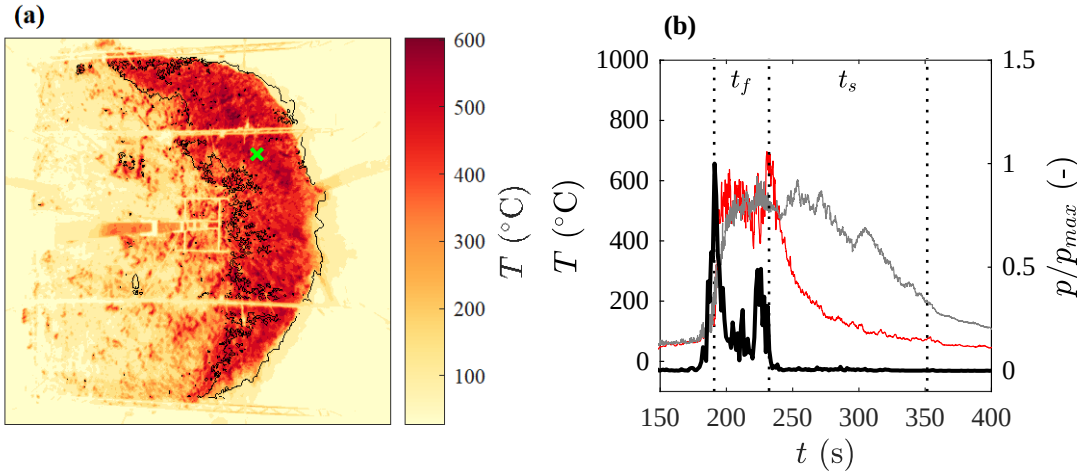

Figure 4- Example of fire spread analysis for one burn, ignited from the west (x = 0 m) with a fuel load of 1.5 kg/m^2. (a) Single frame of IR footage with sample point at the base of a thermocouple array shown as a green x. The region of active flaming is shown by the black contour line. (b) Time history at the sample point in (a): thermocouple temperature (red), pixel temperature (grey), and normalized power of noise (black). Duration of flaming (t_f) and smoldering (t_s) are shown by vertical lines.

The mean and standard deviations of both flaming and smoldering time are shown for each relevant burn in Figure 5. The duration of both combustion modes increases with fuel load, but the ratio may not be constant and requires more analysis. Preliminary results also indicate that wind speed is a less significant factor than fuel load under these conditions.

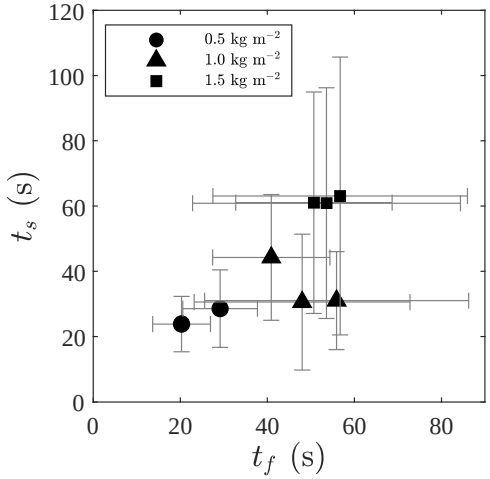

Figure 5- Average flaming time (t_f) and smoldering time (t_s) for all relevant pixels in each of the 8 burns. Error bars represent one standard deviation.

4. Conclusions

We observed a dynamic relationship between flame spread and ambient wind in conditions typical of prescribed burns. This is not fully captured by simple relationships which do not consider fire-atmosphere feedback. The experimental data can help to provide uncertainty bounds to these simple relationships. They can also act as test cases for more complex models which attempt to resolve such interactions and therefore require data with greater spatial and temporal resolution than is often available.

The combustion analysis provides a novel method for obtaining maps of flaming and smoldering times, though there are some limitations associated with this approach. The time of transition between flaming and smoldering can be evaluated against thermocouple data, but sensitivity to the noise threshold requires further examination. The optimal criteria to identify the end of smoldering using these diagnostics is also unknown. Further analysis may be able to identify combustion behavior specific to certain periods of fire behavior (e.g., heading or backing fire) or as a function of spatial fuel distribution. The inclusion of detailed fuel consumption information could also aid in estimating mass loss rates. The current analysis also has implications for understanding emissions and smoke plume development, as a function of the mode and distribution of energy release. Here again, there is also significant value for testing models of fire-atmosphere interactions. Such models either require a parameterization of energy release or endeavor to resolve it directly, but in either case a better understanding of combustion in field conditions is essential.

Prescribed burning, heat transfer, *Pinus laricio* forest, soil macrofauna, soil mesofauna

Abstract

The objective of this preliminary study is to highlight the potential impacts of prescribed fire on soil organism communities in Pinus laricio forests, a species endemic to Corsica. For this purpose, a control plot, and a plot burned on 10th November 2020, were delimited in Bavella (South Corsica). The intensity of the burning was characterized using K-Type thermocouples at different depths in the soil. Soil organisms were collected with pitfall trap and Berlèse method, then identified to the order. Results show a decrease of all orders on the burned plot, with important potential of survival of the organisms in the soil, since heat transfer is weak (+10°C max at 3cm depth) and the burned surfaces heterogeneous. A rapid recolonization is indeed observed in the spring. The contribution of organic matter, minerals, and free ecological niches could encourage this phenomenon.

In order to better understand the heterogeneity of the plots and to highlight the specificities of Pinus laricio forests, a study at the sub-plot level is in progress, as well as an identification of organisms up to the family level.

1. Introduction

In the Mediterranean Basin, forest fires are a recurrent problem. Pines are particularly affected by wildfires, they account for a large proportion (> 2/3) of the total burned areas (Pausas and Vallejo 1999; Quézel and Médail 2003). In Corsica, the most represented pine species is *Pinus nigra* subsp. *laricio* (Poir.) Maire var. *corsicana* (Loudon) Hyl. The development of these ecosystems takes place between 900m and 1800m altitude (Gamisans, 1999); hard to reach and steeply sloping terrain make it difficult to manage and protect these sensitive habitats using mechanical methods. Reintroducing fire into ecosystems through prescribed burning (Fernández et al. 2013) is time saving and allows to circumvent logistical and cost constraints. It removes hazardous understory flammable materials and creates more spatial variability in the structure of the forest (Fulé et al. 2004). Some studies have provided answers on the resistance of *Pinus laricio* to prescribed burning (Cannac et al. 2007, Ferrat et al, 2021). However, the effects of these prevention techniques on the ecology of a forest soil have been little studied.

A cascade of trophic interactions between microorganisms, detritivores and predators (Hunter et al. 2003; Santonja et al. 2015) allows the decomposition of organic matter (Aubert et al. 2010), soil regeneration, and nutrient recycling.

Fire can change the physical nature of the soil (grain size, permeability), but also its chemical quality through ash input (mineralization of organic matter, nitrogen input, pH change ; Shakesby et al. 2015). These modifications can destabilize the balance of the environment, and influence the recovery of the communities of organisms living in the soil (Wikars and Schimmel, 2001).

This study has several objectives:

- A preliminary characterization of the soil organism communities in a *Pinus laricio* forest, little studied so far, under different types of micro-habitats.
- Characterization of prescribed burns intensity and heat transfer in the soil
- Highlight the potential impacts of prescribed burns on the soil fauna

2. Material and methods

The study was carried out in a pure stand of *Pinus laricio* located in Bavella, South Corsica, France (9.224334740328 ; 41.791482512769) at 1218 m above sea level. This forest, managed by the French Forest Office, has been thinned and pruned, leaving an important and heterogeneous amount of branches and trunks on the soil, with a consistent needle litter. Trees are about 30 years old, the average tree height and DBH are 12.72m and 18.12cm respectively. The understory is absent, the herbaceous layer is mostly represented by *Brachypodium pinnatum* (L.) P. Beauv. and the moss is present discontinuously. The slope is about 20% with a west aspect. The site is submitted to supramediterranean climate, with hot summers and mild winters (mean annual temperature : 10,1°C ; min : -7°C ; max : 26°C, 620 mm total precipitation in 2020).

The stand is divided into both 25 m² control (CP) and burned (BP) plots. Each plot is subdivided into 16 subplots of about 6.25 m².

The prescribed burning was carried out on 10th november 2020 by trained forest managers. Temperature measurements were performed for different fuel configuration (litter, branches and trunk from thinning residues) at the surface and at various depths (under litter and – 3 cm) in the soil using K-type thermocouples. Measurements of the different fuel biomass and surface (grass, litter and thinning residues) was realized before and after burning.

Soil fauna was sampled prior to burning, then one week and 4 months after burning, using pitfall traps positioned on all subplots. Pitfall traps allow the study of all organisms present in the litter and humus (macrofauna and mesofauna). Spot corings (5cm*5cm*5cm) in different micro-habitats (moss, moss + litter, litter) followed by extraction with Berlèse (Berlèse, 1905) were also performed just before, and after burning, then one month post-burning, in order to study the mesofauna of humus and soil. Collected organisms are quantified and identified to order.

3. Results

The maximum temperatures were recorded at the litter surface (674–1007 °C), and the average flame residence time (duration of exposure to temperatures > 300 °C) was in the range of 25–173 s. The heat was very little transferred from the litter to the humus (+ 10.08 °C maximum). A typical example of temperature evolution is presented in Figure 1 for litter and branches configurations.

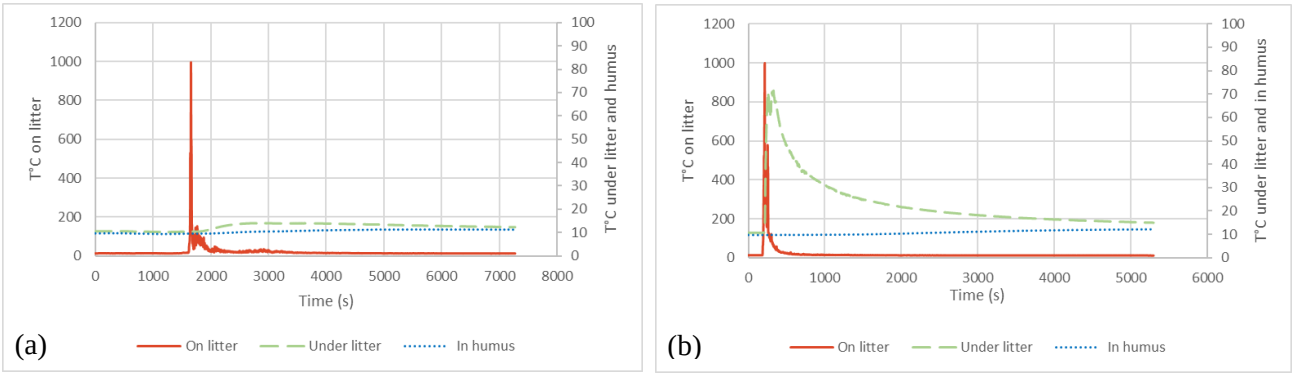

Figure 1- Temperature monitoring at different depths during prescribed burning, (a) under litter and (b) under a pile of branches.

90% of the litter, and particles smaller than 3mm (branches, herbaceous stratum) were heterogeneously removed by the burning. In contrast, larger diameter particles were not removed (Figure 2).

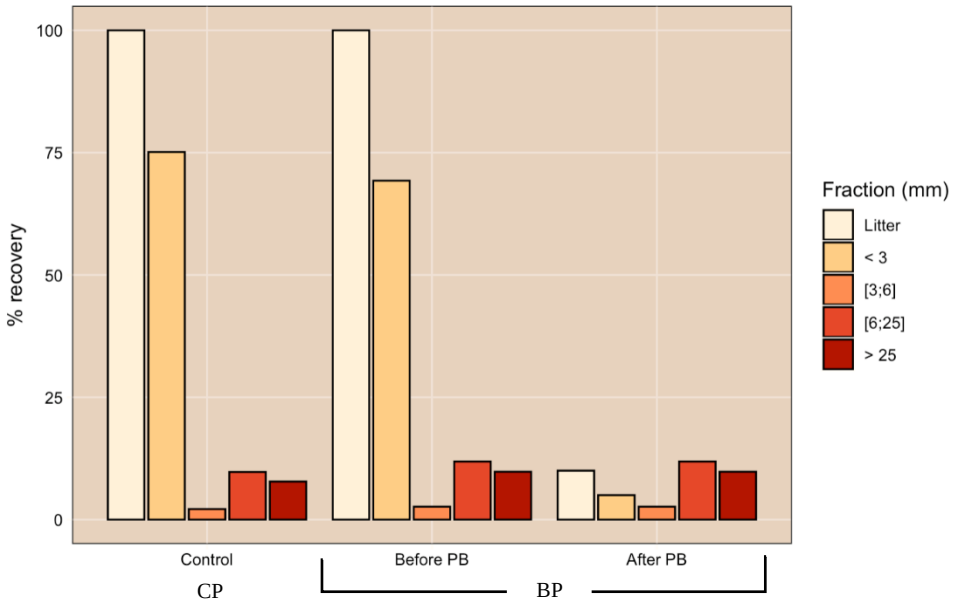

Figure 2- % plot coverage by fuel type (<3: particles less than 3mm in diameter; [3;6]: particles between 3mm and 6mm in diameter; [6;25]: particles between 6mm and 25mm in diameter; >25: particles greater than 25mm in diameter), before and after burning

20 different orders were identified within pitfall traps, all periods and all plots combined. Whatever the plot, Acari, Collembola, Diptera and Coleoptera always represented more than 80% of the total number of organisms (Figure 3). The Shannon index (Shannon & Weaver, 1949) was initially 2.15 for BP and 2.46 for CP. Abundance in the subplots was highly variable, from from 56 to 283 organisms for BP and 30 to 144 organisms for CP.

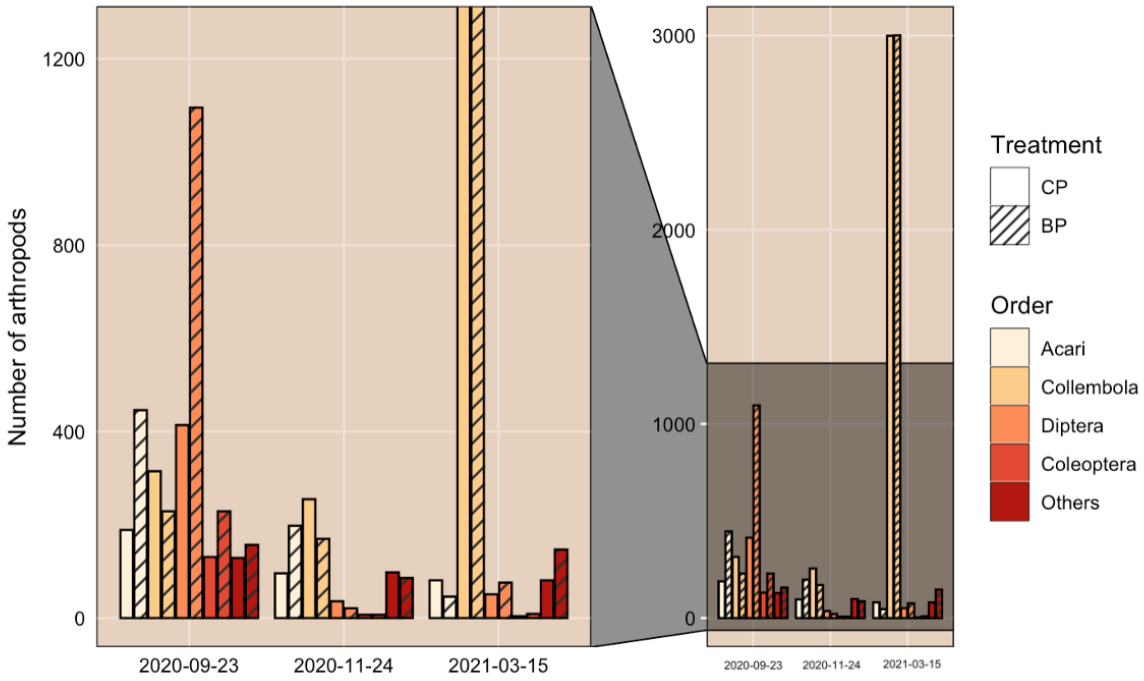

Figure 3- Total count for each order at different dates, collected by Pitfall traps (16 orders with less than 5% total count on all plots, all dates combined, were grouped in "Others")

On 09/23/2020, BP counted 2156 organisms, against only 1178 for CP. This difference can mainly explained by the abundance of diptera and acari, which are 1095 and 446 respectively for BP, and 414 and 189 for CP.

Organisms decreased by 78% after the prescribed burning in BP (482 organisms on 11/24/2020), and only by 58% in CP plot.

In spring, both plots had a similar population of organisms (3279 for BP and 3216 for CP), with a very low diversity (Shannon index of 0.64 for BP and 0.54 for CP).

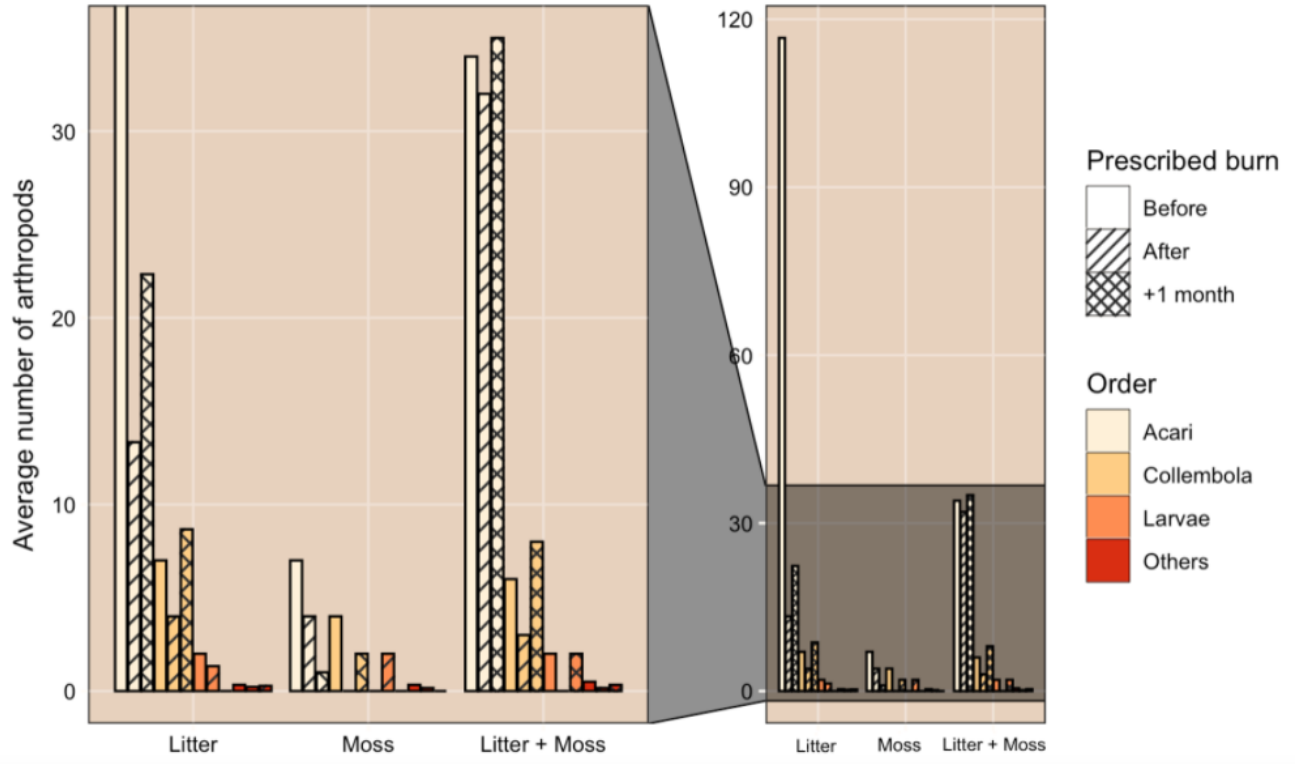

Figure 4- Distribution of mesofauna in the soil of Pinus nigra laricio ecosystems, according to microhabitat type, before and after prescribed burning.

Berlese sampling allowed to highlight the presence of 8 orders in the soil, all types of micro-habitat included. Litter had the highest total population, with an average of 130 organisms, compared to 45 in litter+moss, and 13 in moss, before burning.

Acari were in the majority, representing between 91% (litter) and 54% (moss) of the population in the samples (Figure 4). Next came the Collembola, representing between 5% (litter) and 31% of the total population. The remaining orders were very poorly represented (araneae, coleoptera, thysanoptera, hymenoptera, hemiptera and myriapoda).

The average population of the litter micro-habitat showed a decrease of 84% just after the burn. This decrease was mainly due to the loss of acaris, whose population decreased by 89%. The other orders weree present in too small numbers to show a difference in abundance.

The litter+moss microhabitat showed only a slight decrease of 20% in abundance after the burn. Moss was the poorest environment, with a very low number of organisms before the burn (13 organisms). This number decreased by 46% after the burn.

No difference in the distribution of organisms between the control and burned plots were noted. Pitfall traps and Berlèse samples showed the same trends: a decrease in total abundance after burning.

4. Discussion

Pinus laricio is a Corsican endemic species, its ecosystem is very poorly characterized.

The two types of trapping used in this study provide a preliminary overview of the communities of organisms living in these forests. The orders identified seem to fit very well with the descriptions given for the Mediterranean forests (Mantoni et al. 2020; Samain et al. 2019).

Precribed fire seems to cause a significant decrease in the population of organisms (78% for pitfall traps and 50% for Berlèse). This decrease is much greater than the one observed in the control plot (CP), which is only due to a seasonal effect. As a matter of fact, the average temperatures of November did not exceed 9°C on the pass of Bavella, which slows down biological activites (Mòron-Rios et al. 2010).

Thus, fire does not eliminate all organisms, either locally or at the plot level. Temperature measurements may partially explain these results. Indeed, the surface temperature during burning reached a maximum of 1007°C, which is totally incompatible with the survival of litter organisms. Heat transfer to the soil remained very low, since no more than a 10°C increase was measured. This demonstrates the insulating and protective power of the soil for organisms that live deeper than 3cm, which is the case for many species (acari, collembola, larvae of few Diptera and Coleoptera). Moreover, soil microarthropods can resist temperatures up to 40°C (Malmstrom, 2008) thanks to their cuticule (Moretti et al., 2006). Our finding follows the results of Uotila and Levula, 2011, who showed that the impact of fire on soil is relatively low due to its high insulating capacity.

The study of Berlèse, sampled in entirely burned areas, shows that not all microhabitats react in the same way to the passage of fire. Acari decreased in numbers under the "litter" habitat, composed of combustible pine needles. This could be explained by the fact that soil-dwelling organisms tend to occupy the surface layers of the environment. However, several studies have demonstrated the ability of microarthropods to escape deep into the soil (Certini, 2005; Gongalsky et al., 2012). The remaining organisms may have used this ability to protect themselves from the heat stress of passing through the burn. The low impact on other microhabitats (moss and moss + litter) could be explained by stronger insulation in these areas, it may be interesting to confirm this hypothesis with additional sampling.

Another important aspect of this study, which must be taken into account in the analysis of soil populations, is the evidence that BP did not burn completely during prescribed burning. The plot had about 10% unburned area. Auclerc et al. (2019), demonstrated the importance of both endogenous (i.e., surviving species) and exogenous species in recolonizing the disturbed environment. In this study, the heterogeneity of burning (a mosaïc of burned and unburned areas) could allow a very rapid recolonization of fire-affected areas, which happen to be an available ecological niche, and a source of organic matter and minerals of interest for organisms.

This recolonization is already evidenced by the spring samples (+680% in BP), wich is similar to the seasonal increase of CP (due to the recovery of biological activity, especially for springtails, whose number goes up to 3000). It must be noted that BP had almost twice the number of CP in the initial state and that this level has not yet been found.

This preliminary study clearly shows the difficulty of highlighting the effect of a prescribed burning on the dynamics of soil arthropod populations, as the heterogeneity of the plots and the conduct of a fire are important. A further study at the scale of subplots will allow to better define the heterogeneity of the plots. An identification of the organisms to the family will also highlight the specificities of *Pinus laricio* forests. Finally, to complete the study, sampling of different soil strata, treated with the Berlèse instrument, could allow a better understanding of the degree to which they are impacted by heat transfer.

Abstract

Complex interactions between fuel structure and fire highly affects the fire spread efficiency and localized behaviour. Heterogeneous arrangement of the fuel coupled with variability in fuel characteristics can strengthen or hinder heat transfer efficiency, preheating of unburned fuel and consecutive ignition. In this study, we leverage recently developed non-intrusive unmanned aerial vehicle-based (UAV) methods to spatially resolved field-scale fire behaviour properties and compare them with the Canopy Height Model (CHM) derived from pre-burn lidar measurements. Rate of spread and flaming residence time are calculated and mapped from high-resolution overhead visible footages acquired during a four-hectare prescribed gorse fire. The proposed method allows for quantification of the influence of fuel structure spatial variation on fire behaviour properties by capturing localized fire front and burning time variations associated with negative ("gaps") and positive ("bumps") changes in canopy height. These findings are supported by results obtained from a novel fire flow visualization method based upon image velocimetry, described here for the first time. Complex fire flow is synthetised via 2D time-averaged motion streamlines and compared with CHM fuel structure. Results suggest that localized fire behaviour changes may be related to flow channelling effects induced by the presence of gaps, enhancing fire flow contact and overall heat transfer efficiency.

1. Introduction

Fire behaviour is driven by complex interactions between fire energy exchanges, fuel load and structure, and atmospheric processes (Clements et al., 2007; Dahale et al., 2013; Finney et al., 2015; Sullivan, 2017; Katurji et al., 2021). Understanding these interactions is essential for several critical aspects of wildfire sciences and for informed firefighting operations (Beer, 1991; Page and Butler, 2017), building design in the Wildland Urban Interface (WUI) (Penney, Habibi and Cattani, 2020; Penney et al., 2022) and development of wildfire simulation models (Mell et al., 2007, 2011; Morvan, 2011; Hoffman et al., 2016). Field-scale fire behaviour has primarily been characterised through experimental and analytical properties describing the overall behaviour of the fire (e.g. average rate of spread, residence time and fire intensity) generally accounting for first-order mechanisms. Although this practical approach is deemed reasonable for numerous applications, it falls short of the required level of detail necessary to progress the current knowledge on fire spread mechanisms (Martins Fernandes, 2001; Santoni et al., 2006; Cruz et al., 2013) and to assess the ability of the physics-based models (e.g. WFDS and FireTEC) to predict fire behaviour, among others.

Several efforts have been made to develop deployable techniques able to accurately characterize spatial and transient fire behaviour and their interactions with fuel and overlying atmosphere at field scale. Rossi et al. (2010) developed a 3D imaging technique capable of measuring morphological characteristics of the fire and estimate ROS of complex fire fronts. This technique has been expanded to include UAV technology (Ciullo,

Rossi and Pieri, 2020) aiming to enhance spatial coverage and fire geometry definition, as well as exploring fuel/fire interactions. Recently, Katurji et al. (2021) developed a novel velocimetry technique based upon high-resolution infrared images suitable for understanding fire/atmospheric interactions between the flaming zone and the overlying atmospheric turbulent boundary layer. The technique was tested during stubble wheat prescribed fires and validated with in-field instrumentation.

These aforementioned capabilities are examples of a new generation of experimental techniques capable of capturing complex wildfire interactions at field scale, and they will contribute to further characterising the dynamics of the flaming zone which is essential for the development of future fire spread models. In this context, we present an experimental study of spatially-resolved fire behaviour properties at field scale linked to high fidelity fuel structure derived from pre-burn UAV lidar (ULS) measurements. We leverage on recently developed non-intrusive UAV-based methods to study the influence of fuel structure (canopy height and spatial arrangement) from pre-burn ULS on fire behaviour (rate of spread and flaming residence time) derived high-resolution overhead RGB videos during a four-hectare prescribed gorse fire. Because of word-limit constraints, we only summarize the non-intrusive experimental methods used in this research (Section 2) and we present and comment the derived maps Rate of Spread (ROS) and Flaming Residence Time (FRT) (section 3) in this short paper.

2. Experiments and Methods

2.1. Site description and burning conditions

The research site is located at -43.409, 171.568, 15 km south of the Rakaia Gorge in Mid-South Canterbury, New Zealand. A 200 m × 200 m burn plot was established on flat ground (a dry riverbed with slight undulations), ensuring that it aligns with the prevailing wind directions. The overstory was made up of gorse (*Ulex europaeus* L.) with a small component of matagouri (*Discaria toumatou* Raoul), and the understory consisted of mostly grasses with a component of rose (*Rosa* sp.), California thistle (*Cirsium arvense* (L.) Scop) and Russell lupin (*Lupinus polyphyllus* Lindl). Gorse height ranged from 0.2 m to 2.0 m, and its density and distribution was heterogeneous across the site, with some areas containing tall dense vegetation, and other areas being relatively open with short clumps of gorse interspersed with grassy patches.

The burn was ignited on 2nd March 2020 at 12:11pm and lasted 5 minutes. The mean temperature was 22.9 °C, mean relative humidity was 33.2%, mean wind direction was 311.2° and mean wind speed was 9.8 m/s (35.28 km/hr) as recorded by the on-site 10-meter weather station.

2.2. UAV and lidar Acquisition

UAVs capabilities were used for two different purposes: to record nadir RGB videos of the flaming zone and to obtain a pre-burn high-density point cloud from a ULS. In advance of any flight operations, an extensive set of ground control points (GCPs) was established throughout the study site. Eight ground control points evenly distributed across the study area ensured a suitable level of accuracy of the ULS data. Furthermore, 36 ground control points were established around the individual research burn blocks to be used during the georectification of the acquired frames from the visual imagery and the alignment of the two data streams.

Aerial video data of the flame zone was captured using a DJI Zenmuse XT2 dual thermal RGB sensor with integrated 1/17 inch 12MP RGB camera (DJI Ltd., Shenzhen, China), mounted on a DJI Matrice 210 UAV (DJI Ltd., Shenzhen, China). Video was captured in MP4 format at a framerate of 30 fps. Pre-burn ULS data was captured with a LidarUSA Snoopy V-series system (Fagerman Technologies, INC., Somerville, AL, USA), that incorporates a Riegl MiniVUX-1 UAV scanner (Riegl, Horn, Austria). This sensor was attached to a DJI Matrice 600 Pro UAV (DJI Ltd., Shenzhen, China).

Figure 1. Pilot taking off Matrice 210 with DJI XT2 camera prior to burn commencing; b. Setting up Matrice 210 UAV; c. DJI Matrice 600 craft taking off, carrying MiniVUX lidar sensor as payload.

Processing of the raw point cloud from Lidar was then carried out using two pieces of software. First, the point cloud was tiled and had basic noise filtering applied using the LasTools software version 210,418 (Isenburg, 2014). The tiles output from LasTools were then imported into the R statistical software version 4.0.4 (R Core Team, 2020) and processed using a data processing pipeline developed using the LidR library (Roussel et al., 2018). First ground points were classified and then a digital terrain model (DTM) with a resolution of 1 m was derived from these points. The point cloud was then height-normalised using the DTM, more noise filtering was applied to remove spurious points, and finally a pit-free canopy height model (CHM) with a resolution of 0.25 m was calculated.

3. Description of Techniques

3.1. Flame Residence Time and Fire Perimeter Tracking

In order to calculate the residence time and the pixel-wise rate of spread (ROS) of the fire, the Fire Perimeter Tracking algorithm (Melnik 2021, Schumacher et al. 2021) was used. First, each frame of the stabilized RGB videos was analysed to identify which pixels contain active flames. This was done by manually identifying colour thresholds in the hue, saturation and value (HSV) colour space that indicate the presence of flames in a given pixel. Using the location of active flaming in each video frame, two two-dimensional arrays were created: (1) the ignition array, each pixel of which contained the first timestamp of active flaming in the given pixel of the burn plot, and (2) the extinction array, each pixel of which contained the last timestamp of active flaming. The ignition array was subtracted from the extinction array in order to create the flame residence time array, which contained the burning duration of each pixel across the burn plot.

In order to calculate the pixel-wise rate of fire spread, a 41×41 pixel moving window was established across the ignition array, with every pixel of the ignition array taking its turn to serve as the centre pixel of the moving window. Within the moving window, only timestamps immediately preceding or following the timestamp of the central pixel were retained. Vectors going from the preceding-timestamp pixels to the central pixel, and advancing from the central pixel to the following-timestamp pixels were calculated, and these vectors were averaged to obtain the rate and direction of spread of the central pixel. The window then moved over and the process was repeated for the next pixel in the ignition array to serve as the centre pixel. The resulting array contained the computed rate and direction of fire perimeter spread for each pixel in the burn plot.

3.2. Fire Flow Streamlines visualization and Image Velocimetry

Image Velocimetry was used to derive and map the displacement of fire features from consecutive RGB frames. The method (Schumacher et al. 2021), which has originally been developed for flow velocimetry estimations from infrared image analysis, has been successfully applied in this work to visualise gorse fire flow from RGB images, and to compare it with fuel structure. The technique uses greyscale image processing to estimate direction and magnitude of the displacement of the observed fire features between two consecutive frames (1/30

s). The resulting vectorial field was then derived to calculate the corresponding flow streamlines and visualize the fire flow.

4. Results

4.1. Description of Fuel Structure and Fire Behaviour

Figure 2a shows an image of the fire extracted from the RGB UAV footage ~1 min after ignition. The figure highlights the observable flaming zone and fire front once the acceleration phase is ended. The length of the observable fire in the streamwise direction $y+$, or flaming zone depth, was found to variate across the width of the plot, ranging from ~10 m in regions of low canopy height to ~50 m in regions of high canopy height. Fire spread was characterized by quick progressions of the fire front involving intermittent coverage and subsequent ignition of immediate preheated unburned fuel, resulting in localized progression in short periods of time.

Figure 2b shows the pre-burn CHM obtained from ULS data. The plot was heterogeneous involving interspersed zones of high and low canopy height, with and averaged CHM of 0.75 m and a high standard deviation of ± 0.56, representing 75% of the average value. The right side of the plot was mostly composed of low height fuel with sporadic sectors of high fuel (e.g. dotted line), whereas the opposite occurred in most of the left side of the plot (e.g. dashed line).

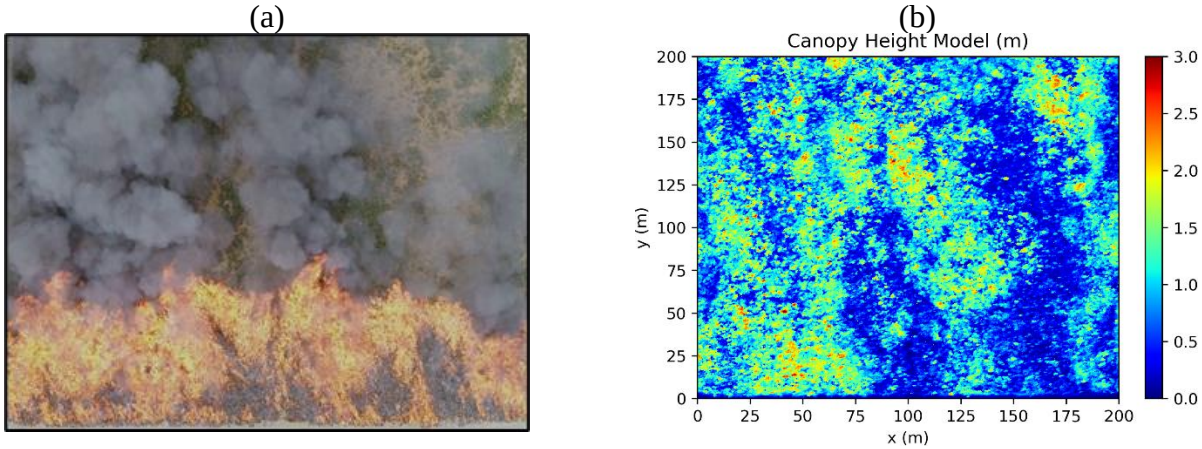

Figure 2. Collected datasets of the burn plot where the ignition took place along the bottom of the x-axis, with the x-axis showing plot width in meters, the y-axis showing the plot length in meters, and the value corresponding to (a) the colour sensed with the UAV-mounted RGB videos, plan view, (b) the height of the vegetation canopy obtained from ULS data. The resolution of the CHM is $7.8 \cdot 10^{-2}$ m/pixel

Figure 3a and Figure 3b show the fire behaviour properties estimated in this study. FRT, shown in Figure 3a, ranged between approximately 10 s to 1.5 min with very high values at the plot edges where liquid fuel was used for ignition purposes. Through qualitative comparison with CHM, FRT seems to present longer flaming combustion in regions of high canopy height. For instance, this pattern can be observed in the bottom-left (x = 50 m y = 25 m) and bottom-right (x = 175 m y = 25 m) sections of the maps. We hypothesize this behaviour results from high canopy height locations linked with high biofuel content participating in the combustion, relationship confirmed through analysis of pre-burn destructive samples. ROS, presented in Figure 3b, was found to be low during the first approximate 20 m where the fire was transitioning from an accelerating fire front with a small flaming zone to the established quasi-steady fire shown in Figure 2a. The ROS map captured the previously described quick progressions of the fire front as localized high ROS values. We hypothesize this could be explained by the presence of greater flame heights and longer fire activity in regions with higher canopy height, most likely associated with higher fuel load.

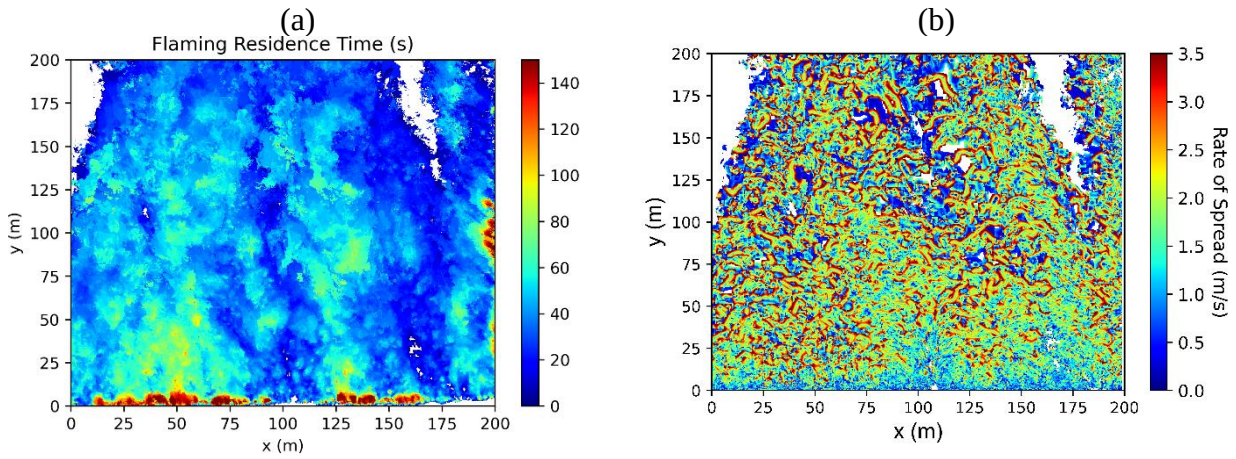

Figure 3. Derived datasets of the burn plot where the ignition took place along the bottom of the x-axis, with the x-axis showing plot width in meters, the y-axis showing the plot length in meters, and the value corresponding to (c) the rate of fire spread derived from the video footage, and (d) flame residence time also derived from the footage. The resolution of both maps is $7.8 \cdot 10^{-2}$ m/pixel

5. Acknowledgments, Samples, and Data

We would like to give a special thanks to all field support teams including technical and general staff. We also thank landowner for their various contributions leading to the success of the field campaigns. University of Canterbury research team would like to acknowledge the very thoughtful, well organized, and proactive support we have received from all the volunteering firefighting crew. The success of our experiments and the safety of our science crew can only be partially attributed to our design but greatly attributed to the safe and well-executed plan from the volunteer crew. A special thanks to the Scion field crew: David Glogoski, Max Novoselov, Richard Parker, Brooke O'Connor, Emma Percy, and Ilze Pretorius. We would also like to acknowledge Peter Massam from Scion's UAV team for assistance with UAV data capture and processing. This research was co-funded by Ministry of Business, Innovation and Employment (MBIE), New Zealand, grant number C04X1603 entitled "Preparing New Zealand for Extreme Fire" and grant number C04X2103 "Extreme wildfire: Our new reality - are we ready?"

Abstract

This paper presents the first steps of a 2-year pilot project on prescribed burning (PB) in Greece. To re-introduce the use of fire in wildfire prevention in the country, as an accurate and effective management tool, more research is needed. Hence, we will conduct planned field PB experiments which will provide us sound knowledge about fire behaviour matched with the fire impact on soil properties, the effects on trees and the plant biodiversity. The experimental fires can serve as an excellent training tool, also, for some of the participants (firefighters, land managers and researchers).

The first efforts to introduce and utilize the PB in Greece begun in the 1970s, when members of the Greek forest scientific community and the Hellenic Forest Service applied PB experimentally, analysed data and drew some preliminary conclusions. They made some steps to document the use of fire and study its impacts before introducing PB as a tool to prevent forest fires. Unfortunately, without constant funding, legal support, logistics, continuous scientific guidance and clear objectives, those sporadic attempts did not tie bonds with the forest and fire management community and the endeavour was soon abandoned. Almost half a century later, fire is still not used in fuel management and fire prevention and there is no institutional framework for the implementation of PB.

Inspired by those first efforts in applying PB in Greece and guided by the fire science and the best practices for wildfire prevention, a core team of researchers and practitioners from WWF Greece, the Institute of Mediterranean Forest Ecosystems of ELGO "DIMITRA", the Forest Directorate of Chios Island, and the Voluntary Action Team "OMIKRON" started in 2021 a pilot project on the implementation of the PB on the island of Chios. Fire Service of Chios Island and Municipality of Chios support the pilot project by supplying water trucks and personnel during the burns. The Project is sponsored by Procter and Gamble corporation.

The project aims to introduce PB as a tool for forest fuel management, increase social– ecological resilience to wildfire and contribute to a climate – resilient future. More specifically, the project is expected:

i. to develop the standards and procedures, through applied research, for the use of the prescribed fire in Greece,
ii. to be a successful paradigm of fuel management,
iii. to strengthen the role of the forest service in fuel management and build the capacity of local stakeholders on potential contribution,
iv. to strengthen the horizontal cooperation among agencies, by introducing compatible methods and techniques,
v. to build the capacity of the volunteer firefighters' teams on issues related to the wildfire prevention and fuel management,
vi. to increase knowledge and improve experience on the fire behaviour,
vii. to further strengthen, improve and expand local alliances in Chios Island
viii. to improve landscape resilience and prevent forest fires.

1. Introduction

Prescribed burning (PB) is a fuel management (FM) method which can be either used alone or in combination with grazing and mechanical treatment (Stephens et al 2012), depending on many factors such as fire management objectives, forest types, location, fire regime (Jain et al 2012, Moghaddas et al. 2010), possible restrictions and on the different spatial and temporal scales at which FM is applied, fine and broad. It improves fire resilience over a particular landscape, reduces the probability of fire ignition, affects fire behaviour (Samara et al. 2018), making firefighting easier and safer, mitigates fire severity and reduces fire damages. PB is both science and technique and it can be a very accurate management tool.

Although increased PB is needed to provide a diversity of public benefits, including wildfire hazard reduction, improved forest resilience, and biodiversity conservation (Varner et al. 2021), there is practically no PB in many parts of Europe (Rego et al. 2010) and progress in adopting the method across the continent remains relatively limited. Only in Portugal, Spain, and south France, PB is practiced quite often, mainly for fuel reduction.

An evidence-based, and flexible approach to prescribed burning with emphasis to the biology and ecology of species and habitats, is needed (Fernandes et al 2013). A shift to 'knowledge' (Castellnou et al 2010) with improved reporting practices to invigorate PB science and suggest minimum reporting standards for future PB experiments, will facilitate future research syntheses, and foster actionable science (Bonner et al 2021). Unfortunately, planned field PB experiments are infrequent in Mediterranean ecosystems up to now, although they can provide sound knowledge about fire impact on soil properties and effects on trees.

In Greece there is no PB application for fuel management and wildfire prevention. In March 2022, Greek Parliament approved a law, making it legal for the firefighters to use backfire and burnout techniques for fire suppression and in June 2022, the government published the technical aspects on how to use them.

The first efforts to introduce and utilize the PB in Greece had begun in the 1970s, when members of the Greek forest scientific community and the Hellenic Forest Service applied PB experimentally, analyzed data and drew some preliminary conclusions. They made some steps to document the use of fire and study its impacts before introducing PB as a tool to prevent forest fires.

In Thasos, an island situated in the northern Aegean Sea, there was periodic application (every 3 years with some repetition i.e., 1974, 1977, etc.) of experimental prescribed burns in plots in mature *Pinus brutia* stands (Papanastasis 1977). Since at those years, there was lack of data and research findings derived from Greece, regarding the use of the fire, the foresters who applied the PB in Greece had followed some U.S. standards. They had met in scientific meetings and workshops, had demonstrated how to use the fire, discussing also ecological and managerial issues as well as its potential combination with grazing and mechanical treatments (Tsiouvaras et al. 1987, Nastis 1989). Unfortunately, without constant funding, legal support, logistics, continuous scientific guidance, and clear objectives, those sporadic attempts did not tie bonds with the forest and fire management community and the endeavour was soon abandoned. In 1980s, according to the legislation, safety standards for the application of the fire, were occasionally defined by the Forestry Administration and the applicant had to file an impact assessment study, including techniques, a time plan, safety precautions and measures during and after the use of fire and attach a plat (contour plan), also.

Almost half a century later, fire is still not used in fuel management in Greece and fire prevention, and there is no institutional framework for the implementation of PB. Inspired by those first efforts in applying PB in Greece and guided by the fire science and the best practices for wildfire prevention, a core team of researchers and practitioners from WWF Greece, the Institute of Mediterranean Forest Ecosystems of ELGO "DIMITRA", the Forest Directorate of Chios Island, and the Voluntary Action Team "OMIKRON" started in mid-2021 a 2-year pilot project on the implementation of the PB on the island of Chios. Fire Service of Chios Island and Municipality of Chios support the pilot project by supplying water trucks and personnel during the burns. The General Directorate for Forests and Forest Environment of Ministry of Environment and Energy provided all necessary permits for the implementation of pilot application of PB in Chios.

The project aims to introduce PB as a tool for forest fuel management, increase social– ecological resilience to wildfire and contribute to a climate – resilient future.

The wildfire problem in Chios is significant, often threatening human lives, disturbing biodiversity and affecting or burning mastic and olive groves. Chios, is the fifth largest of the Greek islands, located in the northern Aegean

Sea and was chosen for two reasons: i) it hosts a variety of Mediterranean forest types with typical characteristics i.e., phrygana, maquis, and thermophilic conifers, so the research findings can be utilized across the country and because ii) of the achieved alliance (Figure 6) and cooperation among the stakeholders, agencies, and the volunteers.

The Chios Voluntary Action Team – Omikron was created in 1999. It is based on Chios Island; operates across the entire island and potentially in the Prefecture of Northern Aegean, and is quite active in wildfire suppression, in prevention [construction of fuel breaks (Athanasiou 2016, 2018, Figure 1), population awareness raising] as well as in restoration and reforestation activities (such as planting seedlings for reestablishing forest vegetation in desertified areas).

Figure 1 Omikron volunteers constructing a fuel break in Chios Island, in 2012 (Photo: Apostolos Flioukas)

2. Methods

The 2-year project started in summer of 2021, and it is to be implemented in at least 4 PB campaigns. Since data-driven decision making is the key to providing effective and efficient wildfire protection (Hogland et al. 2021), we carefully chose 16 plots for the PB application (Table 1, Figure 2). Unfortunately, due to the adverse weather conditions in the 2021-2022 winter in Greece, there were no weather windows for PB application in Chios in the fall of 2021, so we ran two campaigns, in February (Figure 4) and April 2022, and there will be at least two more, in November 2022 and February 2023.

A series of parameters are monitored, measured, and recorded before, during and after the implementation of PB in some of the selected plots:

i. soil infiltration (mm),
ii. soil temperature (ºC) in various depths,
iii. erodibility,
iv. soil texture, nutrients and carbon in the soil,
v. soil respiration,
vi. organic matter decomposition,

vii. soil enzyme and microbial activity,
viii. plant biodiversity,
ix. sap flow ($cm \cdot h^{-1}$),
x. water potential (MPa),
xi. fireline construction rate ($m \cdot h^{-1}$) along the plot perimeter, by mowing and using various hand tools,
xii. surface fuel loading ($kg \cdot m^{-2}$), cover (dimensionless), height (cm) and fuel moisture content (%) through destructive sampling (Figure 3), to describe the fuel situations and complexes before the burn,
xiii. meteorological conditions,
xiv. fire behaviour that is rate of fire spread (ROS, $m \cdot min^{-1}$) and flame lengths (FL, m).

Recording includes ground and aerial photographs. Regarding the aerial perspective, the use of unmanned aerial vehicles (UAVs) provided highly detailed mosaics pre- and post-PB (Figure 5). Fine resolution 3D models were generated by applying low altitude and slow velocity grid flights.

The predefined dimensions of the test areas instructed the use of a versatile, yet robust multirotor UAV, with sophisticated camera load. DJI Phantom 4 Pro was selected as an ideal combination, since it provides wind resistance up to 10 m/sec, more than 20 minutes of autonomous flight per battery and carries an 1'' CMOS, 20Mp sensor, with FOV 84° 8.8 mm/24 mm (35 mm format equivalent) f/2.8 - f/11 auto focus at 1 m - ∞ lens and mechanical/electronic shutter speed of 8 - 1/2000 sec. Images were created in a 3:2 JPEG format of 5472 × 3648 aspect ratio.

Each grid flight was predesigned in Pix4dCapture application, respecting the National Cadastre Digital Elevation Model (2007-2009) and neighbouring obstacles. Data processing (mosaic and dsm/dtm creation) was completed in Pix4d Mapper software.

Figure 3 - Training Omikron volunteers in destructive sampling of surface fuels

Figure 4 - PB application in one of the plots, in February 2022. The upper left photo is taken in July 2021

3. Discussion – conclusions

This pilot project is expected to be the starting point for the application of PB in Greece, using specific standards. More specifically, the project is expected:

i. to develop the standards and procedures, through applied research, for the use of the prescribed fire in Greece,
ii. to be a successful paradigm of fuel management,
iii. to strengthen the role of the forest service in fuel management and build the capacity of local stakeholders on potential contribution,
iv. to strengthen the horizontal cooperation among agencies, by introducing compatible methods and techniques,
v. to build the capacity of the volunteer firefighters' teams on issues related to the wildfire prevention and fuel management,
vi. to increase knowledge and improve experience on the fire behaviour,
vii. to further strengthen, improve and expand local alliances in Chios Island,
viii. to improve landscape resilience and prevent forest fires.

Figure 5 - A post-PB highly detailed mosaic

Figure 6 - The stakeholders showed interest in the kick off meeting of the project, in Chios island, October 2021 which included a training seminar and initial briefing.

Thus, through this effort we expect, in the long run, PB to be institutionalized in Greece, and assimilated by competent services and local communities, as a tool for fuel management and consequently forest fire prevention through documented policy proposals that will be based on the results of this pilot implementation.

Moisture content, live forest fuel, Holm oak, Mediterranean

Abstract

Due to its biological diversity and preservation, the Mediterranean area is an extremely valuable area on Earth. In recent years, the Mediterranean region has been frequently affected by fires. An increasing number of fires are certainly degrading the Mediterranean ecosystem and disrupting its stability, leading to a reduction in biodiversity and an increase in devastated areas. In addition to understanding and knowing the biological and ecological consequences of forest fires and methods of remediation and restoration of burned areas, knowledge of factors that cause forest fires and factors that cause the initial spread of fire is important to reduce burned areas and prepare and conduct preventive activities. The moisture content of living forest fuel is an extremely important factor for the spread of forest fires. It is a factor that is very sensitive and depends on local micrometeorological conditions. The practice is that some very significant variables for forest fires, such as the moisture content of potential fuels, are sought to be obtained by applying various models, although it is known that these models cannot determine the true values of required variables unlike actual, empirical research. The most important meteorological factors that are taken into account when it comes to forest fires are temperature and humidity or water (precipitation). It is a climazonal species in the forest ecosystems of the Mediterranean part of Croatia. The research was conducted at two locations; the island of Rab and Makarska. The results show differences in the influence of meteorological conditions depending on the location of the research. The obtained results confirm that the understanding of meteorological conditions and vegetation characteristics in terms of moisture content of living fuels and their relationship can contribute to improving knowledge about firefighting issues and identify critical periods of high risk of forest fires.

1. Introduction

Due to its biological diversity and preservation, the Mediterranean area is an extremely valuable area on Earth. In recent years, the Mediterranean region has been frequently affected by fires. An increasing number of fires are certainly degrading the Mediterranean ecosystem and disrupting its stability, leading to a reduction in biodiversity and an increase in devastated areas. At the same time, there are high costs of reconstruction that last for decades, there are landscape changes, socio-economic turmoil and conflicts of interest. Among the most important natural destabilizers that cause change are forest fires (Trabaud, 1980; Casal, 1987; Naveh, 1999). When it comes to the factors of occurrence and spread of forest fires, vegetation characteristics, ie combustible material and meteorological factors are the most decisive and most important factors of natural origin and spread of forest fires. Vegetation elements are based on vegetation cover, type, moisture content and availability of combustible material (Pyne *et al.*, 1996; Pellizzaro *et al.*, 2007). Meteorological parameters have a great impact on fires. Thus Viegas *et al.* (1999), Skinner *et al.* (1999), Viegas *et al.* (2004) and Pereira et al. (2005) point out that weather and climate play a key role in determining the fire regime of an area, and the fire regime in turn is very close to climate change. Topographic elements are an important factor influencing the formation and spread of forest fires. Different landforms can be natural barriers or conveniences for forest fires. Slope is a factor on which the spread of forest fires depends. On steep slopes, forest fires spread much faster than on flat terrain. If a forest fire develops uphill, in the direction of rising hot air, it will develop faster, and the rate of spread can further regulate the influence of the wind. At higher altitudes, the temperature is lower, and therefore the intensity of fires is lower. When it comes to the initial occurrence of forest fires, in terms of forest fuels, dead forest fuel plays a key role in the occurrence of fires. It is a fuel that participates in the initial ignition and further flare-up of the fire element, and when a fire develops, in addition to the role of dead fuel, living forest fuel, its

condition and quantity are important for its further progress. The objectives of this study are to determine the moisture content of live holm oak (*Qurcus ilex* L.) for the Adriatic area in Croatia and to analyze the impact of meteorological factors (temperature, humidity and precipitation) on the moisture content of live fuel of this species.

2. Material and methods

2.1. Research area

The island of Rab is located on the northern Croatian coast, and Makarska on the southern Croatian coast. On the island of Rab, research was conducted at the Teaching Experimental Forest Facility Rab, Faculty of Forestry and Wood Technology, University of Zagreb. In Makarska, the research was conducted in an experimental laboratory located within the main meteorological station Makarska.

2.2. Research methods

For two years, once a month, tests were performed at each location. The meteorological data used for the analyzes were taken from the State Hydrometeorological Institute, and were measured at the meteorological station Rab and the main meteorological station Makarska. The moisture content of the tested samples was obtained using a standardized equation for determining the moisture content (percentage of dry weight) by the method of drying in an oven.

The equation is:

$$LFMC = ((FW - DW) / DW) * 100$$

Where is:

LFMC – moisture content of the tested sample

FW – mass of fresh sample

DW – mass of dry sample

3. Results

Table 1. Moisture content of live fuel Holm oak (Quercus ilex L.)

Species	Moisture content of live fuel LFMC (%)	
	Makarska	**Rab**
Holm oak (Quercus ilex L.)	48.99-91.37	66.36-102.86

The moisture content of live holm oak (*Quercus ilex* L.) fuel is higher on the island of Rab than in Makarska. The obtained results indicate that although it is the same type, the moisture content of live fuel is lower on the island of Rab, which belongs to the northern Croatian coast.

Table 2 - Linear correlation of live fuel moisture content (LFMC) for holm oak (Quercus ilex L.) on the island of Rab and in Makarska

Variable	Correlations (Alepski bor – *P. halepensis* Mill. – DI); Marked correlations are significant at p<.05000; N=25					
	LFMC	Mean monthly air humidity	Mean monthly air temperature	Mean monthly maximum air temperature	Mean monthly minimum air temperature	Mean monthly precipitation
Rab – LFMC	1.00	-0.02	-0.44	-0.44	-0.44	-0.43
Makarska – LFMC	1.00	-0.10	0.14	0.14	0.15	0.22

The correlation between LFMC and mean monthly precipitation (0.43 *) is positive, statistically significant and mean, while the correlations are mean monthly air temperature (-0.44 *), mean monthly maximum air temperature (-0.44 *), mean monthly minimum air temperatures (-0.44 *) statistically significant, negative and moderate. In Makarska, the LFMC of holm oak (*Quercus ilex* L.) does not show a statistically significant correlation with the variables used (Table 2.). Makarska belongs to the southern Croatian coast and the role of meteorological factors describing the climate impact is not statistically significant as it is on the island of Rab.

4. Concluding discussion

Fuel moisture content has been identified as one of the most critical factors influencing the occurrence and spread of fires (Van Wagner, 1977; Viegas *et al.*, 1992; Andre *et al.*, 1992; Viegas *et al.*, 1998; Carlson and Burgan, 2003; Chuvieco *et al.*, 2004). Cappelli *et al.* (1983) and Dimitrakopoulos and Papaioannou (2001) found that there is a great connection between the flammability of Mediterranean species and the moisture content in them. The increase or decrease in moisture content of the fuel is the result of weather conditions (Simard, 1968) and depends on the physiological and chemical characteristics of the fuel (Castro *et al.* 2003; Aguado *et al.*, 2007). However, Sun *et al.* (2006) point out that Mediterranean vegetation has structural, morphological and phenological characteristics suitable for the formation and spread of fire in conditions when the amount of available fuel and meteorological conditions are not critical. Therefore, a better understanding of meteorological conditions and vegetation characteristics in terms of flammability and moisture content of fuels and their relationship can contribute to improving knowledge about firefighting issues and identify critical periods of high risk of forest fires. Changes in moisture content are related to meteorological conditions and available soil moisture on the one hand, and the ecophysical characteristics of the species on the other, but also to living conditions in the past (Alessio *et al.*, 2008). Low fuel moisture content is the main reason for the occurrence of fires in early autumn due to drying of fuel during the summer and in the spring before the new leaf mass begins its activities (Rothermel, 1972). According to Pompe and Vines (1966), the occurrence of fires with catastrophic consequences arising in arid conditions is due to the stronger impact of reduced moisture content than high air temperatures. The significant impact of moisture content on fuel flammability can be demonstrated through the evaporation and exclusion of oxygen from the combustion zone (Brown and Davis, 1973). Apparently, the ignition energy is lower with a higher moisture content. On the other hand, the moisture content affects the behavior of the fire, because when combustion is reduced due to fuel humidity and further ignition is limited.

Abstract

Conventional fuels treatments often simplify forest structure by spacing residual trees and thinning from below to optimize fire hazard reduction. Conversely, restoration treatments, aimed at achieving ecological multiple objectives in addition to fire hazard reduction, purposefully retain heterogeneous forest structures. The retention of tree groups and small trees following restoration may however limit reductions in fire behavior. To quantify this potential trade-off, we performed a suite of simulations with the Wildland-urban interface Fire Dynamics Simulator to compare stand-level fire behavior between silvicultural cuttings that either emphasized or reduced forest heterogeneous structure under a range of residual basal areas, surface fuel loads, and burning conditions. These cuttings included distance-based retention, variable retention, and random cuttings, optionally with thinning from below. While all treatments reduced fire behavior, differences between cutting scenarios emerged at low levels of residual basal area. Rate of spread did increase under more severe burning conditions, and slightly increased after thinning from below or after variable retention cuttings due to higher wind speeds associated with the creation of openings. Canopy consumption was lowest when thinning from below and highest after variable retention. The differences we observed support the advantage of using fuels treatments that preferentially space residual trees and remove small trees where fire hazard reduction is of primary importance. Additionally, the effects of residual basal area, surface fuel load, and burning conditions highlight the multivariate considerations required when planning fuels treatments and assessing performance at stand scales.

1. Introduction

Mechanical fuels treatments are a primary tool in forests to reduce the likelihood of undesirable fire behavior and post fire effects at the stand scale (Reinhardt et al., 2008; Stephens et al., 2021). At a minimum, fuels treatments are oriented around four principles (Agee and Skinner, 2005): reduce surface and canopy fuel loads, increase canopy base height, and preserve larger fire-resistant trees. These principles are often implemented silviculturally by removing small trees and leaving widely spaced large trees (Larson and Churchill, 2012; Stephens et al., 2021).

There is a desire in many forests globally however to use silvicultural practices which emphasize the creation of heterogeneous forest structures (Fahey et al., 2018; Puettmann, 2011; Zenner and Hibbs, 2000; Ziegler et al., 2017). For example, dry forest stands of the western USA, for example, were composed of fine-scale (sub-ha) mixtures of openings, isolated trees and tree groups prior to EuroAmerican settlement (Clyatt et al., 2016; Larson and Churchill, 2012). In these forests, restoration treatments aim to dually achieve both ecological and fire hazard objectives. Restoration-based silvicultural practices permit variable tree spacing rather than distance-based minima (Churchill et al., 2013), and shift from a size-centric focus geared towards lifting the canopy to a free thinning approach (Addington et al., 2018; Tuten et al., 2015; Underhill et al., 2014).

Restoration treatments are generally seen as compatible with reducing fire hazard (Addington et al., 2018; Stephens et al., 2021). The long-term persistence of heterogeneously structured forests, historically sparser than their modern counterparts, suggests these forests have been resilient (Larson and Churchill, 2012). In addition, Koontz et al. (2020) found that sparse and heterogeneous forest structures experienced low severity fire effects following wildfires. Further, fire simulation studies confirm heterogeneous restoration treatments reduce fire behavior relative to their state pre-treatment (Ziegler et al., 2017). However, it is suggested that fire behavior reduction may be hindered after restoration relative to homogenizing conventional fuels treatments, implying restoration treatments carry tradeoffs (Addington et al., 2018; Larson and Churchill, 2012; Stephens et al., 2021; Ziegler et al., 2017). These remarks cite the potential for surface-crown transitions facilitated by residual ladder fuels and local crown fire spread within tree groups (Larson and Churchill, 2012; Stephens et al., 2021). Further, the openings created by restoration treatments can increase within-stand wind speeds, exacerbating fire rate of spread and fireline intensity (Linn et al., 2013; Ziegler et al., 2017).

We conducted a systematic study of simulated fire behavior under hypothetical cutting alternatives using data measured in real-world dry forests in the intermountain West, USA. We developed five hypothetical cutting scenarios to manipulate the horizontal and/or vertical arrangements of tree crowns. We implemented cutting scenarios to various levels of residual basal areas. Then we simulated fire using a three-dimensional, physics-based fire model across a range of surface fuel loads and burning conditions. Last, we compared measures of fire behavior and severity between cutting scenarios at each level of residual basal area.

2. Materials and Methods

2.1. Design of Fire Simulations

We planned our experiment to simulate the effects of cutting scenarios on potential fire behavior and severity across a range of burning conditions. With the Wildland urban interface Fire Dynamics Simulator (WFDS) (Mell et al., 2007; Mueller et al., 2014), we simulated fire before and following virtual cuttings on five stem-mapped 4-ha sites. These sites are located within ponderosa pine (*Pinus ponderosa* Lawson)-dominated forests in Colorado and Arizona, USA (Ziegler et al., 2017). Cuttings included: random, distance-based, with or without thinning from below, and variable retention, with or without thinning from below. Each cutting operated by sequentially removing, or retaining, trees until a basal area target of either 5, 10 or 15 m^2 ha^{-1} was met. The random cutting equally sampled trees. The distance-based cutting removed trees nearest to another tree. Our variable retention cuttings used an algorithm previously described by Tinkham et al. (2017) to retain groups of trees. For each WFDS simulation, we populated three-dimensional domains with the residual trees for a given site, its respective cutting scenario at each residual basal area. Our parameterization mimicked related WFDS studies, e.g. Ziegler et al., (2021, 2020, 2017). Table 1 details the forest structure following each cutting scenario.

Table 1- Spatial and aspatial summary of forest structure following hypothetical cuttings, averaged (std. error) across five 4-ha sites.

Cutting scenario	Trees ha^{-1}	QMD	Mean trees $group^{-1}$	Mean opening size (m^2)	Mean nearest neighbor (m)
Pre-cutting	687 (88)	22.8 (2)	10.1 (2.2)	16 (6)	1.6 (0.1)
Residual basal area: 15 m^2 ha^{-1}					
Random	403 (56)	23 (2)	4.1 (0.6)	37 (13)	2.2 (0.2)
Distance-based	292 (46)	27 (2)	2.4 (0.4)	29 (11)	3.6 (0.4)
Variable-retention	386 (60)	23 (2)	4.3 (0.7)	62 (14.4)	2.1 (0.2)
Distance-based w/ thin-from-below	118 (23)	43 (5)	1.1 (0.0)	105 (34)	6.3 (0.7)
Variable-retention w/ thin-from-below	153 (28)	38 (4)	1.6 (0.1)	117 (29)	4.1 (0.4)
Residual basal area: 10 m^2 ha^{-1}					
Random	265 (37)	23 (2)	2.7 (0.2)	68 (19)	2.7 (0.2)
Distance-based	178 (28)	28 (3)	1.3 (0.1)	56 (19)	5.0 (0.5)
Variable-retention	269 (36)	22 (2)	3.1 (0.3)	117 (16)	2.2 (0.2)
Distance-based w/ thin-from-below	62 (12)	49 (6)	1.0 (0.0)	189 (38)	9.0 (1.0)

Variable-retention w/ thin-from-below	83 (15)	42 (5)	1.3 (0.0)	194 (30)	5.6 (0.6)
Residual basal area: 5 m^2 ha^{-1}					
Random	132 (22)	23 (2)	1.7 (0.1)	139 (28)	4.2 (0.4)
Distance-based	82 (13)	29 (2)	1.0 (0.0)	141 (26)	7.9 (0.8)
Variable-retention	144 (18)	22 (2)	2.7 (0.3)	215 (8)	2.6 (0.2)
Distance-based w/ thin-from-below	24 (5)	56 (7)	1.0 (0.0)	312 (21)	15.9 (1.9)
Variable-retention w/ thin-from-below	32 (7)	48 (6)	1.1 (0.0)	304 (22)	9.5 (1.2)

We varied additional parameters in WFDS simulations to capture a range of fire behavior outcomes from moderate to extreme. Our experimental design varied the open wind speed (5, 10, or 15 m s^{-1} at 20-m AGL), surface fuel loading, and surface fuel moisture (5%, 8%, or 11%) to generate a range of burning condition severities. Median surface fuel loads were 0.4, 0.8 or 1.2 kg m^{-2}. We distributed surface fuel loads heterogeneously to reflect the influence that canopy cover has on the composition of the surface fuelbed locally (Figure 1) (Banwell and Varner, 2014; Matonis and Binkley, 2018). First, we calculated the distances from any location to a tree, then inverted these distances, and last re-scaled these distances to fuel load using a triangular distribution with a minimum of 0.2, maximum of 3.0, and median of either 0.4, 0.8, or 1.2. Where the surface fuel load was 0.2 kg m^{-2}, we assigned a fuel bulk density of 2 kg m^{-3}. For each surface fuel load increase of 1 kg m^{-2}, we increased fuel bulk density by 6.25 kg m^{-3}.

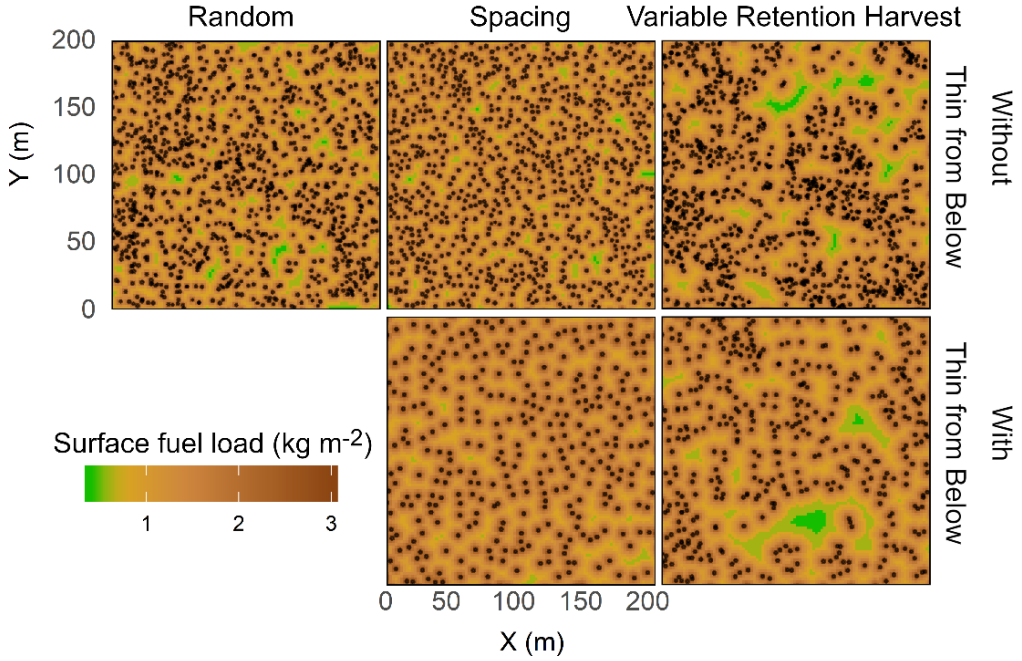

Figure 1- Example of simulated cuttings on one site, Long John, mapping the locations of residual trees (black dots) given a target basal area of 10 m^2 ha^{-1}, and the arrangement of surface fuel loads, given a spatial median of 1.2 kg $^{-2}$

2.2. Experimental Design & Analysis

We performed 200 simulations of fire behavior after cutting. We used an implementation of C-optimized Fedorov's exchange algorithm (Atkinson and Donev, 1992) as implemented by the AlgDesign v1.2.0 package (Wheeler, 2019) in R to choose a subset of simulations to run among a full factorial candidate list. We also simulated fire behavior a total of 40 times across sites pre-cutting across all variables, again using C-optimized Fedorov's exchange algorithm.

We measured mean rate of spread and logit-transformed percent canopy consumption for each WFDS simulation. First, we used linear mixed-effects regressions, with nlme v.3-1-152 (Pinheiro et al., 2021) in R, to measure the estimators for each variable, using the form (Eq. 1):

$$\{ROS, CC\} = U_{10} + SFL + SFM + BA + Cutting + BA \times Cutting + Plot, \quad (1)$$

which includes fire rate of spread (ROS), percent canopy consumption (CC), open wind speed (U_{10}) measured at 10 m above the ground, surface fuel load (SFL), surface fuel moisture (SFM), residual basal area (BA), cutting scenario, and plot as the single random variable. Second, we then applied a subsequent analysis of deviance test to assess statistical significance of variables, using an α of 0.05 for all hypothesis tests in this study.

3. Results

Fire rate of spread (ROS) was lower after all cutting scenarios relative to pre-cutting (Dunnett's test, all *p*-values < 0.002). ROS averaged 0.67 m s^{-1} before cutting, and from 0.48 m s^{-1} to 0.53 m s^{-1} across cutting scenarios. There was a significant main effect between cuttings (Analysis of deviance, $\chi^2(df = 5) = 24.6$, $p < .001$). Further, while there was no trend with respect to residual basal area (Analysis of deviance, $\chi^2(df = 1) = 3.4$, $p = .064$), we found that the differences between cuttings increased with lower residual basal area (Analysis of deviance, $\chi^2(df = 5) = 13.9$, $p = .016$; Figure 2a). At the highest basal area, pairwise comparisons tests showed that ROS was not different between cutting scenarios, averaging 0.51 m s^{-1}. But when thinning to 5 m^2 ha^{-1}, ROS decreased to 0.47 m s^{-1} within distance-based and random cuttings. Meanwhile, ROS increased to 0.54 m s^{-1} after variable retention.

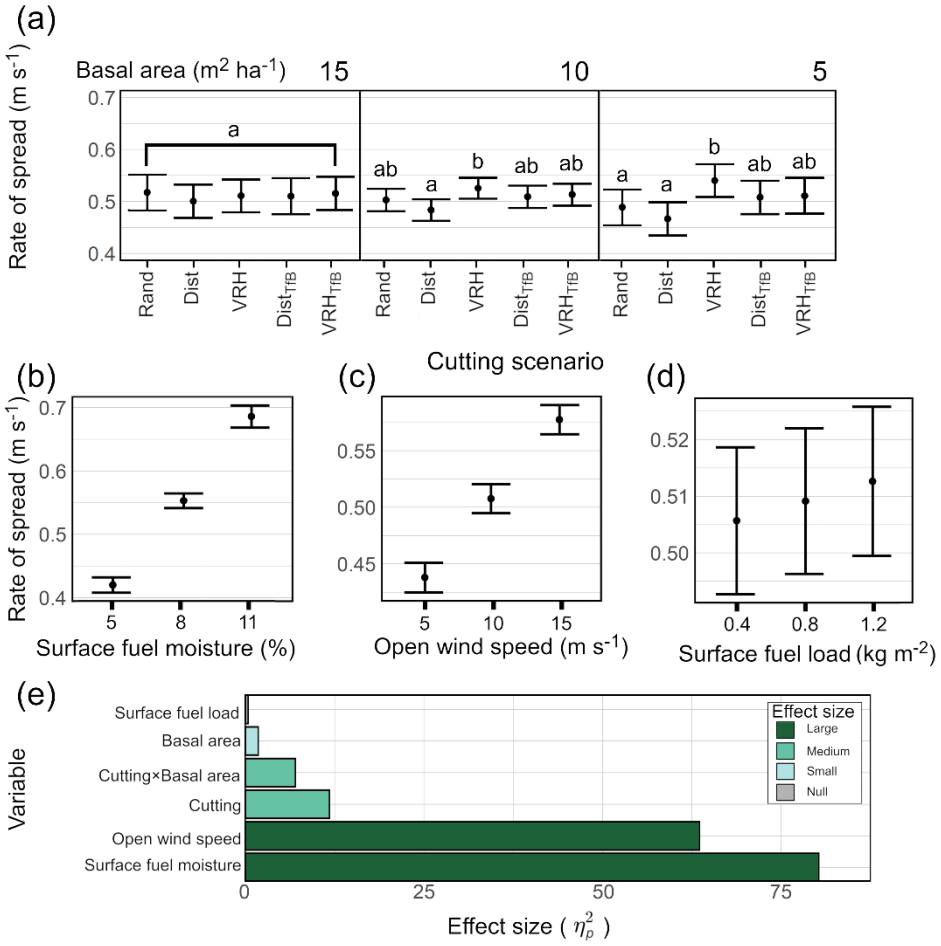

Figure 2- Marginal effects of a) cutting scenario × basal area, b) surface fuel moisture, c) open wind speed, and d) surface fuel load following mixed effects modelling on rate of spread, and e) effect size of variables. Letters indicate significant differences between cuttings using pairwise comparison procedures.

Among the other independent variables, surface fuel moisture most explained ROS (Analysis of deviance, $\chi^2(df = 1) = 759.9$, $p < .001$; Figure 2e), with 0.42 m s^{-1} ROS at 11% surface fuel moisture to 0.69 m s^{-1} ROS at 5% surface fuel moisture (Figure 2b). Meanwhile, ROS ranged from 0.44 to 0.58 m s^{-1} as open wind speed increased from 5 to 15 m s^{-1} (Analysis of deviance, $\chi^2(df = 1) = 323.1$, $p < .001$; Figure 2c). Surface fuel load was the only variable which did not explain variability in ROS (Analysis of deviance, $\chi^2(df = 1) = 0.8$, $p = .381$; Figure 2d).

The percent canopy consumption (CC) averaged 73% before cuttings and significantly dropped to 43% to 54% across cuttings (Dunnett's test, all *p*-values < 0.001). CC did vary between cutting scenarios (Analysis of deviance, χ^2(df = 5) = 65.6, $p < .001$) and explained the most variance alone of any variable (Figure 3a, e). In general, we found that the cuttings including thinning from below had lower CC than those cuttings without any thinning from below; of the latter scenarios, variable retention harvests were the highest. While CC diminished with lower residual basal areas (Analysis of deviance, χ^2(df = 1) = 34.5, $p < .001$), we identified an interaction with cutting scenarios. Specifically, the spread in CC between cutting scenarios was greater with less residual basal area (Analysis of deviance, χ^2(df = 5) = 23.3, $p < .001$).

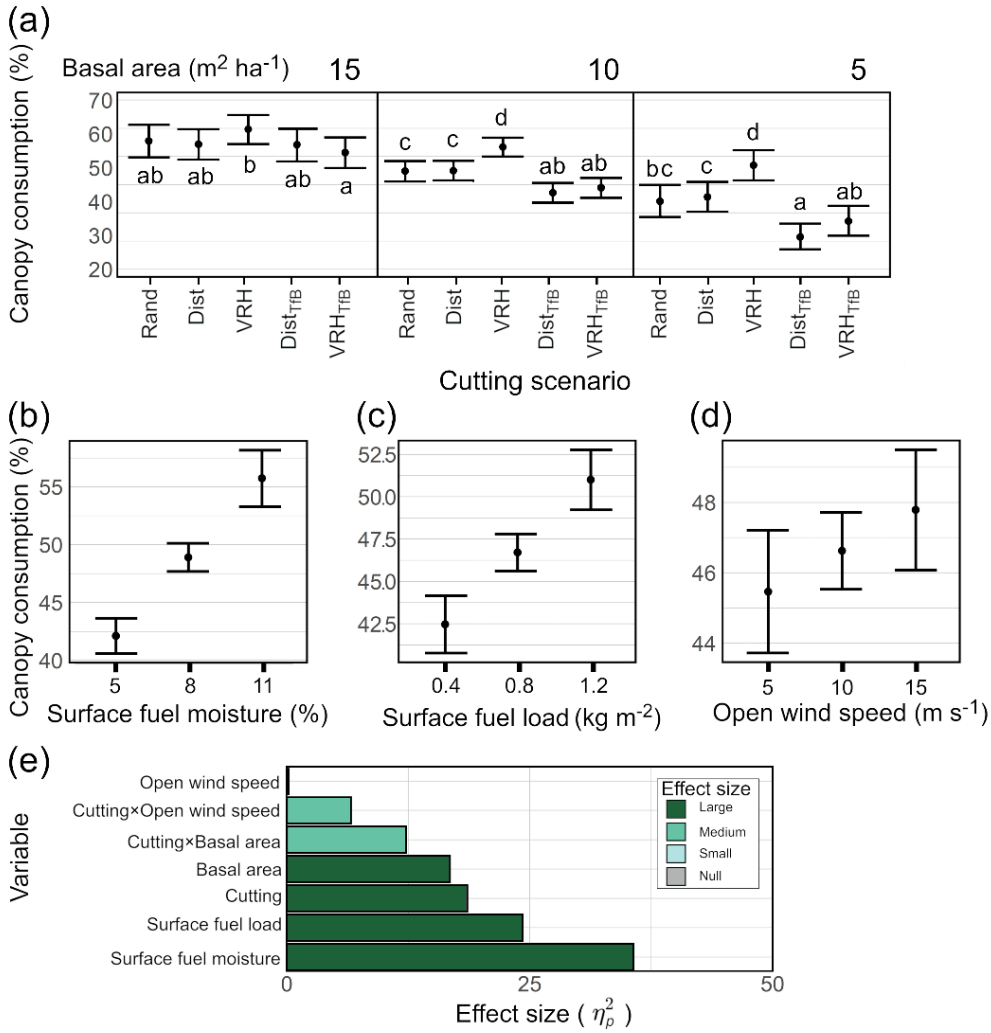

Figure 3- Marginal effects of a) cutting scenario × basal area, b) surface fuel moisture, c) surface fuel load, and d) open wind speed following mixed effects modelling on canopy consumption, and e) effect size of variables. Letters indicate significant differences between cuttings using pairwise comparison procedures.

Surface fuel moisture was the second most important variable (Analysis of deviance, χ^2(df = 1) = 95.7, $p < .001$) as CC rose from 42% to 56% while surface fuel dried (Figure 3b). As surface fuel loads increased from 0.4 to 1.2 kg m^{-2}, CC rose from 42% to 51% (Analysis of deviance, χ^2(df = 1) = 56.4, $p < .001$; Figure 3c). Open wind speed was a significant predictor of CC (Analysis of deviance, χ^2(df = 1) = 4.0, p = .045; Figure 3d), but had only a small effect size (Figure 3e).

4. Discussion

Most notably we found that all cuttings reduced fire behavior relative to pre-cutting scenarios, at all residual basal areas and burning conditions. This gives silviculturalists and fuels managers more opportunity to decide how remnant trees are arranged to realize other objectives. Where forest managers seek to maximize every

potential gain in fire haz-ard reduction with few other considerations, our results validate the use of conventional fuels treatments which combine distance-based specifications with thinning from below (Addington et al., 2018; Stephens et al., 2021). We found lower rates of canopy consumption because isolated trees experience greater convective cooling (Ritter et al., 2020) and lower heat fluxes between tree crowns (Contreras et al., 2012) (Figure 4). In contrast, restoration treatments which create both vertical and horizontal heterogeneity in forest structure were less effective at reducing fire behavior; wind entrained in openings pushing fire rate of spread higher, and the retention of both small trees and grouped trees allowed for instances of group torching, resulting in higher canopy consumption (Figure 4). This affirms a trade-off between retention of heterogeneous forest structure and fire hazard reduction (Stephens et al., 2021).

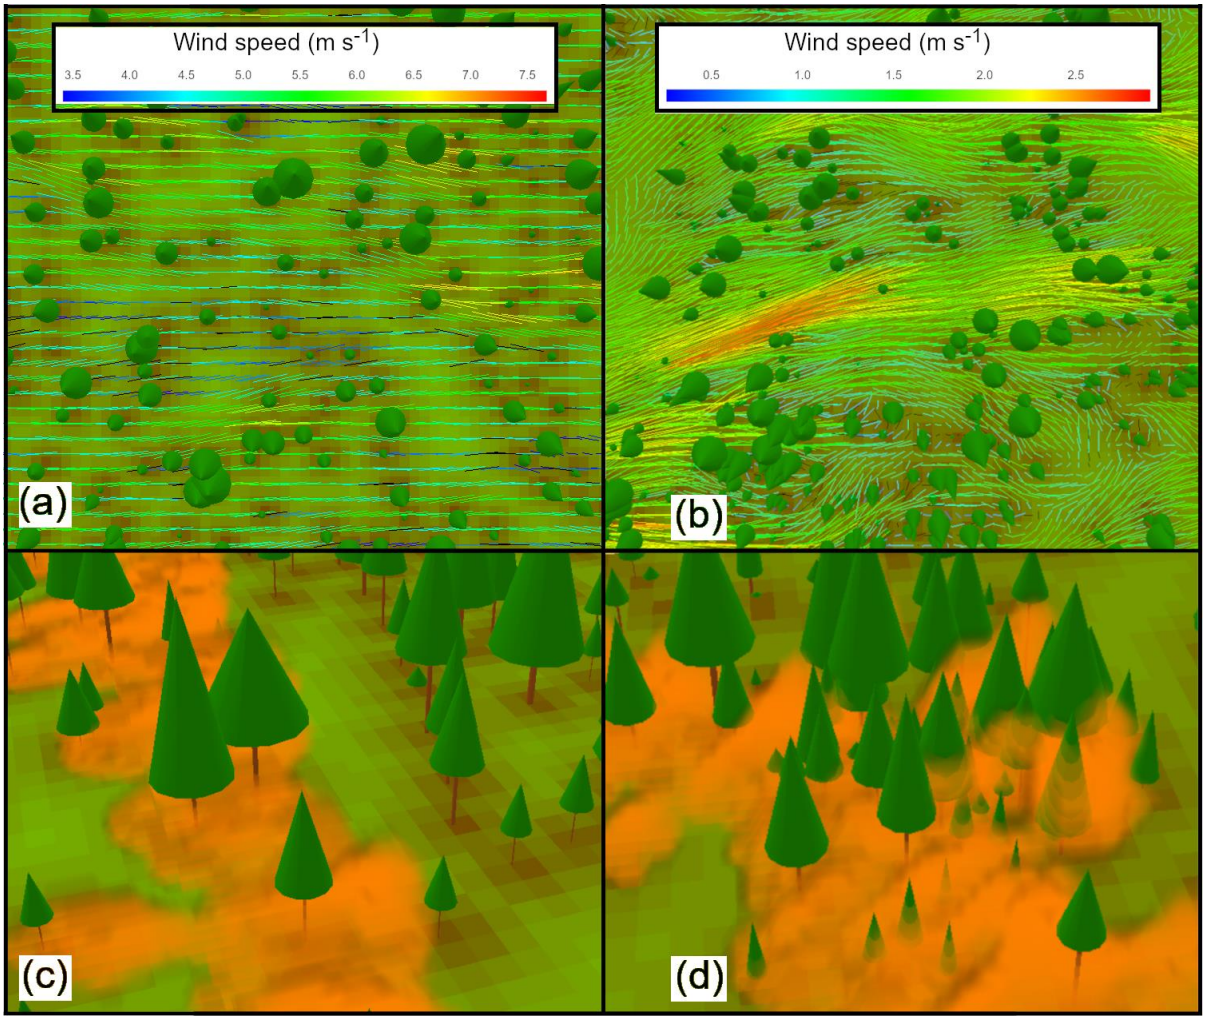

Figure 4- Demonstration of regimes of pre-fire (a) laminar flow with distance-based cuttings and (b) entrainment of wind following variable retention harvest, with wind vectors at 2 m above ground level flowing from left to right. During fire spread, (c) fire passed under large trees after distance-based cutting, while (d) groups torched after variable retention harvest.

Forest managers can close the spread between conventional fuels cuttings and forest restoration. Firstly, silviculturalists can undertake more aggressive reductions in basal area. As reported by Underhill et al. (2014) and Ziegler et al. (2017), recent implementations of restoration treatments in the forests simulated by this study have been retaining a basal area of 10 to 20 m^2 ha^{-1}. In contrast, these forests historically had an average basal area of 6.3 and density of 97 trees ha^{-1} (Battaglia et al., 2018). Forest managers have an opportunity to further reduce residual stocking and potential fire behavior without deviating outside of the range of natural variability and impairing ecosystem functioning. Secondly, some removal of small trees can increase fire behavior reduction; specifically, retaining tree groups without ladder fuels (Churchill et al., 2013) while preserving clusters of smaller, regenerating tree groups (Addington et al., 2018) can reduce the potential for surface-crown fire transition while maintaining younger cohorts of trees.

Residual biomass; pyrolysis; biochar; forest cleaning

Abstract

Forest management operations adequately integrated in the forestry value-chain are the gold standard in wildfire prevention. However, these operations generate considerable amounts of residual forest biomass (RFB) that cannot be legally disposed in land and further require suitable management. Residual biomass also includes highly flammable plants existing in the Portuguese forest such as gorse, broom, giant reed and acacia. Quite often wildfires in Portugal are linked with spreading of this residual biomass that promotes fuel accumulation. Besides deleterious impacts on rural and forestry economy, wildfires are also a driver for desertification and soil degradation.

Alternative uses for this residual biomass to promote its valorisation and enable proper models of management of forest areas are needed, thus providing economic and environmental benefits towards decreasing of the fuel load. Though this biomass has reasonable carbon content and heating value, they also present inorganic composition (e.g. Na, K, Cl) that promotes operating problems in thermochemical conversion processes as combustion and gasification for useful energy production because of ash related problems (e.g., sintering/fouling), thus restricting their use in such applications.

As such, biochar production by pyrolysis is a potential alternative to generate added-value. During pyrolysis the volatile matter of biomass is released to the gaseous phase, resulting a solid product, biochar, which is carbon-rich and contains most of the inorganics (nutrients) of the raw biomass. Exposure of biomass inorganics as free ashes is prevented in this process, and hence pyrolysis mitigates their negative effects. Nonetheless, the efficient pyrolysis of these types of biomass requires development of novel solutions optimized for energy and environmental performance. Enhancing of the energetic sustainability of the process and minimizing of the environmental impacts associated to the emission of gaseous pollutants are aspects of major relevance. Additionally, the biochar quality depends on biomass type, technology and operating conditions used.

The BioValChar project (https://biovalchar.web.ua.pt/en/) seeks to answer these challenges related to valorisation of low-quality residual biomass through production of biochar by pyrolysis, which can return back to forest and rural soils. This approach will provide both carbon/nutrient cycling and synergies within forestry management, wildfire prevention, improvement of soil quality and rural development, under the circular economy principle. The research focus valorisation of residual forest biomass in full-control pyrolytic batch and continuous (auger-type reactor) processes, and testing of the resulting biochar performance as soil amendment. Moreover, a prototype of an integrated mobile unit for auto-thermal and continuous biochar production by pyrolysis of biomass is also being developed, by using the pyrolysis gases to provide the energetic needs of the process. Here we present the project overview, as well as some preliminary results on pyrolytic valorisation of one selected biomass (acacia) into biochar through distinct operating modes and conditions.

1. Context

Portugal territory has a significant fraction of forest supporting economic activity. However, as a result of improper forestry management, forest and rural areas have been subjected to strong pressure from wildfires, with negative impacts on natural resources (ecosystem degradation) and human life (socio-economic threats). The Portuguese Government launched a commitment program to develop Scientific and Technological

Research (S&TR) related to forest management and valorisation and prevention of forest fires (Conselho de Ministros, 2017), in line with the National Strategy for Forest (Conselho de Ministros, 2015). The goal is to generate applied knowledge to integrate perspectives of management and valorisation of forest resources, and underlying prevention to forest fires. Valorisation of residual biomass in rural areas is of the most relevant topics requiring applied S&TR.

Previous studies have identified distinct types of residual biomass from forestry operations with potential to be valorised to energy (Lopes *et al.*, 2013). In turn, forest cleaning for wildfires prevention also results in significant amounts of residual biomass without quality enough to be valorised into energy. This includes shrubs (acacia, gorse, broom, giant reed), which inorganic contents (e.g. K, Cl, Na) and resulting ash pose operating problems during combustion or gasification (van Loo and Koppejan, 2008; Niu *et al.*, 2016). These shrubs are highly flammable and have been identified recently as drivers for wildfire propagation in Portugal, as the Independent Technical Commission that investigated the wildfires that occurred in 2017 recommend their proper management towards wildfire prevention (Comissão Técnica Independente, 2017).

Since some of this residual biomass has considerable carbon content and heating value (van Loo and Koppejan, 2008), alternative valorisation must be developed. Biochar production by pyrolysis is an option. The pyrolysis process allows generation of distinct products, namely gases, liquids (bio-oils) and solids (biochar), with relative yields and composition depending on biomass type, pyrolysis reactor and operating conditions (Neves *et al.*, 2011). During pyrolysis the volatile matter of the biomass is released to the gas phase, thus remaining a solid fraction (biochar) where most of the inorganic content (ash constituents) of the raw biomass is embedded onto a carbon-rich matrix (Neves *et al.*, 2011; Neves *et al.*, 2017; Tarelho *et al.*, 2020), thus minimizing ash related problems that otherwise would be experienced during combustion or gasification.

The appropriate process for biochar production is slow pyrolysis (or carbonization), and several technologies have been referred as applicable, yet most of them derive from those applied to charcoal production from woody biomass (Neves *et al.*, 2011; Tarelho *et al.*, 2020) to be used as fuel. These technologies are mostly of type batch operated, large size, with low energy efficiency and high environmental impact. Considering the characteristics of residual biomass, more appropriate reactor configurations need development (Qureshi *et al.*, 2018) by addressing fuel flexibility, continuous operation, energy efficiency, portability/mobility, and this is a major challenge since existing information on technologies for biochar production relies on conventional configurations. New standards of product quality and energy efficiency can only be achieved with high level of process integration, e.g. by using the pyrolysis gas as fuel to satisfy the process energy needs (Salgado *et al.*, 2020; European Biochar Certificate, 2022). As such, these subjects require further applied research and technological development (R&TD), as most of the knowledge on biochar production concerns laboratorial small-scale.

Biochar produced from this low-grade residual biomass has no interest as fuel (charcoal) in typical energy applications due to its inorganics content and particle size, so alternative applications to boost its added-value have been suggested (Qureshi *et al.*, 2018; Salgado *et al.*, 2020; European Biochar Certificate, 2022; Lehmann and Joseph, 2015) yet lacking of technical evaluation and scale-up. The pyrolysis variables (e.g. feedstock, reactor type, heating rate, peak temperature, residence time) should be defined in order to obtain biochar with suitable characteristics (e.g. surface area, porosity and chemical composition) for specific applications and with economic profits, and that depends on biomass and pyrolysis conditions (Tarelho *et al.*, 2020; Salgado *et al.*, 2020; Lehmann and Joseph, 2015). As a way of improve physico-chemical and biological properties of soils, it has been shown that biochar significantly increases soil water holding capacity (Qian *et al.*, 2015; Verheijen *et al*., 2019), while increased infiltration in Mediterranean soil can increase available soil moisture during dry periods (Abrol *et al.*, 2016). Biochar in soil contributes to carbon sequestration and nutrient recycling (European Biochar Certificate, 2022; Lehmann and Joseph, 2015). Biochar contains (in)organic forms of N and P that can improve the nutrient use efficiency in plant-soil systems. This feature can provide N/P recycling and enhanced crop nutrition and yield, thus decreasing the application of inorganic fertilisers (Gul and Whalen, 2013) with associated environmental and economic gains. However, besides soil type, the agronomic value of biochar also relies on its redox chemistry that rules nutrient dynamics (Gul and Whalen, 2013; Palansooriya *et al.*, 2019), which in turn strongly depends on feedstock and process conditions. Therefore, trade-offs between pyrolysis conditions, biochar characteristics and impact on soil nutrient pools of specific agro-ecosystems require deeper research to boost the agronomic value of biochar.

Applied knowledge on biochar production from pyrolysis of residual biomass in a decentralised (in-situ) and energy sustainable process, and its valorisation in soil, is a key subject requiring innovative R&TD to support proper management and valorisation of residual biomass in rural areas. Demonstration of this integrated approach will both assist wildfires prevention and enable business models based on circular economy.

2. Project objectives and overview

The BioValChar project is public-funded and aims at valorisation of low-grade residual forest biomass (RFB) resulting from forestry maintenance operations for wildfire prevention. The valorisation process involves biochar production by pyrolysis, followed by biochar use as soil amendment and demonstration of the economic gains of the process towards development of sustainable business models. The methodology gathers scientific competences related to thermochemical conversion processes of biomass to energy vectors and organic products, waste management, biochar application, restoration of soil functions and energy/engineering economics, as well as collaborating companies. Furthermore, project demonstration targets two contrasting edaphoclimatic study areas in Portugal (north-central coast and central inland) in which wildfires often occur and where one of the partner companies has on-going forestry cleaning activities. This way the project outputs and impacts become validated to possibly apply to other countries experiencing wildfire issues.

The BioValChar research is being developed over four integrated axes:

1) Development and characterisation of the pyrolysis process at bench-scale under batch (fixed-bed reactors) and continuous (auger-type reactor) modes of operation. It will allow evaluate the influence of processes conditions (e.g. peak temperature, heating rate and soak time) in the yields and properties of each of the products (biochar, bio-oil and gas). Both fixed-bed and auger-type reactors were designed and developed at the University of Aveiro.
2) Design and construction of a prototype of a mobile integrated pyrolysis unit with a biomass processing capacity up to 10 kg h^{-1}, including a continuous pyrolysis reactor integrated with a combustion reactor to deliver heat for the pyrolysis process. It will be optimised for considering energy efficiency and environment performance. This will advance significant innovation and scientific knowledge on energy efficiency and mitigation of emission of air pollutants during biochar production in integrated pyrolysis-combustion systems, in order to suppress the existing knowledge gaps in this field.
3) Valorisation of the biochar produced by studying its performance as soil amendment at bench- and field-scale. This will allow obtaining dose-response curves in several variables (e.g. pH, CEC, organic matter/carbon/nutrient contents, geochemical reactive content, respiration, biomass productivity, among others), aiming at determining and demonstrating the biochar agronomic value. Ultimately it will help to close the loop between biomass pyrolysis and return of carbon and nutrients to soil.
4) Techno-economic analysis of the several operations (e.g., biomass collection and processing, pyrolysis unit construction and operation, biochar application costs, and greenhouse gas offset) involved in the solution proposed towards establishment of feasible business models applied to the forestry sector. It will also comprise field-scale demonstration activities to stakeholders to upscale and transfer of the key-results.

3. Preliminary results

Since most of the work packages are currently still on-going, we present here an example of results obtained during the work progress in Axis 1 (bench-scale pyrolysis) applied to one of the selected biomass species (acacia). Biomass was collected from a coastal pine forest in north-central Portugal, as a result from forest cleaning operations for wildfires prevention. It was further chopped till a maximum particle size of c.a. 1 cm, and characterised for proximate and elemental analysis.

Pyrolysis experiments took place in both batch and continuous modes with full control and monitoring of the operating variables. For the batch experiments, a fixed-bed tubular quartz reactor with 20 mm internal diameter, 23 mm outer diameter and 350 mm length, and a tubular furnace with 25 mm internal diameter and 300 mm length was used. The tubular furnace is operated by means of a control and data acquisition electronic system that allows the definition of heating rate and peak temperature of the tubular quartz reactor. For the continuous experiments, an auger reactor was used. The experimental facility is composed of a biomass silo, a screw-type

reactor made in stainless steel with 0.05 m internal diameter and an overall length of 2 m (including biomass feeding section, pyrolysis section and biochar discharge). The reactor comprises three sections, namely biomass feeding section, pyrolysis section, and biochar and gas discharge section. The biochar is discharged by means of a continuous screw feeder, and the pyrolysis gas produced is burned in a downstream combustion reactor.

Two peak temperatures were tested (450 and 550 ºC). In the batch process, soaking time and heating rate were set it 30 min and 20 ºC min^{-1}, respectively. In the continuous process, residence time (in the pyrolysis section) was set in 5 min. Biochar yields and proximate analysis are presented in Figure 1.

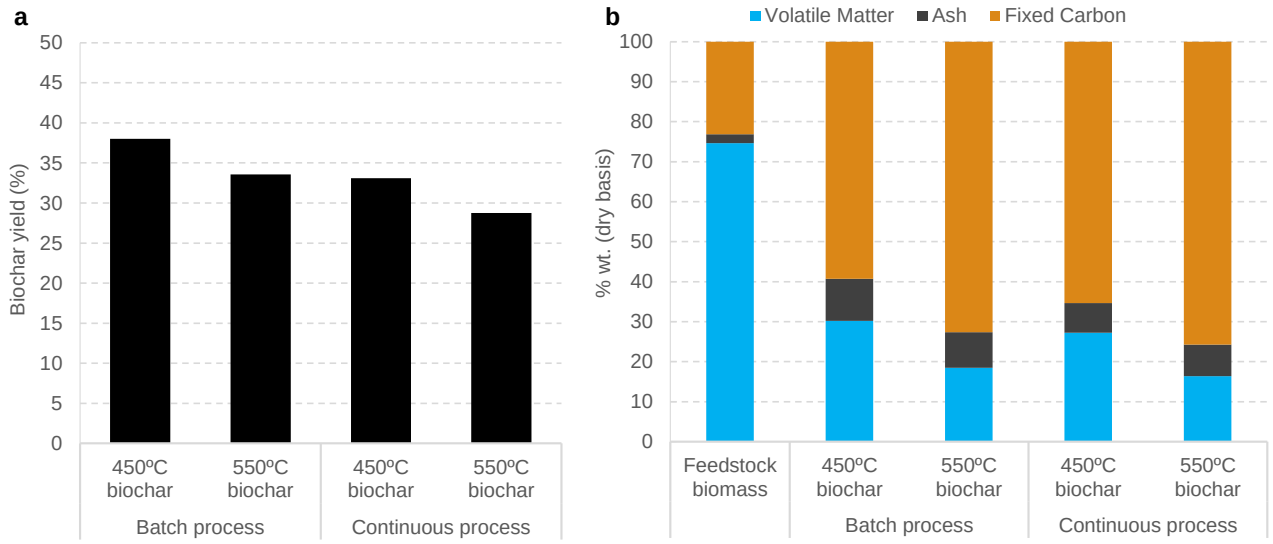

Figure 1- Biochar yield and properties, from batch and continuous pyrolysis of acacia: (a) biochar yield; (b) biochar proximate analysis

Biochar yields over the tested conditions and processes varied in the range 29 to 38%wt (Figure 1a). The biochar yield was influenced by both temperature and process mode. Peak temperatures of 450 ºC yielded 13 to 15% more biochar than 550 ºC peak temperatures, regardless of the process type. In turn, when reproducing pyrolysis batch processes in the auger reactor, a 13 to 14% drop in biochar yield was observed, regardless of the process temperature tested. The reasoning for this effect is under study, and its understanding is of upmost relevance to consider when designing scale-up of pyrolysis processes.

Regarding biochar proximate analysis (Figure 1b), similar trends are observed regardless of the pyrolysis operation mode. In both cases, the fraction of fixed carbon is substantially higher in the highest process temperature (73 to 76%wt) when compared to the lowest process temperature (59 to 65%wt), with the opposite trend observed in the volatile matter content. When comparing the process mode, continuous pyrolysis resulted in biochar with 4 to 10% higher fixed carbon content and 10 to 12% lower volatile matter than in the batch processes.

The ash content is systematically greater in the biochar resulting from the batch processes (9 to 11%wt) when compared to that produced through continuous processes (7 to 8%wt). When comparing process temperature, the increasing of 450 to 550 ºC resulted in a 15% decrease in the biochar ash content produced through batch pyrolysis. In turn, the same temperature shift in the continuous process resulted in a slight increase (5%) of the biochar ash content.

These preliminary results highlight the influence of the pyrolysis conditions and parameters in the key characteristics of the resulting biochar, and hence its further behaviour and feasibility as an added-value product in selected applications. Therefore, ensuring of a full control of the pyrolysis process, not only at prototype-scale, but especially considering upscaling scenarios, is of major importance to effectively provide a strategy to manage and valorise residual forest biomass, and thus enabling both wildfires prevention and profitable business models in the forestry sector. Moreover, the scope and outcomes of the BioValChar project are expected to provide a comprehensive basis towards replication of the models for management of residual forest biomass.

Its valorisation into biochar that can be applied to increase soil quality is of most relevance in ecosystems affected by recurrent wildfires and soil quality issues, such as the Mediterranean region.

4. Acknowledgements

BioValChar project "Sustainable valorization of residual biomass for biochar" (PCIF-GVB-0034-2019) is funded within the scope of the Scientific Research and Technological Development Project Call on Prevention and Fighting of Forest Fires - 2019, of the Fundação para a Ciência e a Tecnologia (FCT), being financed exclusively by national funds. Abstract

Quaking aspen (*Populus tremuloides* Michx.) is a keystone species in the western US, and readily regenerates following high-severity disturbance (historically stand-replacing fire). Aspen forests are thought to be in decline as a result of fire suppression, herbivory, and drought, such that restoration has become a priority. Typically, restoration involves prescribed fire or harvest to regenerate aspen, but these methods are not applicable everywhere, due to heavy coarse fuel loads that make prescribed fire risky and harvesting challenging. The need for alternative, stand-replacing treatment methods that regenerate aspen has led to the development of a mechanical method, termed 'roller-felling'. Like fire or harvest, roller-felling can reset succession and rearrange fuel loading in late-seral stage, conifer-dominated aspen communities. We examined the ecological impact of roller-felling by investigating factors that contributed to post-treatment aspen regeneration, in a replicated experimental design containing variable levels of post-treatment cleanup (i.e., residual slash amount). Prior to treatment, we collected stand structural and compositional characteristics from 5 plots per unit to allow for post-treatment comparison. One year after treatment, we quantified aspen regeneration stem densities. We also assessed possible factors that could have influenced aspen regeneration, including herbivore browsing pressure, topography, and pre-treatment composition. Additionally, we determined the impact this treatment had on vegetative ground covering. Post-treatment aspen stem density varied from 0 to 237,000 stems/ha across 30 plots among all treatment areas. There were significant differences in post-treatment stocking among cleanup levels, with full cleanup densities averaging ~100,000 stems/ha, while partial cleanup densities averaged ~23,000 stems/ha. Cleanup level and topography (i.e., slope) best predicted aspen densities post-treatment, and pre-treatment aspen composition had less effect on regeneration than predicted. Approximately 44% of aspen regeneration stems were browsed by herbivores one year after treatment. While the long-term effects of this method have yet to be quantified, the one-year results in this study lay the groundwork for longer-term monitoring of roller-felling treatment outcomes and their application to forest and fire management regionally, where goals are to reduce fire risk and maintain aspen communities across the western US.

1. Introduction

Quaking aspen (*Populus tremuloides* Michx.) is North America's most widespread broadleaf tree species, valued for providing many ecosystem services, such as increased biodiversity, making management of these communities a priority across the western US. (Little, 1971; Kuhn et al., 2011; Long and Mock, 2012). As an early successional species, aspen require disturbance to persist, establishing in high densities post-disturbance. Aboveground stem removal stimulates aspen's primary reproduction strategy of suckering, or establishment of a genetically identical ramet (i.e., sucker) from a root, which is initiated by interruption of auxin transport from leaves to roots (Frey et al., 2011; Wan et al., 2006). Within seral aspen forest types, conifers establish under mature aspen and dominate the canopy in later succession. When they burn, late-seral aspen communities are susceptible to high-severity fires due to high fuel loading (Shinneman et al., 2013). Stand-replacing fires historically reduced fuel loading and promoted aspen regeneration, but have become increasingly rare due to fire suppression efforts (DeByle and Winokur, 1985). Currently, prescribed fire and harvesting are the most feasible stand-replacing treatments in practice but can be difficult to implement with weather or infrastructure limitations. The need for alternative treatments that regenerate aspen and reduce fire risk by resetting succession has led to the development of roller-felling. This treatment method involves pulling a large barrel attached via cable between two bulldozers (Fig. 1) to restart succession within aging aspen communities. Recently, roller-

felling has been implemented in late- stage, mixed aspen-conifer stands, however, treatment efficacy (i.e., aspen regeneration) and associated impacts have yet to be quantified.

Prolific aspen regeneration via suckering is expected after treatment, as aspen preferentially establish in disturbed areas with high light (DeByle and Winokur, 1985). However, various factors influence aspen regeneration densities, such as aspen composition pre-disturbance, amount of residual coarse woody debris (CWD) post-disturbance, topography, and herbivore pressure. Because regeneration is primarily via suckering, larger proportions of pre-disturbance aspen correlate with greater regeneration, and were predicted in this study (Graham et al., 1963; Frey et al., 2011). Conversely, higher pre-treatment conifer proportions were expected to decrease aspen regeneration (Smith et al., 2011; Margolis and Farris, 2014). Pre-treatment understory advance regeneration (<10 cm diameter) was predicted to increase regeneration (Britton et al., 2016). Greater amounts of CWD can increase shading and decrease surface area, which has been correlated to lower regeneration (Doucet, 1989; Sheppard 1996, 2001). Lower aspen densities were expected with increased CWD, or slash retention. Additionally, the role of CWD as refugia from herbivory is well-documented (Grisez, 1960; Rumble et al., 1996; Ripple and Larsen, 2001), and a lower percentage of aspen stems browsed, primarily by elk (*Cervus elaphus* L.), were expected with increased slash retention. The objective of this study was to determine the regeneration response of aspen to roller-felling and then assess the impact of (1) pre-treatment stand conditions, (2) the amount of slash retention, (3) topography, and (4) herbivory on aspen stem densities. Better understanding of the efficacy and impacts of this treatment will set the baseline for long-term monitoring of treated sites, with possible application to regional forest and fire management.

2. Methodology

2.1. Study area

Treatment areas were on private property in Utah, USA, and were split into 3 experimental units with similar edaphic, climactic, and elevational characteristics. Prior to roller-felling, stands were characterized as mixed-conifer, primarily subalpine fir (*Abies lasiocarpa*). Pre-treatment basal area varied minimally by unit, averaging 30 m^2/ha, while aspen comprised 29% to 63% basal area. Units differed moderately in potential productivity (aspen site indices 44 to 52) and were characterized by very high woody surface fuel loadings (26.9-46.3 Mg/ha across all size classes).

2.2. Study design

We applied a replicated, variable treatment design at 3 experimental units, totaling 18 treated hectares. Each 6-hectare unit contained 3 adjacent blocks (i.e., cleanup levels) approximately 2 hectares in area, containing a gradient of residual slash densities, and an untreated control (Fig. 2). These cleanup levels were: 1) all slash pushed into burn pile (full), 2) moderate residual densities of slash, with most slash pushed into pile (partial), and 3) no slash pushed into piles (none). Woody surface fuel loadings (i.e., residual slash) outside of piles in full cleanup averaged ~ 8 Mg/ha, 37 Mg/ha in partial cleanup, and 174 Mg/ha in no cleanup areas.

Prior to treatment, 60 variable radius plots were sampled using a 4m basal area prism to quantify stand structure and composition. At each plot, we measured diameter at breast height (DBH) and species of every overstory tree (>10 cm DBH) and the height of every other tree; the tallest tree was cored for site index determination. Fixed-area, 1/1000th (1.78 m radius) hectare plots were measured to determine understory (<10 cm DBH) advance regeneration. Woody fuel loads were quantified by diameter classes on two transects using protocols outlined in Brown (1974), and 1 m^2 quadrats were surveyed along these transects to quantify ground covering by functional group (delineated by biotic: forb, shrub, grass, tree, and abiotic: CWD, bare soil, etc.). After treatment, five, 1/1000th hectare regeneration plots were sampled within full cleanup, partial cleanup, and untreated control areas, totaling 45 plots (direct sampling in no cleanup areas was omitted as high slash restricted access; Fig. 2). We identified seedlings and suckers to species, delineated stems by height class, and noted apical meristem as browsed or unbrowsed. Measurements were taken along two transects to determine ground covering and residual slash/fuel loading. Twenty-seven ungulate exclosures (1.2m^2 x 1.22m height) were constructed, with 3 in each cleanup level and control area (again, omitting no cleanup), and sampled identically to regeneration plots (Fig. 3).

2.3. Analytical Approach

Linear regression was used to explore relationships between predictor variables (percentage and absolute aspen basal area, advance regeneration, conifer composition, topography, residual slash) and post-treatment aspen regeneration densities. Percentages of browsed stems were also compared across cleanup levels and units with linear regression and analysis of variance. Analysis of variance was used to compare differences between units. T- and F- tests were used to determined differences in densities between cleanup levels and ground covering percentages before and after treatment.

3. Results

Aspen regenerated in high densities after roller-felling. Stem densities were significantly higher and more variable (P-values <0.0001) in full cleanup compared partial cleanup areas, where densities averaged ~102,000 stems/ha and ~23,000 stems/ha, respectively (Fig. 4). Pre-treatment composition was not highly predictive of post-treatment density (P-value = 0.18) and higher proportions of both advance regeneration and overstory aspen pre-treatment did not predict of greater post-treatment densities when analyzed independently ($r^2 \leq 0.15$). Collectively, cleanup level, slope, and pre-treatment composition were highly predictive of aspen regeneration densities ($r^2 = 0.71$). When cleanup areas were analyzed independently, pre-treatment variables became more predictive in full cleanup areas. Additionally, in full cleanup areas, steeper slopes were associated with lower stem densities, however, densities remained constant across the same slope gradient in partial cleanup areas.

After roller-felling, the percentage of ground occupied by bare soil changed significantly (P-value < 0.0001) from a pre-treatment average of 2% to ~30%. Proportions of bare soil and CWD varied significantly between the two cleanup levels (all P-values <0.0001). Partial cleanup contained less bare soil (14%) and greater CWD (38%) than full cleanup, in which bare soil occupied 42% of ground covering and CWD only 9%. Full cleanup areas generally had slightly greater biotic ground covering. Partial cleanup areas had significantly greater residual slash than full cleanup areas, with all CWD diameter classes of greater densities (P-value <0.0001); however, this did not deter herbivory, as percentages of observed browse on aspen stems remained similar between full and partial cleanup areas (42% and 46%, respectively). Browse percentages were relatively uniform across units and cleanup levels with no significant differences observed. Aspen stems within exclosures were significantly greater in height, but not density, in contrast to unfenced, browsed stems (Fig. 3).

4. Discussion and Conclusion

4.1. Discussion

Many outcomes of roller-felling were consistent with our predicted hypotheses. Generally, the response of aspen to treatment was suckering in high densities, as expected, but thresholds indicating 'successful' regeneration vary in the literature (e.g., Kitchen et al., 2019). A regional, applicable regeneration threshold of 2500 stems/ha was met one year after treatment, with 93% of plots meeting this objective (Kitchen et al., 2019). Furthermore, a predictable, negative relationship between residual slash and regeneration was observed: increased CWD post-treatment resulted in decreased aspen density. Greater proportions of CWD and lower proportions of bare soil within partial cleanup areas resulted in less area for unobstructed sucker establishment, increased shade, and consequentially lower stem densities. Increased slash did not deter ungulate browse; this could be due to low (<1m) pile heights observed after roller-felling, as debris piles reducing browse are typically >1m (Ripple and Larsen, 2001; Nichols, 2005).

Ungulate herbivory of young aspen can alter regeneration dynamics, and high amounts of browse can stunt growth and promote unhealthy growth structure (i.e., bush-like); insufficient aspen recruitment is a common result of repeated browse (Baker, 1918, 1925; Bartos and Campbell, 1998). Taller aspen stems within exclosures confirm a negative impact of browse on regeneration. A sustainable, 30% maximum threshold of repeated browse allows for long-term, healthy stand structure and development (Olmsted, 1979). In the first growing season, roughly 45% of all aspen stems were browsed. By this metric, browse levels immediately violated sustainable thresholds. However, this was not strong enough to denote *absolute* levels of unsuccessful regeneration (i.e., 10,000 stems/ha at 45% browse still provides 5,500 stems/ha). Nevertheless, if browsing pressure remains constant (or even moderately declining) and compounded across future growing seasons,

regeneration will be insufficient, failing to reach 2500 stems/ha. High levels of observed browse in this short-term study are concerning from the standpoint of long-term stand health and development.

Some well-established, pre-treatment factors we hypothesized as predictors of aspen regeneration were not strongly correlative in this study. Prior to treatment, units varied significantly in both aspen percent of total basal area and absolute aspen basal area, ranging from 4 m^2/ha to 20 m^2/ha. Many metrics quantifying pre-disturbance aspen composition have been linked to greater regeneration, such as increased "vigor", greater height and DBH of overstory aspen (Worrall et al., 2008, 2010; King and Landhäusser, 2018; Jean et al., 2019), and advance regeneration (Britton et al., 2016). However, these pre-treatment variables were weakly correlated to greater one-year, post-treatment regeneration densities unless other variables were added.

While many biotic, pre-treatment variables were not predictive, cleanup level (i.e., amount of residual slash) and slope were more strongly correlated to increased aspen densities. We presume that residual slash mitigated the negative effect of slope in full cleanup areas because increased slash provided soil stability and decreased erosion potential. This finding has notable implication on management: if roller-felling is to be considered, leaving residual CWD on steeper slopes may increase regeneration and promote soil stability. Overall, lack of overt correlation between pre-treatment aspen and regeneration also has interesting management implications (i.e., pre-treatment aspen composition alone has little effect on regeneration, allowing for application in later-stage stands with little aspen).

4.2. Conclusion

The short-term, regeneration response of aspen to roller-felling generally mimics conditions of a stand-replacing disturbance by restarting succession and reducing fuel loading. Topography and residual slash strongly influenced regeneration densities, highlighting the importance of context within management application. Importantly, this study assessed the impact of roller-felling one-year following treatment, but long-term impacts warrant further study. The groundwork set by this study will further the understanding of aspen regeneration dynamics, which will apply to forest and fire management regionally, where goals are to reduce fire risk and maintain aspen communities.

Fig. 1. Roller-felling barrel situated centrally between two cables and dragged between a pair of bulldozers. The cable fells trees, while the large barrel drum keeps the cable roughly >1m above the ground surface, providing necessary leverage to pull over trees. Once felled, variable amounts of slash can be retained, while remaining debris is pushed into a pile and burned at a later time. Inset photo for scale.

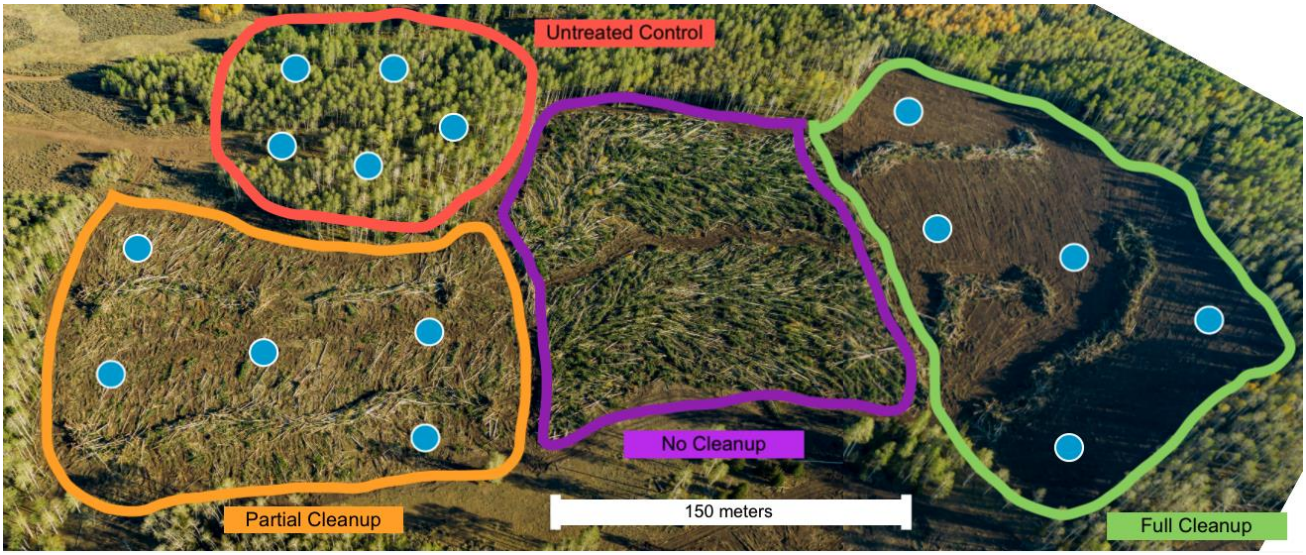

Fig. 2. Study design of variable treatment cleanup levels within experimental unit. Left to right: partial cleanup (orange), no cleanup (purple), and full cleanup (green). An adjacent, untreated control area above the treatment areas and shown in red. Sampling plots, shown in blue, are independent, spaced at a minimum of 45 meters apart, and do not intersect with slash piles. No plots were established in the no cleanup treatment, as slash levels restricted sampling.

Fig. 3. Contrasting aspen regeneration within fenced exclosure and browsed stems outside of exclosure in partial cleanup treatment area (photo taken one year after treatment). Inset: completed exclosure in partial treatment area, constructed prior to aspen regeneration emergence.

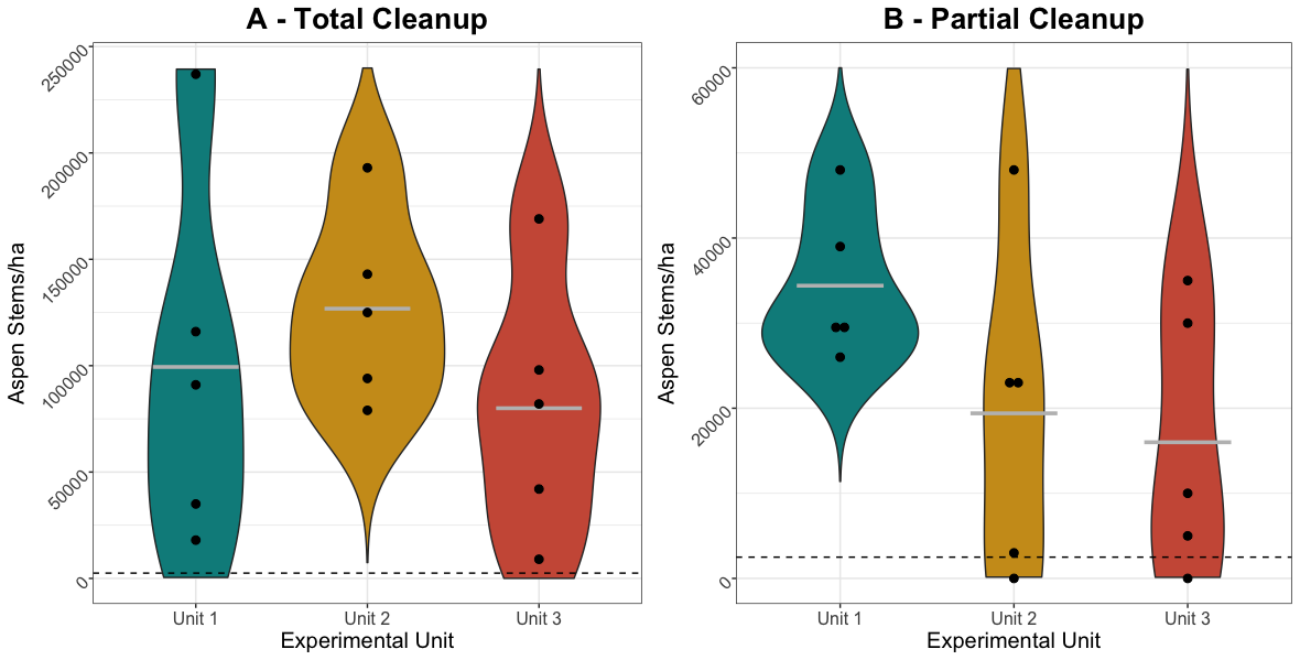

Fig. 4. Post-treatment aspen regeneration stems per hectare, delineated by (A) total and (B) partial cleanup treatment areas. Note different scales for stems per hectare on y-axis. The three experimental unit areas are indicated by different colors. The dashed line (near x-axis) indicates the 2500 stems/ha objective. Black points indicate stem densities at 5 plots within each treatment area. Gray bars denote stem density averages of each respective unit. Total cleanup (A) vastly exceeds this objective, while partial cleanup (B) stem densities largely meet this objective. Two individual sampling points within partial cleanup areas fell below the 2500 stems/ha objective, indicating insufficient regeneration.

Risk communication, mental model, rural fires, burning

Abstract

Fire is a traditional method used for the elimination of residual materials from agricultural and forestry activities, but its improper and negligent use increases the risk to cause significant social, economic, and environmental impacts. Translating the nature and magnitude of the risk, a mental model approach has been used for a deeper understanding of what can be done to reduce future socioeconomic and environmental impacts. Considering the rural fire risk context, in this study we applied the mental model approach to (1) systematize the aggregated knowledge of experts on rural fire risks, focusing on the burning problem, and (2) explore the different perspectives of experts on the subject. Experts are actors with in-depth involvement and experience in fire and forest management in Portugal, including actors from industry, academics, third sector, and public entities. Semi-structured interviews that included real-time interactions with the proposed mental model on the MURAL platform were remotely conducted with twenty-eight experts. The contributions were periodically validated by the research team and included in the reference mental model to translate the aggregated knowledge of the expert community. The data collected was transcribed, coded, and analyzed following a thematic analysis approach with NVivo software support. After nine iterations, the expert's mental model was concluded encompassing the burning motivators, alternative solutions, associated risks before and during the burning, underlying causes, natural elements and factors, and impacts.

Overall, the study provides an in-depth and holistic understanding of rural fire risks, focusing on burning, which is essential for identifying incorrect beliefs and existing risk factors that are often neglected. The participatory and dynamic process of actors' knowledge systematization on burning risks through a mental model allowed the identification of divergent perspectives between expert groups, especially concerning the effectiveness of the current legislation on the use of fire, indicating the need to improve the dialogue between experts. Moreover, the study shows how risk communication campaigns do not replace technical monitoring closer to the population, given that the diversity of people inhabiting fire-prone areas in peri-urban landscapes (that holds widely varying experiences, beliefs, attitudes, and values relating to fire) can influence people's understanding and interpretation of risk messages. Thus, it is recognized the importance and need of sensitization and communication actions to disseminate adequate and safer burning practices and available alternatives. Still, it indicates that alternative solutions of burning (such as on-site pellet processing, local micro-plants for heat production, community initiatives of composting, as well as crushing and distribution of crushed material to be incorporated into the soil) may be achieved with strong local and sectoral involvement. Finally, this research provides a baseline to help decision-makers and stakeholders identify the relevant associated risks before and during the burning practice, which can support the design of effective risk communications strategies and mitigate social and environmental impacts in the future.

1. Introduction

Ignitions from human activity are responsible for 98% of all fire incidents in Portugal (SGIF, 2020). The improper use of fire corresponds to more than half of the 41% of fires attributed to negligent causes in 2020, according to presented data by the Institute for the Conservation of Nature and the Forest (ICNF), which increase the risk to cause significant social, economic, and environmental impacts. However, fire is a traditional method used for the elimination of residual materials from agricultural and forestry activities, it is also commonly used as a cleaning method to eliminate of excess biomass in the control of invasive species, and its misuse causes the

positions it as the main cause among the rural fires that occurred in Portugal (Nunes et al. 2021; Meira Castro et al. 2020; Pereira et al. 2013)

Most fires start in the proximity of agricultural areas and at the interface of urban spaces (Pacheco et al. 2020). The proximity of forest and agricultural spaces to the urban context and the accumulation of variables linked to climate change, namely, the increase in average temperatures, the reduction of precipitation and relative humidity of the air, justify the recurrence of rural fires (Nunes et al. 2021). In addition, high temperature and drought, acting as important drivers for the burned area in Portugal (Turco et al. 2019), the risk of rural fires can be aggravated due to the accumulation of fuel load. Despite efforts to improve fire management, as Decree-Law 14/2019 that make burning prior communication and authorization mandatory, the risk of rural fires stems in part from the absence of effective management policies aimed at rural areas (Coelho et al., 2020). Furthermore, some studies point out that implementing risk-based long-term planning would improve fire management efforts (Turco et al., 2019). But governmental efforts to reduce wildfire risk are not enough on their own, and it is recommended that risk mitigation strategies be a joint effort between public agencies and private landowners (Doerr et al. 2013). A current poor translation of risk information materials into mitigation actions may be attributed to the diversity of people inhabiting fire-prone areas in peri-urban landscapes. The widely varying experiences, beliefs, attitudes, and values relate to fire can influence people's understanding and interpretation of risk messages and constrain their actions (Eriksen and Prior 2011).

Resorting to the literature on risk communication and wildfire (Steelman and McCaffrey 2013), we came across studies that address "mental models" approach. That approach has been used to translate the nature and magnitude of the risk, allowing for a deeper understanding of what can be done (Morgan et al. 2002) to mitigate social and environmental impacts in the future.

The mental model's concept was originally defined as "small-scale models" of reality that [the mind] uses to anticipate events, to reason, and to underlie explanation' (Craik, 1943), being essential to choose safe alternatives in critical situations, highlighting its relevance in risk communication. The application of mental models in studies of communication and risk perception aims to identify specific information needs (e.g., gaps in knowledge, misunderstandings, questions, concerns about terminologies and beliefs of the population) for decision by contrasting the mental models of specialists and lay people concerning a specific risk (Morgan et al., 2002). Therefore, it is a method that continues to receive attention in different contexts and fields of study, for example: to capture and compare the mental models of those conducting restoration activities to inform potential policy changes (Walpole et al. 2020), to investigate perceptions of risk and mitigation of employees (Stege et al., 2019), to compare perspectives of government agencies, academic experts, and suppliers on providing risk information (Aliperti et al., 2020).

According to Zaksek and Arvai (2004), risk management information and topics vary considerably between experts, actors from different stakeholder groups, and laypeople. In addition, groups may have different windows of knowledge about a particular risk, leading to an agreement between groups and management decisions that are not aligned with the most current scientific knowledge. The fundamental notions about risk, its characteristics, impacts, and forms of control are always necessary, so the level of understanding of the target group adjusts with the new information (Breakwell, 2001).

As such, in this study, we use a mental model approach to (1) systematize the aggregated knowledge of experts on rural fire risks, focusing on the burning problem, and (2) explore the different perspectives of experts on the subject. Based on scientific data about rural fire risks and the aggregated knowledge of the expert community, a mental model was built that encompasses the motivators, alternative solutions, associated risks, underlying causes, natural elements and factors, and impacts about burning. An in-depth and holistic understanding of rural fire risks, focusing on burning, is essential for maintaining cohesion between actors and building effective risk communications strategies to mitigate social and environmental impacts in the future.

2. Method

Based on the literature review, the methodological premises for the development of the study were established; the first one was the mental model's elaboration, commonly represented by an influence diagram. The research design involved the development of the data collection instrument (semi-structured interview scripts), the

systematization of data collection with different stakeholders (mental model development in a digital visual collaboration platform, called MURAL) on the risk of rural fires, focusing on the burning problem. Interviews were conducted virtually (by Zoom), and each interview took, on average, 1h30min. To gather a richer understanding of the expert's perspective, this study involved a comprehensive sample, that included experts from academia (7), industry (5), public entities (9), and third sector (7), accounting for 28 interviews, as shown in table 1.

Table 1 - Sample description

Experts	Number of participants (% sample)	Role
Industry	5 experts (18%)	Executive Director, Head of Department, Directors, and Manager
Academy	7 experts (25%)	Ph.D. and Associate Professors
Third sector	7 experts (25%)	Executive Director, Chairman of the Board, Engineers and Technical consultant
Public entity	9 experts (32%)	Cavalry Colonel, Commanders, Operations Deputy, Engineers, Landscape architect
	N = 28 experts	

Between the entities, we had representants from National Military Security Force, Volunteer Firefighters, National Emergency and Civil Protection Authority, National Guard, Agency for the Integrated Management of Rural Fires; National Institute for the Management and Conservation of Nature and Forests, forestry companies, electricity, and natural gas transport industries, multinationals that operate in telecommunications and other segments, associations, universities.

Following ethical standards, the interviewed participants consented to record the interviews for further analysis, accounting for approximately 39 hours of recorded data.

The experts' contributions were periodically validated by the research team and incremented in the reference mental model to translate the aggregated knowledge of the expert community. The data collected were transcribed, coded, and analyzed following a thematic analysis approach with NVivo software support.

3. Findings

Given the focus of the mental model on the practice of burning and in order to explore the risks, associated variables, and mitigation modes in-depth, we set three periods (before, during, and after) to delimit the burning process from start to finish. After nine interactions of contributions validation, the expert's mental model was concluded. In total, 170 changes were counted in the mental model (including node description changes; adding, relocation, and removing nodes; adding, relocation, and removing edges). Between changes made to the mental model, 50% were made by actors from public entities, 18% by actors from academia, 23% by actors from the third sector, and 9% by actors from the industry, as shown in table 2.

Table 2 - Changes made in the mental model by experts' group

The expert's mental model encompasses eight main blocks (Figure 1), such as motivators to burning, alternative solutions, associated risks before and during the burning practice, underlying causes and natural elements that can increase the burning risk, and potential impacts.

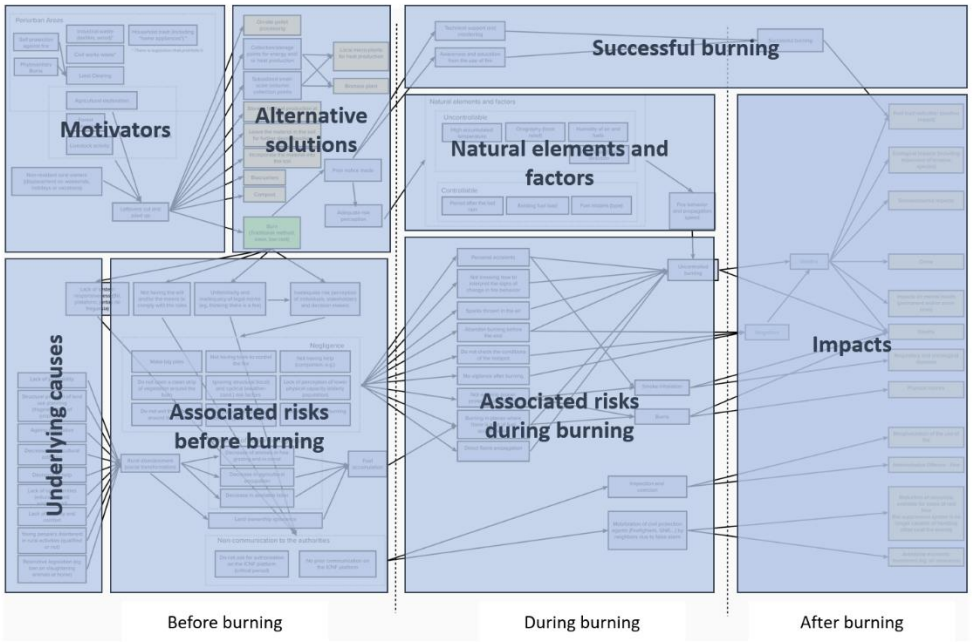

Figure 1- Expert mental model in main blocks

Before burning, the mental model shows burning motivators in peri-urban and rural areas, such as land clearing to self-protection against fire or phytosanitary burns, agricultural and forest exploration, etc.; in addition to considering the non-resident rural owners (displacement on weekends, holidays, or vacations).

Associated risks before burning block listed several risk factors and aspects that precede the practice of burning that often lead to neglect action, such as inadequate risk perception of individuals (e.g., not having a companion, ignoring structural (local) and cyclical (weather-cond.) risk factors, etc.), stakeholders, and decision-makers; unfamiliarity and inadequacy of legal norms (e.g., thinking there is a fee regarding the request for authorization to conduct a burning); lack of system responsiveness from Voluntary Fire Service, platform, Municipal Councils; or simply not having the will and/or the means to comply with the rules, leading to no prior burning communication to the authorities, thus not complying with the Portuguese Decree-Law 14/2019. Tied to this, underlying causes block describe rural abandonment causes represents indirect factors that contribute to increasing rural fire risks (e.g., lack of profitability, aging population, decrease in agricultural activities, structural problem of land use planning (fragmentation of properties), etc.), because of the absence of active management and fuel accumulation.

In contrast, alternative solutions include crushing, on-site pellet processing, leaving the material in the soil for further decomposition or incorporation to improve the structure and quality of the soil, collection/storage to use for biomass, composting, energy production, at small or large scale.

During the burning,natural elements and factors block include controllable (e.g., existing fuel load and fuel models) and uncontrollable (e.g., the humidity of air and fuels, orography, wind speed, and direction) elements that can potentially impact fire behavior and propagation speed. Associated risk block encompasses risk factors such as, not knowing how to interpret the signs of change in fire behavior, abandoning burning before the end, not wearing proper protective equipment, sparks thrown in the air, and other risk factors that can cause an uncontrolled burning or their reignition.

After burning, the mental model included twenty variables of impact, beyond the social, environmental, and economic impacts, we can mention for instance the fuel load reduction, which represents a positive impact and the reduction of resources available if there is a mobilization to false alarm of fires, which could be an avoidable investment. Lastly, successful burning block highlight actions to mitigate the risk, such as technical support and monitoring, awareness, and education from the use of fire.

4. Implications and conclusion

The findings indicate three preliminary theoretical and practical implications. First, there is a need to improve the dialogue between experts, which corroborates other research in which the mental model's approach was applied (Aliperti et al., 2020). This dialogue should focus on the perception of the administrations and decision-makers risk in the practice of burning and its relationship with the effectiveness of the current legislation on the use of fire, as some specialists have the perception of the imposition of punitive law, of repression, which leads to marginality and the illegal practice of burning. Still, many actors see the beneficial ecological role of fire, especially about reducing accumulated fuel and consequent mitigation of large fires, while other actors simply fail to identify any positive impact in this issue.

Second, alternative solutions of burning (such as on-site pellet processing, local micro-plants for heat production, community initiatives of composting, as well as crushing and distribution of crushed material to be incorporated into the soil) may be achieved with strong local and sectoral involvement. Experts agree that biomass plants are viable in some regions, where there is a market logic, the volume of material, and the plants are close for supply, making the market economically sustainable. However, this does not happen in regions where the land is fragmented, as there is no supply of material in the necessary volume, and in some cases the plants are far away, not compensating for the cost of transport, as it is a material of low value. Therefore, micro-biomass plants are identified as a relevant solution to reduce the risk of burning. Still, on this topic, specialists also state that the incentive to disseminate the use of biomass would potentially originate from public policies (e.g., percentage of energy sources must be renewable, and another percentage must contribute to the active management of fuels, in the latter case the use of biomass for home heating), what does not exempt the local and sectoral actors' involvement.

Finally, understanding that risk communication campaigns do not replace technical monitoring closer to the population. Experts believe closer technical monitoring is the main factor to contribute to rural fires risk mitigation, but given the limited operational capacity in relation to demand, they recognize the importance and need of sensitization and communication actions to disseminate adequate and safer burning practices and available alternatives.

Most effective communication practices are associated with flexible fire management and interactive communication (before and during the event), that strives to address local contextual concerns, explain actions, and provide honest, timely, accurate, and reliable information while leveraging local relationships (Steelman and McCaffrey 2013). As such, by understanding relevant actors' perception about traditional burnings, a mental model approach can support an effective risk communication strategy.

TGA/TDA, Py/GC-MS, Cupressus sempervirens L., Quercus suber L., wildfires, silviculture measure

Abstract

The frequencies of wildfires in the Mediterranean climate regions (MCRs) have amplified due to the increased temperatures and drought periods resulting from climate change. Vast areas of forests are consumed by wildfires and certain species are threatened by extinction due to their high flammability and weak thermotolerance to climate change whereas, other species with high thermotolerance are exploited as silviculture measures in forest management strategies. Canopy and litter foliage are the first ignitable structures in a forest fire. In this context, the foliar flammability characteristics of two fire resilient Mediterranean forest species are tested and compared on a laboratory scale; Quercus suber L. (Q.s.L.) and Cupressus sempervirens L (C.s.L). Thermo gravimetric/thermo differential analysis (TGA/TDA) and low- to high- temperature analytical pyrolysis tests and gas chromatography-mass spectrometry (GC-MS) were conducted on live and dry foliar samples of Lebanese C.s.L and Algerian Q.s.L. Branch and cork samples of Q.s.L were also pyrolyzed (Py/GC-MS) for their volatile content. The hemicellulose/cellulose degradation temperatures of C.s.L. were in the order of 30 to 50°C more than those of Q.s.L. Lignin degradation started later in the Q.s.L. and took place at temperatures higher than those of C.s.L. (≥30°C), while the heat release rates (HRR) were greater for the latter than the former in both degradation phases. The pyrolysis tests showed higher volatile content of C.s.L compared to Q.s.L. The high thermotolerance characteristic of C.s.L may be referred to its high terpene content which was negligible in Q.s.L given the fact that it is a non-monoterpene emitter oak species with no terpene storage compartments. The use of C.s.L as a fire barrier could be justified given their thermotolerance characteristic. Q.s.L. fire resilience is justified for their bark characteristics however; their foliage fire resilience should be further experimented.

1. Introduction

Climate change with increased temperatures and prolonged drought periods promote a positive trend in the frequency of wildfires in the Mediterranean climate. The Mediterranean vegetation is adapted to natural wildfires but is vulnerable to the abiotic stresses brought by the prolonged dry and hot summer seasons which is suspected to affect their BVOCs (biogenic volatile organic compounds) reserves. Therefore, an accurate determination of the flammability characteristics of the Mediterranean vegetation is needed in order to implement effective forest management strategies. Flammability descriptors define the vegetation ignitability, combustibility, consumability, and sustainability. However, the methods for evaluating these descriptors have not yet been standardized but are strongly linked to their BVOC reserves at the event of the wildfire. Cork oak or Quercus suber L. (Q.s.L.) and Cupressus sempervirens L. (C.s.L.) are abundant Mediterranean forest species with distinctive morphological characteristics. C.s.L. species which possess foliar monoterpene storage compartments (resin ducts) (Hamidpour et a. 2011) are recognized for their high thermotolerance characteristics and are being considered in silviculture measures as green barriers against wildfires (Della Rocca et al. 2015).

A cypress plantation in Spain (Valencia), was slightly affected by a wildfire that burnt all trees arounds whereas only 12.7% of the cypress trees were burned, 37.1% were dehydrated and 61.6% were not affected (Della Rocca et al. 2015). Although, this same species is dangerous as a house hedge because when it is regularly cut to form a clean hedge, dead fuel accumulates inside the trees. This dead fuel constitutes a powerful source of radiation once a fire reaches it. On the other hand, Q.s.L. found abundantly in countries of the Mediterranean basin and in Portugal, are considered non-monoterpene emitters because they are incapable of endogenous monoterpene production (Loreto 2002) and their photosynthesis is inhibited at temperatures >30°C (Delfine et al. 2000). Therefore, they possess the lowest thermotolerance levels amongst other Mediterranean forest species and are largely consumed in wildfires. The flammability and thermotolerance characteristics of the two species were investigated by undergoing thermogravimetric/differential thermal analysis (TGA/DTA) and low- to high-temperature pyrolysis testing (Py/GCMS) on foliar live and dry samples of the Lebanese Cupressus sempervirens L. and Algerian Quercus suber L. The TGA/DTA and Py/GC-MS tests were conducted in the IC2MP laboratories of the University of Poitiers, France.

2. Materials and Methods

2.1. TGA/DTA:

The device used is SDT Q600 (DSC-TGA) equipped with a horizontal dual-balance mechanism which provides a high level of accuracy in the measurements of weight and temperature differentials. 20 mg of live and dry foliar samples of the two species: Cupressus sempervirens L. and Quercus suber L. were tested in an air medium with a flow rate of 50 $mL.min^{-1}$ at a temperature range from 20 to 900°C with a ramp of 10°C/min. The same method was used to analyze branches and cork of Q.s.L., and compare seasonal (winter and summer) dry foliar samples of C.s.L.

2.2. PY/GC-MS

The pyrolyzer is a Frontier Lab EGA 2020 pyrolyzer equipped with an AS-1020E auto-shot sampler coupled with a GCMS (Shimadzu QP 2010 Ultra). GC separations were done using a SLB-5MS (Supelco) capillary column (30 m long, 0.25 mm i.d, 0.25 μm phase thickness). Low- to high- temperature pyrolysis experiments were done on seasonal live and dry foliar samples of Cupressus sempervirens L. and live and dry foliar samples in addition to branches and cork samples of Quercus suber L. The designated pyrolysis temperatures were correlated to the TGA/DTA results which defined the different degradation temperatures of the cellulose, hemicellulose and lignin of the vegetation species. Also we were interested to simulate the effects of the thermal stresses of the fire-front approaching the vegetation in an open forest fire. The program of the pyrolysis tests is shown in Table1.

Table1. Pyrolysis program and designated temperatures of the experiments

	Cupressus sempervirens L. (Foliar samples)	**Quercus suber L. (Foliar, wooden, cork)**
Single Shot	50 - 80 - 120 - 180	800
Double Shot	350 - 550	350 - 550
Triple Shot	120 - 350 - 550	

2.3. Materials

Dry foliar samples of C.s.L. were collected and transported by airplane from a Lebanese forest in the summer season in August with an average ambient temperature high at 28/30°C, and in the winter season in January with an average temperature low at 5/10°C and annual rainfall of 700 to 1000 mm. Live foliar samples were obtained from irrigated cut branches of the same tree in both seasons and brought to France to be experimented in 3 days period. The Q.s.L dry foliar samples branches and cork were collected randomly from a mature Quercus forest in M'sila, Algeria by our collaborated research team of the University of Oran, Algeria. The live foliar of Q.s.L. were taken from a 1year old Quercus tree planted in Algeria and transported to France and were cut at the day of experimenting. All specimens were stored in the lab freezer at temperatures (-21±1°C) prior and during the experiments. The experiments showed similar fuel moisture content between the dry and live samples of the two species.

3. Results

The TGA/DTA (Figures 1&2) provided the temperature evolution of the specimen degradation phases that are likely to occur in an open fire for each of the two species. First trough indicating the endothermic thermal dehydration (distillation/drying) followed by the first peak signaling the exothermic ignition of the semi volatiles resulting from the degradation of cellulose/hemicellulose. The second peak at the higher temperature ranges is due to the combustion of the partially charred biomass and the aromatics released from the degraded lignin. The temperature ranges for each of the processes allowed us to correlate them to their flammability descriptors: ignitability and combustibility.

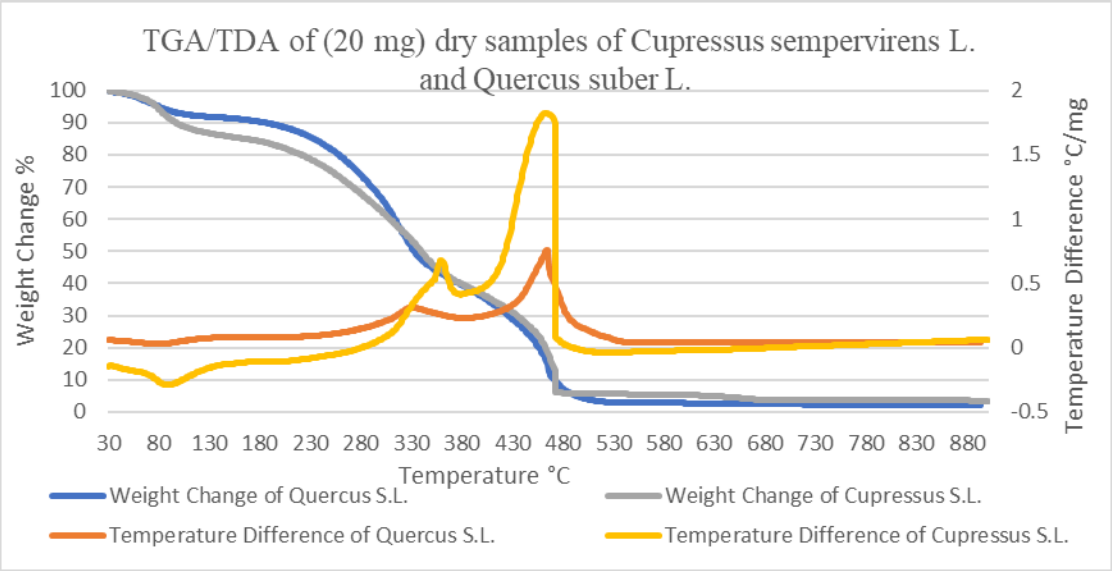

Figure 1- TGA/TDA of foliar dry samples of Cupressus sempervirens L. vs Quercus suber L.

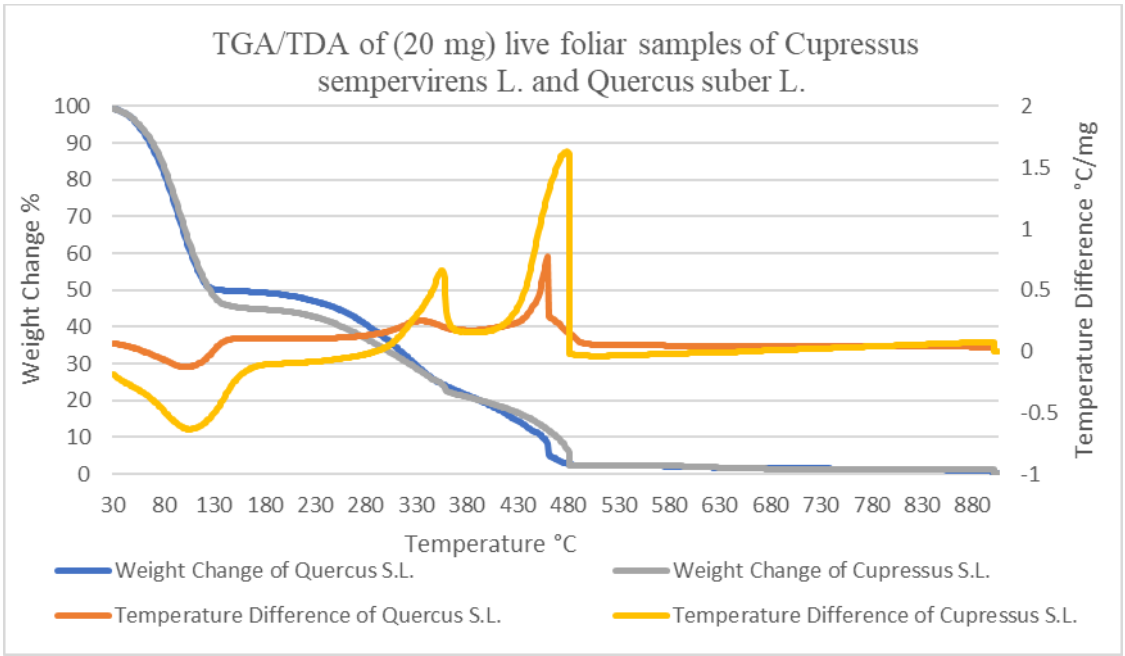

Figure 2- TGA/TDA of foliar live samples of Cupressus sempervirens L. vs Quercus suber L.

The time to ignition (TTI) (Dehane et al. 2017) or the ease to ignite (Fernandes et al. 2012) described vegetation ignitability. The combustibility is measured by HRR, and the consumability depends on the burnt mass residue. TGA/TDA of dry and live foliar C.s.L and Q.s.L. (Figure 1&2), showed cellulose degradation (first peaks) of C.s.L. at higher temperatures than those of Q.s.L and the inverse for lignin degradation (second peaks). The HRR in both degradation phases was higher C.s.L. compared to Q.s.L. Therefore, we can argue about the better combustibility of C.s.L. probably due to its larger volatile content. We were also able to compare the thermal

degradation profiles of seasonal (summer and winter) dry foliar of C.s.L. (Figure 3). The thermotolerance of summer foliar C.s.L. is clearly greater than that of winter C.s.L., and the (HRRs) of the former were higher than the latter probably due to higher volatile reserves; a characteristic of resinous conifers.

Table 2. Temperature profiles of each degradation phase from the TGA/TDA of live and dry foliar samples of C.s.L. and Q.s.L.

	Vegetation Species	Approximate Temperature range °C		
		Thermal Dehydration	Hemicellulose/Cellulose Degradation	Lignin Degradation
Dry Foliar	Cupressus sempervirens L.	80 - 130	330 - 380	400 - 480
	Quercus suber L.	75 - 80	280 - 330	430 - 500
Live Foliar	Cupressus sempervirens L.	80 - 180	330 - 380	400 - 480
	Quercus suber L.	75 - 130	300 - 330	430 -50

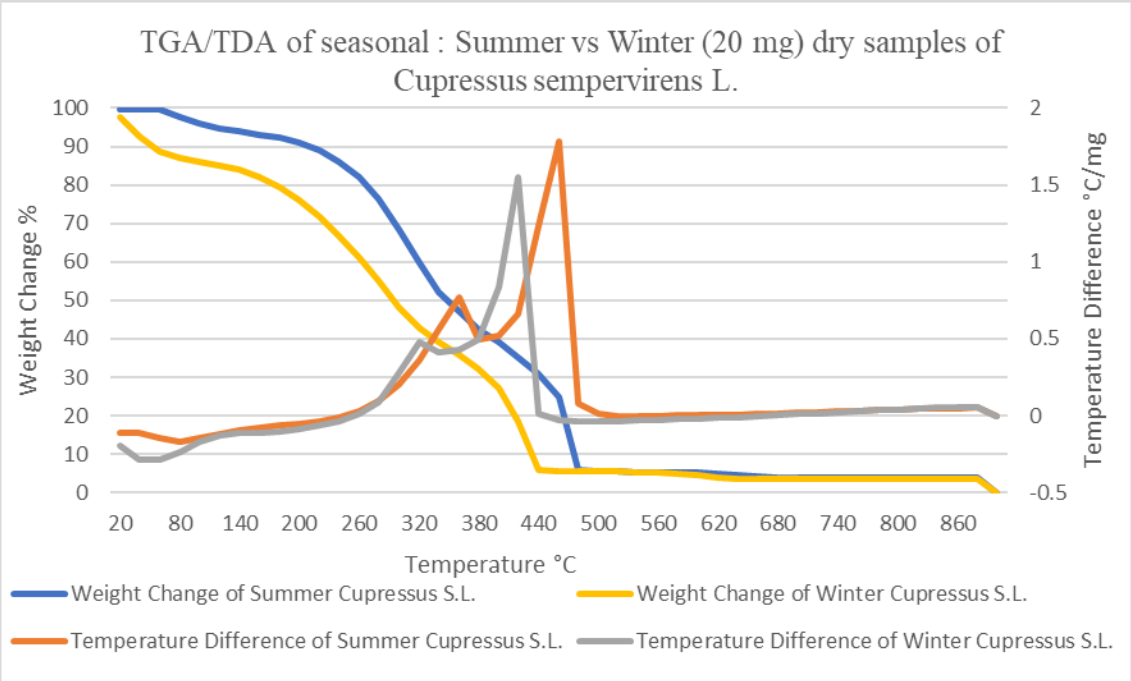

Figure 3- TGA/TDA of seasonal (summer & winter) foliar dry samples of Cupressus sempervirens L.

The Py-GC-MS experiments were conducted on the dry foliar samples of the two species. The pyrolysis products were identified on the basis of their GC retention times and by comparison of their mass spectra with those of standards and library data (NIST), (Figure 4). We identified terpene reserves (monoterpenes, sesquiterpenes, diterpenes) in the C.s.L. samples and none in the Q.s.L. (non -endogenous monoterpene emitter). Pyrolysis of Quercus cork released phenols of guaiacyl-type and syringyl type while the acetic acid indicated the thermal degradation of suberinic acids.

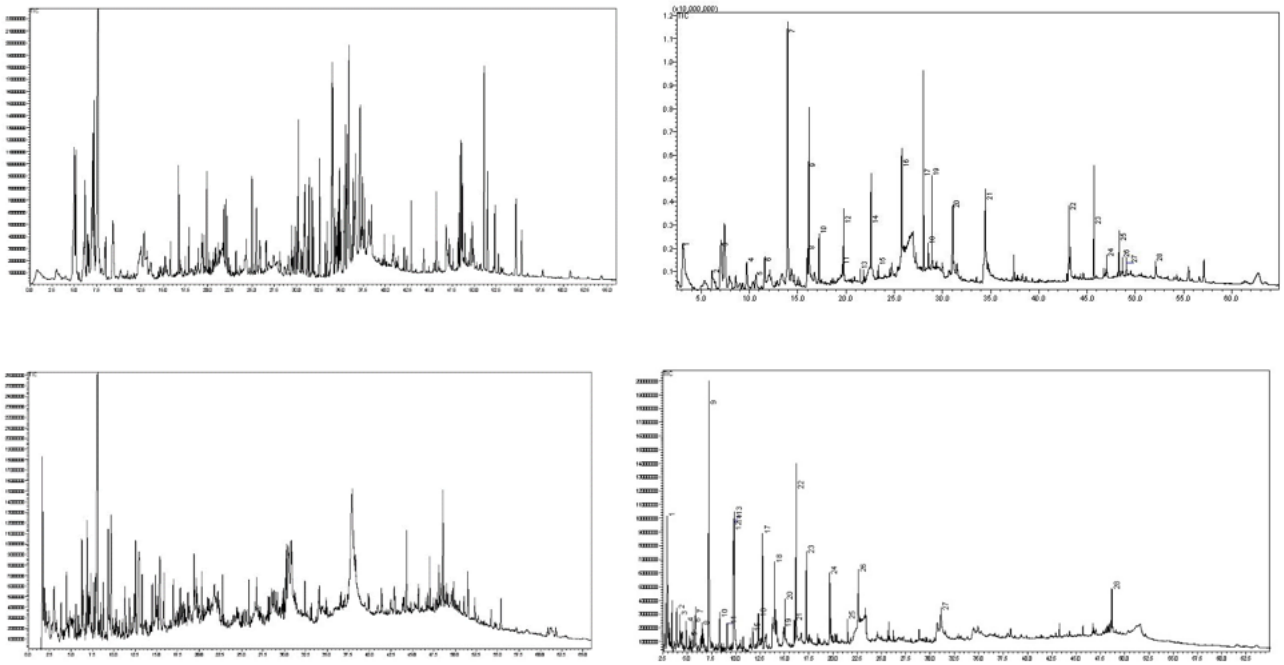

Figure 4- Pyrograms of dry C.s.L. (left) and dry Q.s.L. (right): up at 350°C, below at 550°C.

The aromatization of Q.s.L. to produce phenol and phenol homologues (i.e., methoxyphenol, dimethyl phenol, vinyl methoxyphenol, …) was remarkable at 350°C due to the degradation of lignin in dry foliar, branches and cork of with percentages of 51%, 71%, and 36%, respectively. These percentages increased remarkably at 550°C to 81%, 67% and 47%, respectively. The yield of suberin (insulation characteristic of Quercus suber) from cork pyrolysis was null at 350°C, 45% at 550°C, and 22,8% at 800°C. Phenol-derived compounds emerged humbly from C.s.L. dry foliar pyrolysis at 350°C while furanics (furfural, furan) of cellulosic origin and terpenes (mono, sesqui and di) were still dominant. Remarkably, sesquiterpenes were still identified from C.s.L. pyrolysis at 550°C and the percentages of mono aromatics (toluene), phenolics (phenol, methoxy-phenol, benzenediol) increased remarkably. Comparison between the pyrolysis products from dry foliar C.s.L. showed bigger reserves of VOCs in summer versus winter samples. Unlike the case of C.s.L., the degradation of Q.s.L. foliar lignin at 350°C (a temperature easily reached in wildfires), with the release of phenols and aromatics would accelerate flame propagation in wildfires hitting Quercus suber L. forests. The complete analysis of the experimental pyrolysis results will be presented in detail in the full paper edition.

Abstract

A methodology based on an automated optimisation technique is applied to interrogate the relationship between fuel bed structure and effective heat transfer properties. The methodology uses optimisation of the heat equation to resolve the temperature of the fuel bed upon exposure to an external heat flux and is coupled with thermogravimetric data to generate data on mass loss rate. The experimental mass data are provided by undertaking ignition experiments conducted on Pinus rigida Mill. fuel beds in the Fire Propagation Apparatus. Fuel solid fractions ranging from 0.03 to 0.51 are used. The fuel bed structure is represented by the solid fraction and the effective fuel bed properties (conductivity, convective heat loss coefficient and absorptivity) are posed as a function of the fuel bed structure. Each property is considered individually and the relationship between the property and the fuel structure is optimised using a genetic algorithm. In this way a methodology for interrogating the relationship between the fuel bed structure and the effective properties is presented.

1. Introduction

Wildfires are a natural phenomenon but can occur, and be exacerbated, due to human activity. Regardless of origin an uncontrolled fire poses a potential risk to life, property and environment. Nevertheless, the risk is difficult to define if wildfires are not fully understood. By understanding the processes that control the evolution of a wildfire it is possible to define the risk for different situations and a strategy for tackling the risk can be developed. Furthermore, by intervening with measures that alter the processes underpinning a wildfire the risk can be reduced. There are many parameters that affect the processes that control a wildfire including weather, topology and fuel. In this work we focus on the role of the fuel structure on the processes that underpin ignition.

One of the major challenges in understanding wildfire behaviour is defining the structure of the fuels and how this impacts the burning behaviour. Wildland fuels are defined by their thermophysical and thermochemical properties, and their structure (i.e. arrangement of the fuel elements). The thermochemical properties affect the combustion processes whereas the changes in fuel bed structure lead to changes in the heat and mass transfer mechanisms in the fuel bed. Describing the fuel bed structure in a way that is appropriate to resolve the heat and mass transfer processes remains largely elusive. Therefore, an approach to explore how different fuel bed structures affect the heat transfer mechanisms during ignition of porous fuel beds is presented.

This work develops flammability studies previously undertaken to capture the response of wildland fuels at different fuel bed conditions (Schemel, 2008; Mindykowski, 2011; Simeoni, 2012; Houssami, 2016; Jervis, 2016; Thomas, 2017; Walker-Ravena, 2019). Experiments have been conducted on fuel beds of *Pinus rigida* Mill. needles over a range of solid mass fractions (0.03-0.51) to determine the mass loss (and mass loss rate) before ignition as a function of the fuel solid mass fraction. This approach allows the effects of fuel structure to be studied independently of the species-dependent thermochemical properties.

The porous structure of wildfire fuel beds means that classical ignition theory, in which ignition is defined as a surface temperature (Torero, 2016), is unlikely to apply. Instead, a finite thickness of fuel will be heated and will undergo pyrolysis prior to ignition (an 'active region'). This has been observed previously (Thomas, 2017). Modelling ignition therefore requires that the temperature distribution inside the fuel be modelled, in order that a pyrolyzing region can be identified. This requires knowledge of the effective thermal properties as a function of the fuel solid mass fraction.

To address this issue, Genetic Algorithms (Launtenberger, 2006) are used to identify the relationship between the fuel bed effective properties and the fuel bed solid fraction by simultaneously optimising against experimental data of ignition of a range of fuel bed structures of the same material. The assumed relationship between the effective fuel bed properties and the fuel bed structure is varied until the best agreement between the numerical and experimental results is obtained.

Due to the challenges associated with measuring temperatures in porous media, the numerical and experimental results are compared on the basis of mass loss. Modelled temperatures are used to identify the mass loss using data from thermogravimetric analysis of the fuels. In this way the changes in the heating response are modelled to be due to relationship between the fuel bed effective properties and the fuel bed structure.

2. Methods

2.1. Sample preparation

To manufacture the different fuel beds, individual needles were cut to predefined lengths as shown in Figure and Table 1. The needle size determines the packing efficiency of the fuel bed and hence the solid fraction. Six different types of sample were prepared: two using full length needles with different masses, and four samples with needles cut to different lengths (3-4 cm, 1-1.25 cm, <1.5 cm) and one sample was manufactured by grinding the needles to a powder. The solid fraction was calculated by dividing the mass by product of the volume of the sample basket (diameter = 128 mm, depth = 30 mm) and the density of a single pine needle (density = 607 kg/m^3) (Houssami, 2016).

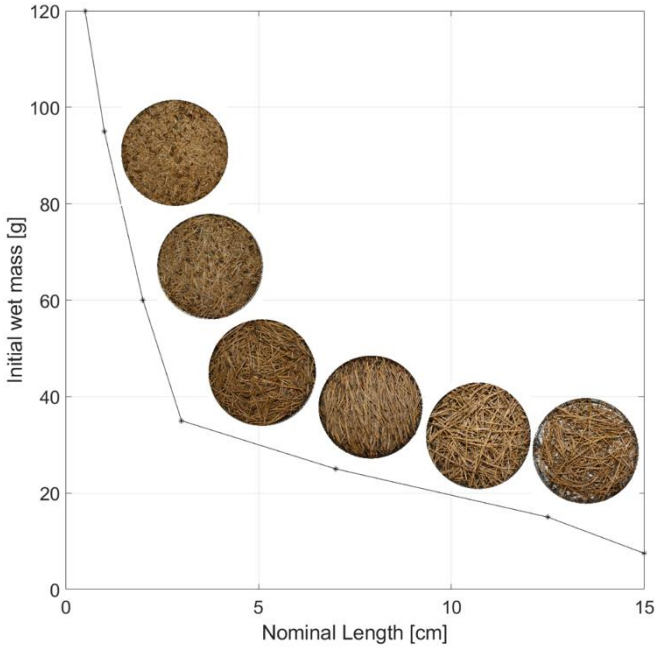

Figure 1 – Initial wet mass of fuel bed as a function of the approximate cut length of the Pinus Rigida needle

Table 1 - Manufactured fuel beds

Sample Preparation	Wet Mass [g]	Solid Fraction [-]
None	7.5	0.03
None	15	0.06
3-4cm	35	0.15
1-2.5cm	60	0.26
<1.5cm	90	0.38
Powder	120	0.51

2.2. Fire Propagation Apparatus

Samples were prepared in closed circular baskets. Closed baskets are used to minimise the contribution of the convective flow. Samples were conditioned by drying in an oven at 60°C for 24 hrs before testing. The preconditioned average fuel moisture content was ~8% whilst the conditioned fuel was <1% (Walker-Ravena, 2019).

Samples were exposed to heating of 25 kW/m^2 using the Fire Propagation Apparatus. The pilot flame was positioned 20 mm above the sample. The sample mass was recorded up to ignition. Repeat tests were averaged at each time-step to compute an average pre-ignition mass loss for each fuel bed.

2.3. Thermogravimetric Analysis

Thermogravimetric analysis (TGA) was carried out in air with a heating rate of 5 K/min for the *Pinus rigida* Mill. needle samples. Needles were ground and put in alumina crucibles. A representative TGA curve was generated by averaging repeat experiments, as shown in Figure 2b. The TGA data are used with the solution of the heat diffusion equation to generate mass data. The temperature at each depth is modelled and the normalised mass, for that temperature, is defined using the TGA data. This is illustrated in Figure 2a and the mapping shown in Figure 2b.

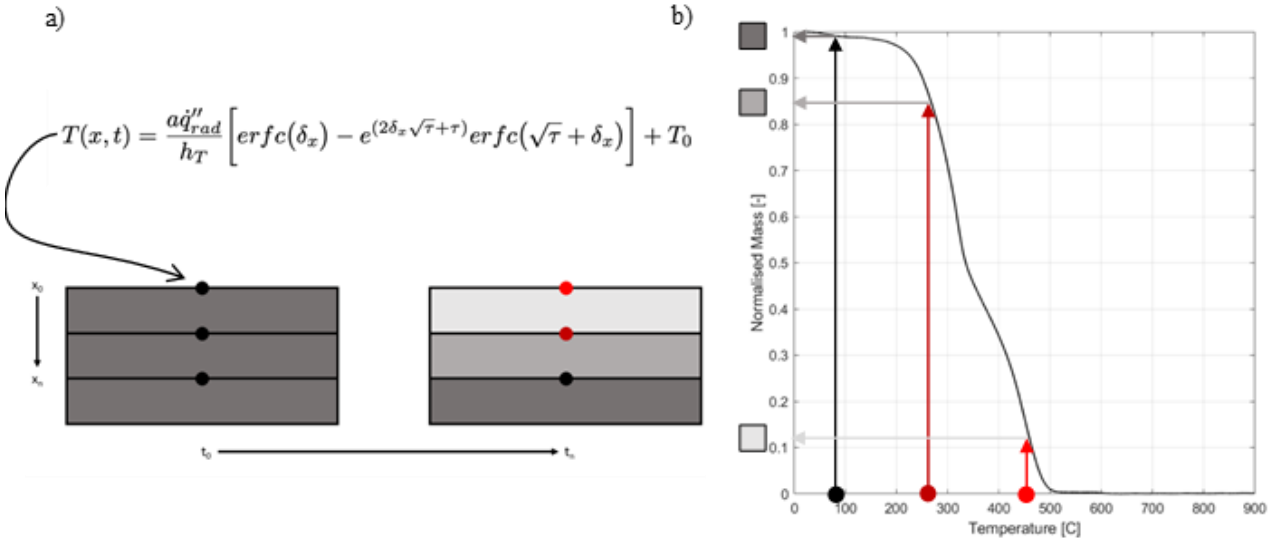

Figure 2 – a) Illustration of heat transfer model at t=0 and t=t_n. Red nodes indicate higher temperature and lighter shades of grey indicate increased mass loss b) TGA experimental data used as a look-up table

2.4. Genetic Algorithm

Genetic algorithms have been used to find material properties from bench-scale experiments (Launtenberger, 2006). A similar approach is followed here whereby optimisation of the model to the experimental data is conducted through minimising an objective function.

The solution to the heat diffusion equation (Torero, 2016), as presented in Figure 2a, is used to determine the temperature distribution in the solid phase. The mass loss rate is computed using the TGA data as indicated on Figure 2b. The objective function quantifies the difference between the model and the experimental data. In this work the relationship between the effective fuel bed properties and the fuel bed structure is sought. As such the different conditions are considered simultaneously by summing the value over each experimental condition as well as each time-step. The objective function is split into two parts so that both the mass and mass loss rate are used to compare the model and the experimental data.

$$R_1 = \sum^{\text{exp.}} \frac{\sum^{\text{t}} (m_{exp} - m_{mean})^2 - \sum (m_{exp} - m_{model})^2}{\sum (m_{exp} - m_{mean})^2}$$

$$R_2 = \sum^{\text{exp.}} \frac{\sum^{\text{t}} (\Delta m_{exp} - \Delta m_{mean})^2 - \sum (\Delta m_{exp} - \Delta m_{model})^2}{\sum_{\text{t}} (\Delta m_{exp} - \Delta m_{mean})^2}$$

$$R = R_1 + 0.5 R_2$$

Equation 1 - Objective functions minimised in genetic algorithm optimisation.

2.5. Effective Fuel Bed properties

The effective fuel bed properties (conductivity, convective heat loss coefficient and absorptivity) were assigned by assuming they are a function of the solid fraction of the fuel bed. This represents how the fuel bed properties are different to the material properties. In Equation 2 the material property is represented by *A* subscript whilst *B* represents the deviation due to the solid fraction. Moreover by assuming a continuous function the number of variables that need to be optimised is reduced.

$$k = k_A + k_B e(m)$$
$$H = H_A + H_B e(m)$$
$$a = a_A + a_B e(m)$$

Equation 2 – Assumed relationships between the heat transfer properties (k is conductivity; H is convective heat loss coefficient and a is absorptivity). Where e(m) is the solid fraction as a function of mass.

3. Results and Discussion

A series of images showing the process of piloted ignition, burning and extinction of a sample is shown in Figure 3. The pyrolysis gases are clearly visible before ignition.

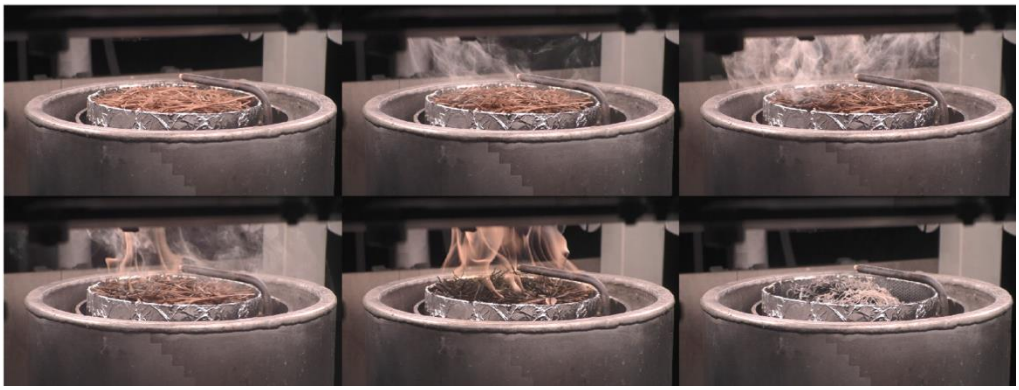

Figure 3 - Collage of 15g subjected to25 kW/m^2. Chronological order from left to right and top to bottom.

3.1. Experimental results

The experimental results shown in Figure 3 show that the mass lost at ignition and time to ignition are non-monotonic functions of the solid fraction. A minimum is observed at a solid fraction 0.15. Changes in the solid mass loss rate will lead to changes in time to form this gas mixture and therefore changes to the time to ignition. A higher mass loss rate indicates that the gas phase environment is such that it is harder to obtain a flammable mixture e.g. it is subject to higher levels of dilution or heat losses.

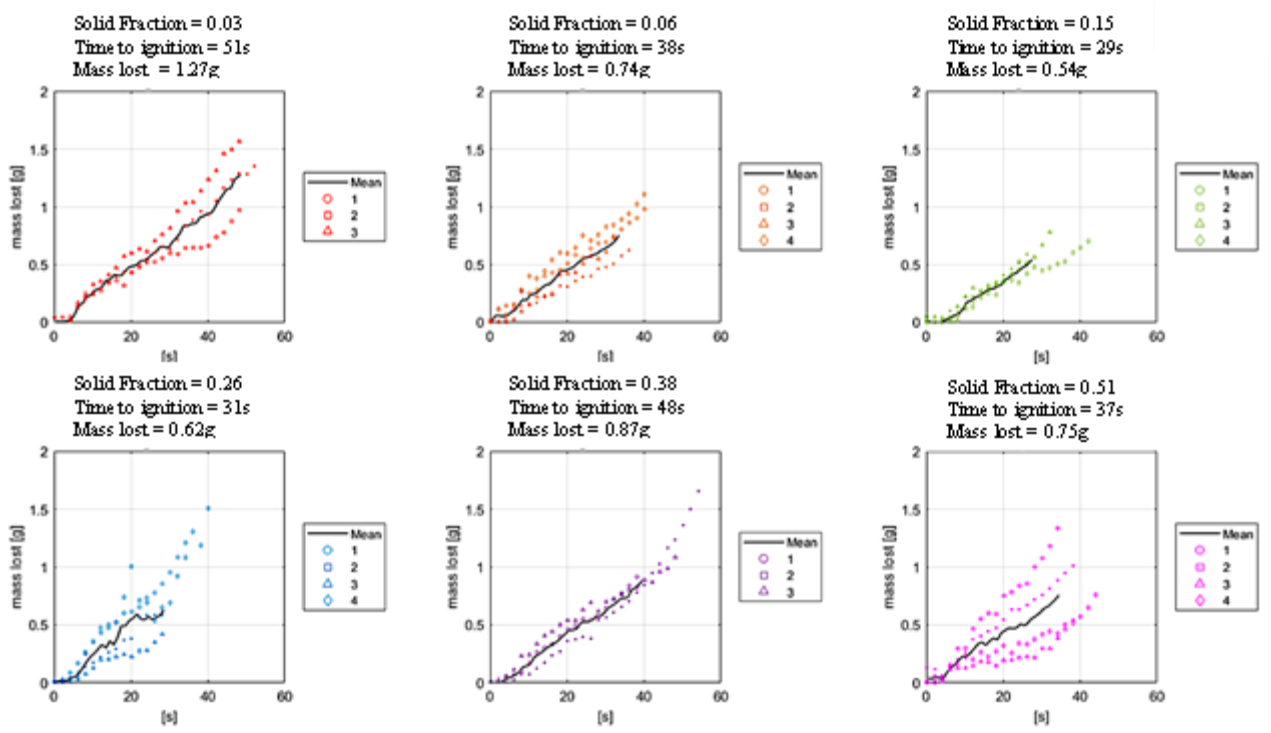

Figure 3 - Pre-ignition data for bench-scale testing conducted in the FPA. Markers represent individual tests whereas the black line is the experimental average. The values above are the experimental averages.

3.2. Genetic Algorithm

The changes in the fuel structure will be affect the conductivity, absorptivity and convection. To determine which is the most sensitive to the changes in fuel structure they are considered on a case-by-case basis. These cases are positive linear conduction, positive linear absorptivity and negative linear convection. These respectively represent the assumed trends of an increase in heat transfer through the bed due to an increase in needles connectivity; an increase in heat absorbed at the upper surfaces due to an increase in needle density per depth and decrease in convective heat loss due to a decrease in the fuel bed permeability causing lower fluid flows. The effective fuel bed properties are compared to literature values (Houssami, 2016).

3.2.1. Positive Linear Conductivity

The first case is positive linear conductivity as a function of the fuel solid fraction. The intention here was to represent the increase in conductivity that is assumed to occur with a decrease in the porosity of the fuel bed. That is to say smaller spacing between needles is assumed to lead to an increased effective thermal conductivity due to increased particle to particle contact. An increase in conductivity may also represent the heat transferred through the fuel bed due to needle-to-needle radiation (Simeoni, 2012). Optimisation gave the values for k_A and k_B as 2.41×10^{-6} W/mmK and 8.96×10^{-5} W/mmK, respectively.

Nevertheless, the output values did not capture the experimental behaviours appropriately. The lowest solid fractions showed similar behaviours but the mass loss at the high fuel loads were over estimated. In the low solid fractions it is expected that radiation penetration into the depth of the fuel bed is significant resulting in higher in depth temperatures.

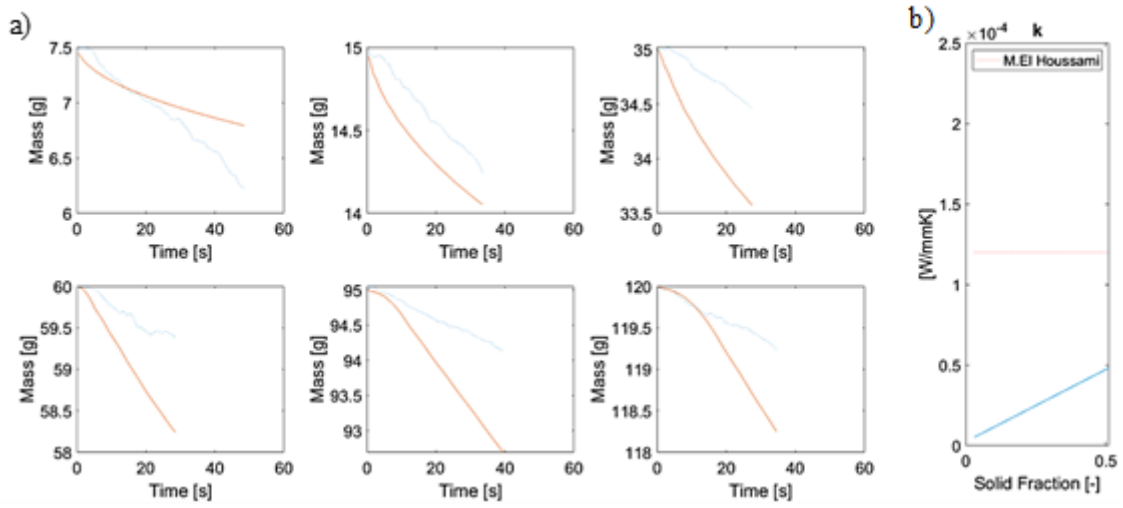

Figure 5 - Positive Linear Conductivity model outputs. Blue line shows experimental mean whilst red line shows the model output. Clockwise from top left, the fuel loads shown are 7.5g, 15g, 35g, 60g, 95g, 120g. b) Conductive coefficient as a function of solid fraction.

3.2.2. Positive Linear Absorptivity

The next case is positive linear absorptivity. Here the intention is to represent the increase in heat absorbed at the upper surfaces of the fuel bed due to there being a greater amount of exposed surface area due to increase in needle density. Optimisation gave the values for a_A and a_B as 0.46 and 0.56 respectively.

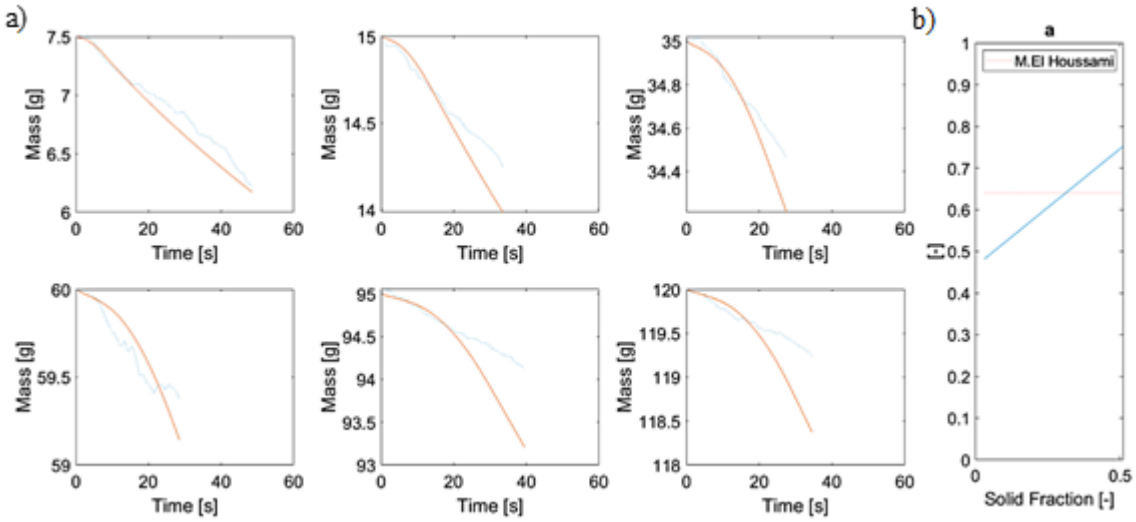

Figure 6 - Positive Linear Absorptivity model outputs. Blue line shows experimental mean whilst red line shows the model output. Clockwise from top left, the fuel loads shown are 7.5g, 15g, 35g, 60g, 95g, 120g. b) Absorptivity coefficient as a function of solid fraction.

These conditions seem to capture the behaviours at low fuel loads well however the high fuel loads are seen to overestimate the mass loss rate at longer times. This indicates that the temperature in the system is too high. This suggests that, the effects of fuel structure are not represented by the change in the absorptivity alone.

3.2.3. Negative Linear Convection

The next case is negative linear convection. This intention here is to represent the increase in convective heat loss that is assumed to occur as the bed becomes more porous. The increase in the porosity of fuel bed leads to an increase in its permeability and so the fuel bed is more susceptible to fluid flows and therefore convective losses (Simeoni, 2012). Optimisation gave the values for H_A and H_B as 3.35e-5 W/mm^{2}K and -8.54e-6 W/mm^{2}K respectively.

The output leads to improved representation of the experimental results in both the low and high fuel load cases. Although the lines do not overlap in the high fuel cases, a similar gradient is found at long time. This indicates that the rates of degradation are similar and as such some of the experiment physics are being captured.

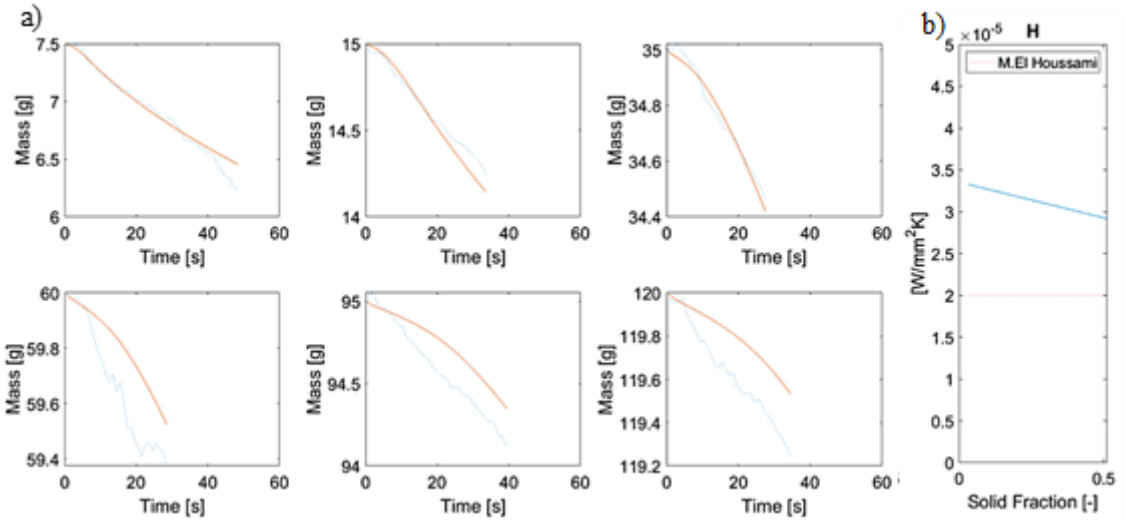

Figure 7 – a) Negative Linear Convection model outputs. Blue line shows experimental mean whilst red line shows the model output. Clockwise from top left, the fuel loads shown are 7.5g, 15g, 35g, 60g, 95g, 120g. b) Convective coefficient as a function of solid fraction.

4. Conclusion

This study has explored the effect of fuel solid fraction on the ignition of fuel beds. Experimentally the mass lost from the fuel bed before ignition and the time to ignition is shown to vary as a function of the fuel solid fraction. This indicates that the structure of the fuel bed and the heat transfer within the fuel bed play a key role in determining the ignition characteristics. Using a simple genetic algorithm approach, we show that the absorption of radiation and the heat losses of the system play a governing role in these experiments. The study also showed that the convective flow through a porous fuel has a large impact on determining the flammability due to convective cooling of fine elements air. This finding is important for the design of future studies of the burning of wildland fuels as the fuel bed structure is generally not considered beyond the level of fuel loading or bulk density. This approach also results in the need to move away from a surface temperature condition for ignition of porous fuel beds to one that considers the temperature distribution through the porous media.

Fire-atmosphere interaction, Turbulence, Energy transport, Large eddy simulation

Abstract

Understanding near surface fire-atmosphere interactions at turbulence scale is fundamental for predicting fire spread behavior. This study investigated the fire-atmosphere interaction and the accompanying energy transport processes within the convective boundary layer. Three groups of large eddy simulations (LES) representing common ranges of convective boundary layer conditions (resulting from land surface heat flux ranging from 120 to 360W/m2) and fire intensities (50 to 150kW/m2) were used to examine how ambient buoyancy-induced atmospheric turbulence can impact fire region heat and momentum transport.

In a relatively weak convective boundary layer, the change of near-surface atmospheric turbulence caused by the buoyancy force from the fire heat release is substantial and can cause an anticorrelation of the helicity between the ambient atmosphere and the fire-induced flow. Fire-induced impact becomes much smaller in a relatively strong convective environment with ambient atmospheric flow maintaining coherent structures including vortices across the fire heating region. The helicity also shows strong correlation between the ambient atmosphere and the fire-induced flow. A further energy transport efficiency analysis shows a narrow heat transport zone above the fire line for the weak convective boundary layer scenario. This indicates confined heat release and stronger fire-induced buoyancy force. The high-efficiency heat transport zone becomes much wider in a stronger convective boundary layer which leads to a wider distribution of heat released from fire, the weaker fire-induced buoyancy force and causes less fire-induced flow-field change. The work also found counter-gradient transport zones of both momentum and heat in fire cases in the weak convective boundary layer group. The counter-gradient transport might indicate the existence of strong buoyancy-induced mixing processes.

1. Introduction

Atmospheric motions vary in scale from thousands of kilometers (planetary circulations) to sub-meter turbulence eddies (Orlanski, 1975). These atmospheric motions can interact and influence fire behavior at different scales and aspects (Potter, 2002). The thermal internal boundary layer caused by localized heating of fire, and the atmospheric boundary layer (ABL) that envelops it, develop at integral time scales spanning from seconds to tens of minutes (Stull, 2012). Within this fire turbulence environment (hereafter referred to as the FTE, Figure 1), atmospheric turbulence plays an important part in energy transfer between the fire and the surrounding atmosphere ((Dickinson et al., 2021; Finney et al., 2015; Kremens et al., 2012; Sullivan, 2017).

Quantifying turbulent heat and momentum fluxes is important to better describe the coupled processes within the FTE which can lead to spatial and temporal variation in fire behavior. This work aims to describe the role of the background atmospheric flow in fire-atmosphere interactions and discuss the physical mechanisms driving these interactions. The main objective is to understand processes that control the spatial and temporal development of turbulent heat and momentum transport under different convective boundary layer (CBL) turbulence intensities.

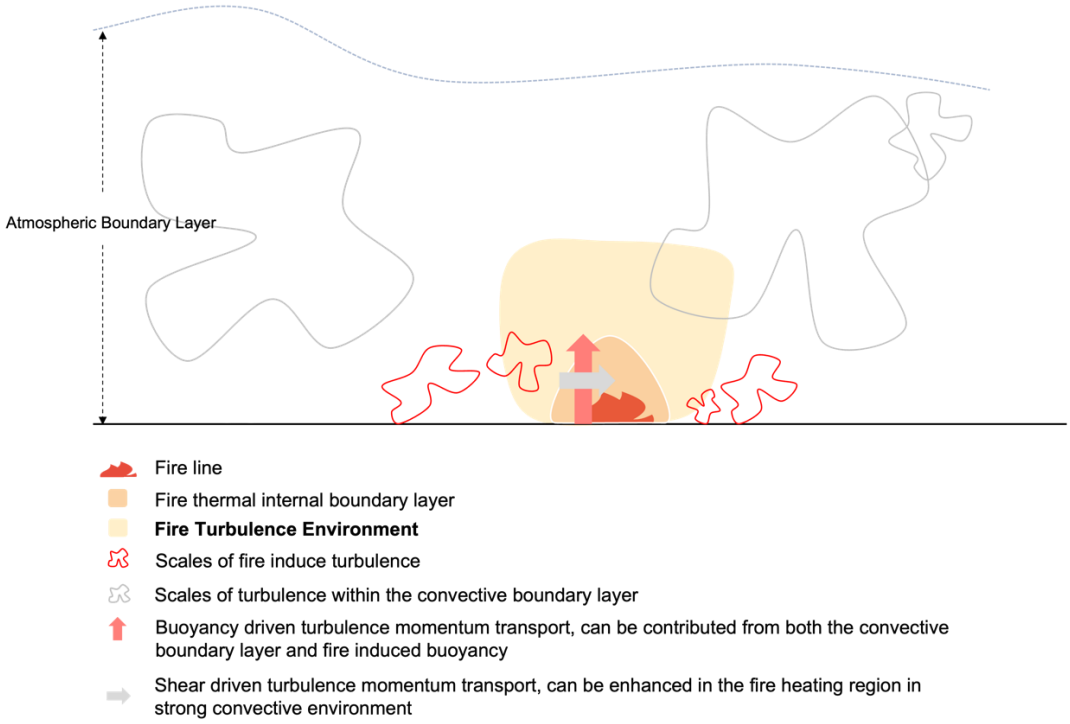

Figure 1- Conceptual diagram showing the fire turbulence environment (FTE).

The impact of different fire intensities for each turbulence regime is also considered using a 2D hot patch with different fixed heat flux intensities. The novel quantitative partitioning of heat and momentum flux using spatially distributed energy partitioning (referred to as spatial quadrant analysis) allowed the definition of spatial energy transfer zones that define the scales and intensities of these interactions. Finally, and by calculating the helicity above the fire region influenced by atmospheric motion, the potential for fire behavior influenced by atmospheric turbulence is discussed in relation to fire and atmospheric turbulence intensity levels.

2. Methods

2.1. Model description and set-up

The PArallelized LES Model (PALM) model (Maronga et al., 2015; Raasch & Schröter, 2001) is the model employed here . A matrix of simulations was carried out with three ambient land surface heat fluxes and three fire intensities (Table 1). A base case, with no simulated fire, was also run for every ambient land surface heat flux group to represent the ambient atmospheric flow field. In all cases, three nested domains with one-way nesting were used, downscaling from 32m to 4m grid resolution (Figure 2). A 12m wide 2D hot patch with different heat fluxes was placed in the center of the inner-most domain (D3) to represent fire with different intensities for the fire cases.

Table 1- Simulation naming convention including a total of 12 simulations. Note the difference in magnitude between the land surface heat flux and the fire intensities.

Group	**Land Surface Heat Flux**	**Fire Intensity**			
		Base	Low	Med	High
C1	120 $W\ m^{-2}$	No Fire	50 $kW\ m^{-2}$	100 $kW\ m^{-2}$	150 $kW\ m^{-2}$
C2	240 $W\ m^{-2}$				
C3	360 $W\ m^{-2}$				

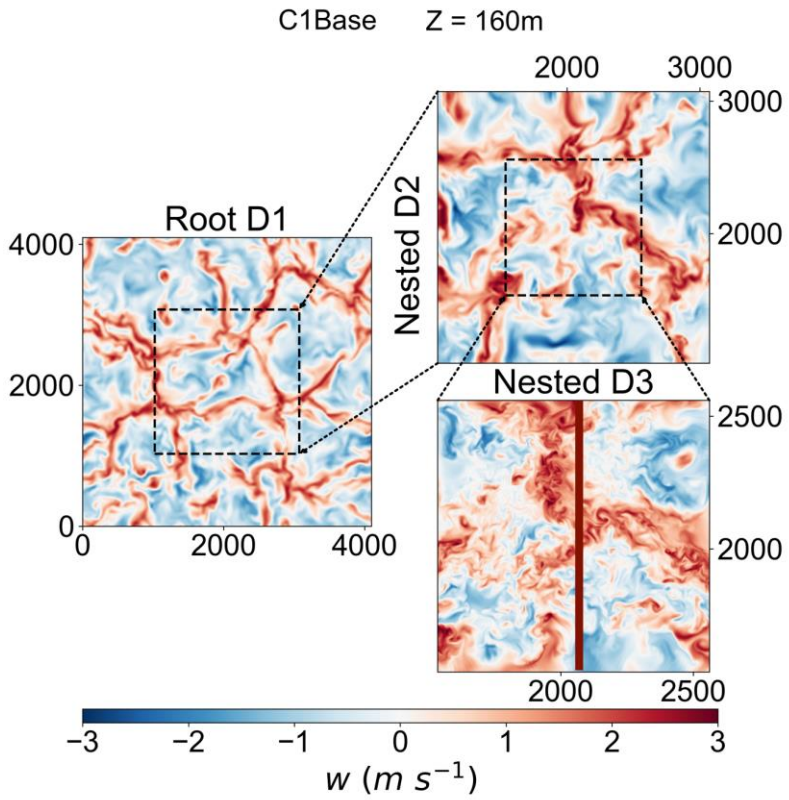

Figure 2. Instantaneous horizontal cross-section of vertical velocity at 160m above ground level (AGL) (z=160m) from one of the simulations (C1Base). D1, D2, D3 are for the nested Domains 1 (root or outermost domain), 2 and 3 (innermost domain). The red line in the D3 domain illustrates the hot patch location which was only set up at the surface of the fire cases after 03:30:00 simulation time.

The same initial profiles were used for all the simulations. For the potential temperature profile, constant potential temperature of 293K is used from the surface up to 1km with an inversion then applied. The initial wind speed is set to be 0m/s at all locations. All cases were run for 4 hours with the first 3 hours as spin up period and the fire set up after 3.5 hours.

2.2. Helicity

Helicity is used to explore the changes or transfer of vorticity caused by the interaction between the fire-induced buoyancy and the ambient atmospheric flow. The helicity is calculated using the non-integral form (Equation 1). To better quantify the domain-wide helicity, the averaged magnitude of the vertical helicity component is calculated from the horizontal cross-section of the innermost (D3) domain.

$$H = (\nabla \times \vec{v}) \cdot \vec{v} \quad (1)$$

where $\vec{v}$ is the velocity vector and $\nabla \times \vec{v}$ is the vorticity vector $\vec{\omega}$.

2.3. Quadrant analysis

In any point location, the time series of instantaneous vertical transfer of horizontal momentum (w'u') and kinematic heat flux (w'θ') can be drawn in the Cartesian coordinate system with w' and the respective perturbation variable as the coordinates (Figure 3; Shaw et al., 1983). Each quadrant in the coordinate system has different physical interpretation.

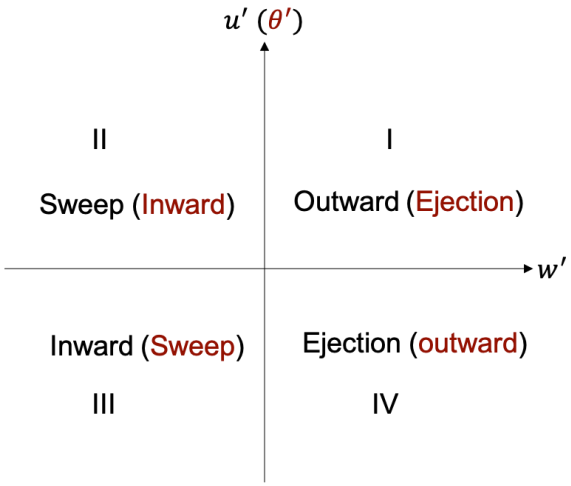

Figure 3. The terminology and convention used for the quadrant analysis. A time series of w'u' (or w'θ') can be classified into each quadrant. For the momentum flux (w'u'), quadrants I and III represent the outward and inward motions which account for counter-gradient momentum transport. Quadrants II and IV represent the sweep and ejection motions and contribute to downgradient momentum transport. For the instantaneous kinematic heat flux (w'θ'), the sweep/ejection and outward/inward quadrants are reversed and illustrated using the red color.

Based on quadrant analysis, Wyngaard and Moeng (1992) implemented the concept of energy transport efficiency, which was defined as the ratio of downgradient flux to total flux. The mathematical form of energy transport efficiency is further discussed by Li and Bou-Zeid (2011) and is shown below,

$$\eta = \frac{F_{\text{total}}}{F_{\text{downgradient}}} = \frac{\overline{w'c'}}{\overline{w'c'}_{\text{ejections}} + \overline{w'c'}_{\text{sweeps}}} \tag{2}$$

where c represents variables like velocity, temperature or other scalars. The flux in each quadrant is calculated using the equation below,

$$\overline{w'c'}_i = \frac{1}{t}\sum_{j=t_0}^{t} w_j{}' \, c_j{}' I_{ij} \tag{3}$$

where I_j is defined as,

$$I_{ij} = \begin{cases} 1 & \text{if } w_j{}' c_j{}' \text{ is in quadrant } i \\ 0 & \text{otherwise} \end{cases} \tag{4}$$

From the above definition, the transport efficiency (η) is positive when the F_{total} and $F_{downgradient}$ have the same sign. This means the down-gradient transport is dominating the energy transport process and the turbulence is mainly shear driven. On the other hand, when the counter-gradient transport component is strong enough to counteract the down-gradient transport, the transport efficiency can be very small and even negative. To obtain spatial information about the momentum and heat transport within the FTE, the work extended the transport efficiency to the spatial modelling data.

3. Results

3.1. General flow patterns

Figure 4 shows the horizontal cross-section of the 1-minute averaged u velocity component at 10m above ground level (AGL) after the fire had been set up for 20 minutes. In the C1 group, a clear fire-induced convergence zone is formed across all fire cases while no such zone exists in the base case. In the C2 group, vortex structures can be found in both the ambient atmosphere (represented by the base case) and the fire cases. These vortex structures remain and are strengthened with the addition of the simulated fire. All C3 group cases show similar flow patterns with predominant negative values in the center of the domain and positive values at the edge.

Although not shown here, the fire cases in the C2 and C3 group maintain similar flow patterns of all velocity components to the respective base case up until 20 minutes after the fire line set-up.

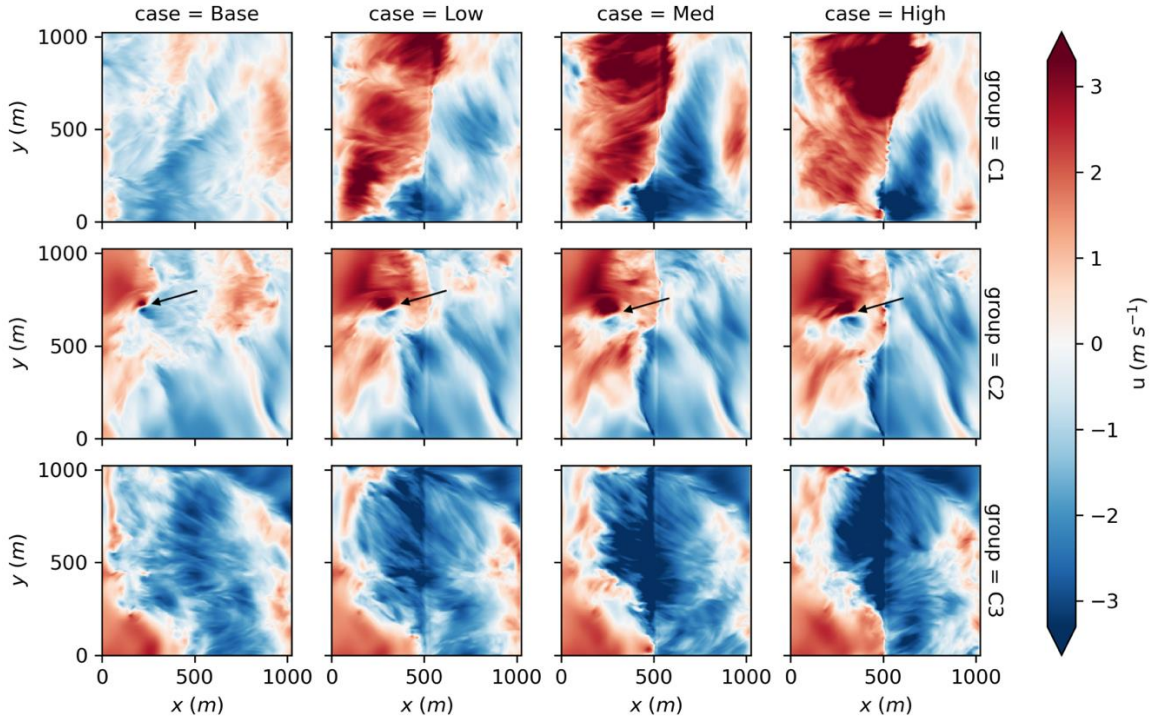

Figure 4. Horizontal cross-section (10m AGL) of 1-minute averaged horizontal u-velocity component 20 minutes after the fire lines were set up). Each row represents simulation groups with different ambient land surface heat flux (120W/m² for the C1 group, 240W/m² for the C2 group and 360W/m² for the C3 group). From left to right, each column represents the fire line intensity (heat flux) (no fire for the base case, 50kW/m² for the low intensity fire scenario, 100kW/m² for the medium intensity scenario and 150kW/m² for the high intensity scenario).

The temperature anomaly caused by fire also shows distinctive characteristics between C1 and the two other groups. Even 10 minutes after the fire line is set up, the high temperature zone caused by the fire maintains a relatively straight and narrow line at 10m AGL in all fire cases in the C1 group (Figure 5). Conversely, the high temperature anomaly in the fire cases in the C2 and C3 groups show much wider horizontal extent. From the vertical cross-section (not shown here), this is caused by tilting of the hot plume.

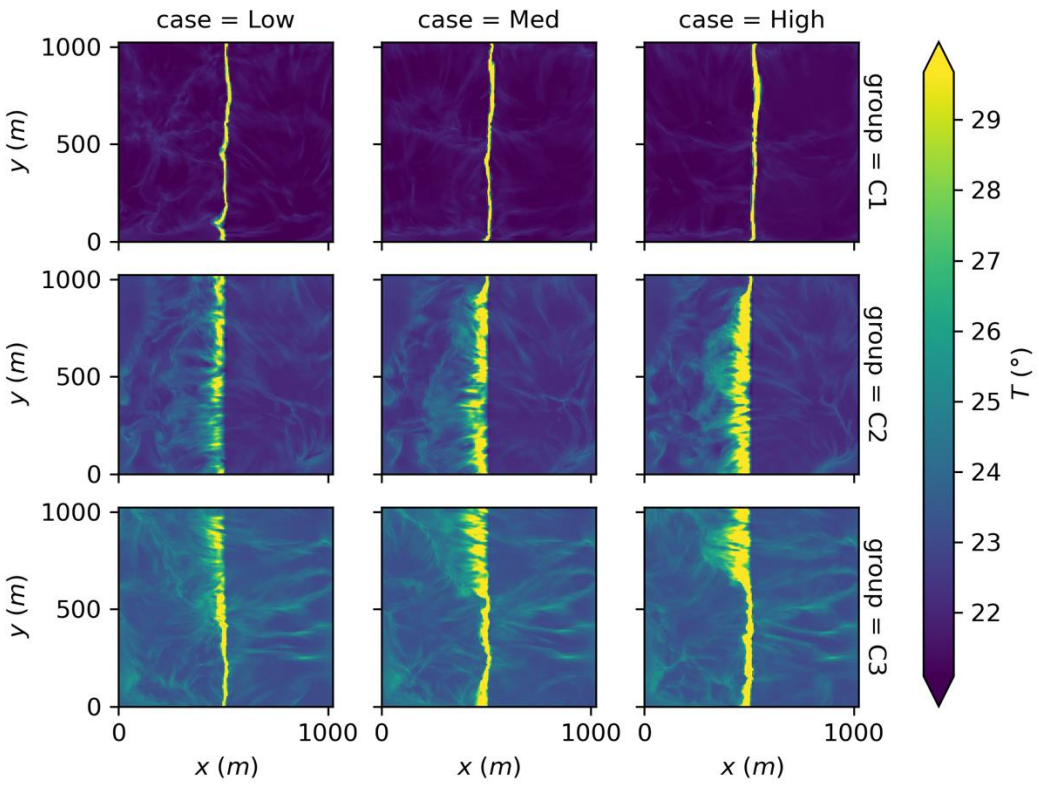

Figure 5. Horizontal cross-section (10m AGL) of 1-minute averaged air temperature after 20 minutes of the fire lines being set up). Each row represents simulation groups with different ambient land surface heat flux (120W/m^2 for the C1 group, 240W/m^2 for the C2 group and 360W/m^2 for the C3 group). From left to right, each column represents the fire line intensity (heat flux) (50kW/m^2 for the low intensity fire scenario, 100kW/m^2 for the medium intensity scenario and 150kW/m^2 for the high intensity scenario).

3.2. Helicity

The magnitude of the domain average vertical helicity component ($|H_z|$) is much lower in the base case in the C1 group (Table 2a) while the magnitude is higher in the base cases in the C2 and C3 groups. In all groups, fire cases have higher $|H_z|$ which might be caused by the reorganizing and tilting of the ambient vortices from the fire-induced buoyancy. This aligns with the framework suggested by Potter et al. (2012).

Table 2a- Average magnitude of the vertical helicity component $|H_z|$ at 10m AGL.

$\|H_z\|$	Base	Low	Med	High
C1 group	0.009	0.018	0.026	0.030
C2 group	0.015	0.023	0.028	0.031
C3 group	0.019	0.026	0.030	0.033

Table 2b- Correlation coefficient (r) of the vertical helicity magnitude $|H_z|$ time series (domain averaged at 10m height) between fire cases and the base (no fire) case from the same group.

r	Base	Low	Med	High
C1 group	N/A	-0.74	-0.76	-0.77
C2 group	N/A	0.69	0.55	0.60
C3 group	N/A	0.86	0.90	0.87

Time series of $|H_z|$ show some similarity between the fire cases and the base case, especially in the C2 and C3 groups (Figure 6). The similarity can be confirmed by the correlation coefficient (Table 2b). In general, fire cases and the ambient atmospheric flow represented by respective base cases have high correlation coefficients up to 0.9 in the C2 and C3 groups. The high correlation coefficients indicate that ambient atmospheric flow can maintain its coherent turbulent flow structures and impact fire behaviors under the convective boundary layer conditions similar to the C2 and C3 groups. On the other hand, strong anticorrelation can be found between the fire cases and the base case in the C1 group which means an increase of $|H_z|$ in the fire cases corresponds to a decrease of the $|H_z|$ in the ambient atmosphere. This indicates that fire-induced processes like vortex stretching/tilting might be dominating and changing the rotational flow field in a relatively weak convective boundary layer.

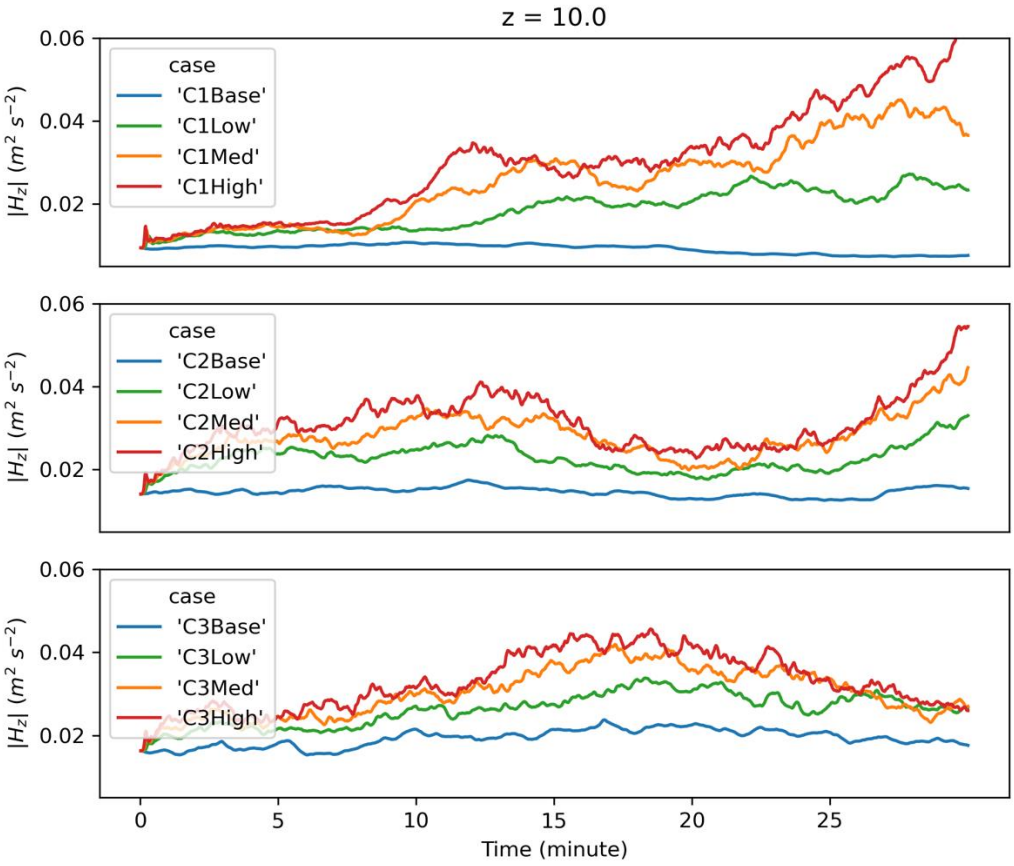

Figure 6. Time series of the vertical helicity magnitude (domain averaged at 10m AGL) from each case in each simulation group from the moment fire was set up. (a), (b), (c) show results in the C1, C2 and C3 groups respectively while blue, green, orange, and red lines represent base (no fire), low, medium, and high intensity fire case in each group respectively.

3.3. Energy transport efficiency

While the above analysis has shown evidence of different fire-atmosphere interaction under different CBL conditions, to understand the physical processes behind these results, the turbulent transport efficiency is further investigated.

Horizontal and vertical cross-sections of the vertical heat transport efficiency ($\eta_{w'\theta'}$) from all cases are shown in Figures 7 and 8. From both horizontal and vertical cross-sections, a much narrower and more distinctive high-efficiency transport zone can be found in the C1 group compared to other groups. In both the C1 and C2 groups, counter-gradient heat transport zone (negative values) can be found.

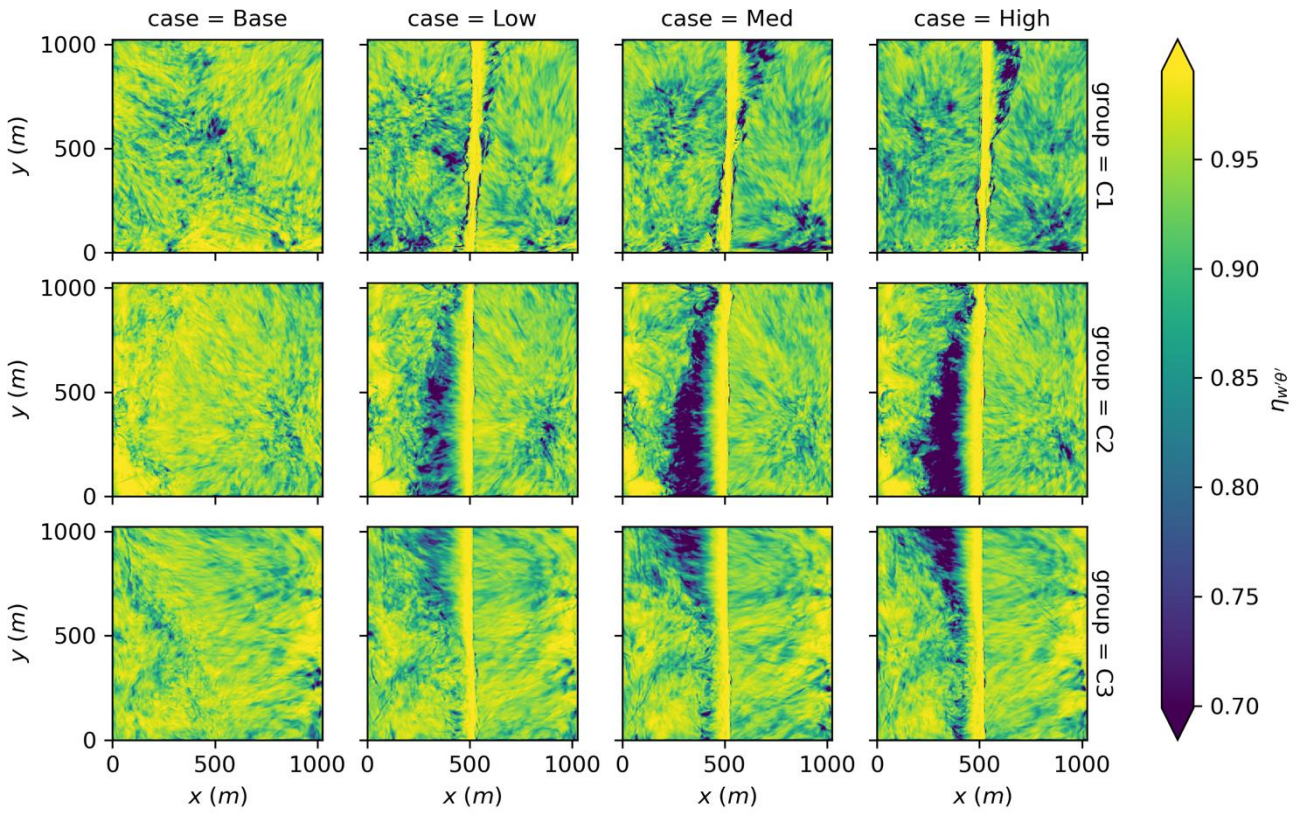

Figure 7. Horizontal cross-section of heat transport efficiency $\eta_{w'\theta'}$ at 10m above the surface from all cases during the first 15 minutes of the fire being set up. Each row represents different groups while each column represents either the base cases or the cases with the different fire intensities.

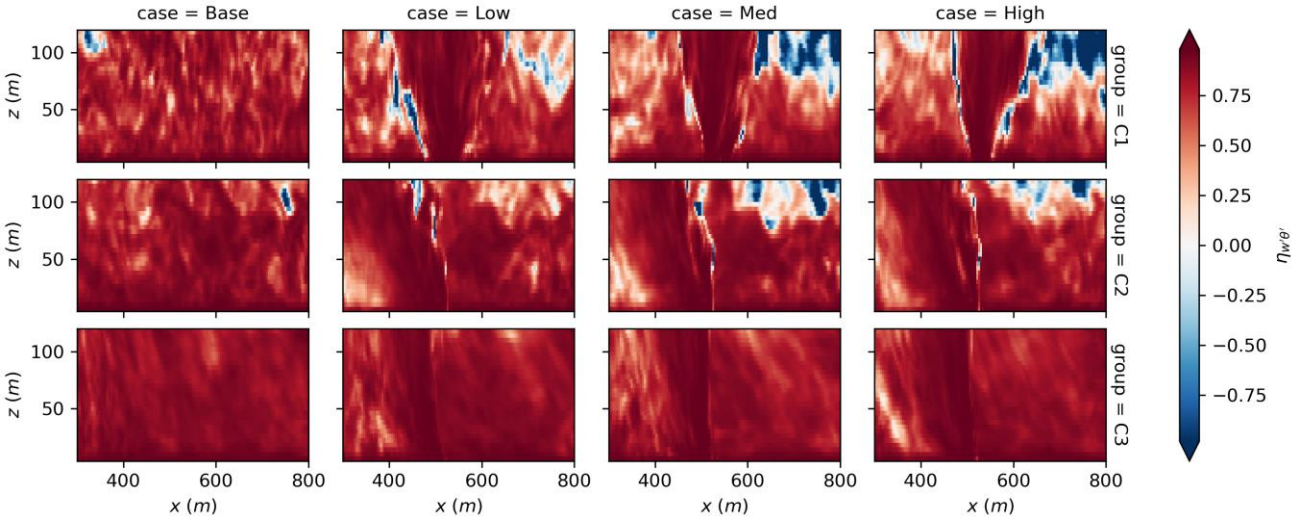

Figure 8. xz cross-section of heat transport efficiency $\eta_{w'\theta'}$ at the center of the domain from all cases during the first 15 minutes of the fire being set up. Each row represents different groups while each column represents either the base cases or the cases with the different fire intensities.

From both the horizontal and vertical cross-sections of the momentum transport efficiency ($\eta_{w'u'}$) (Figures 9 and 10), a new counter-gradient (negative values) momentum transport zone can also be found in the fire cases in the C1 group. This is in consistent with the analysis above and might be caused by the strong fire-induced buoyancy.

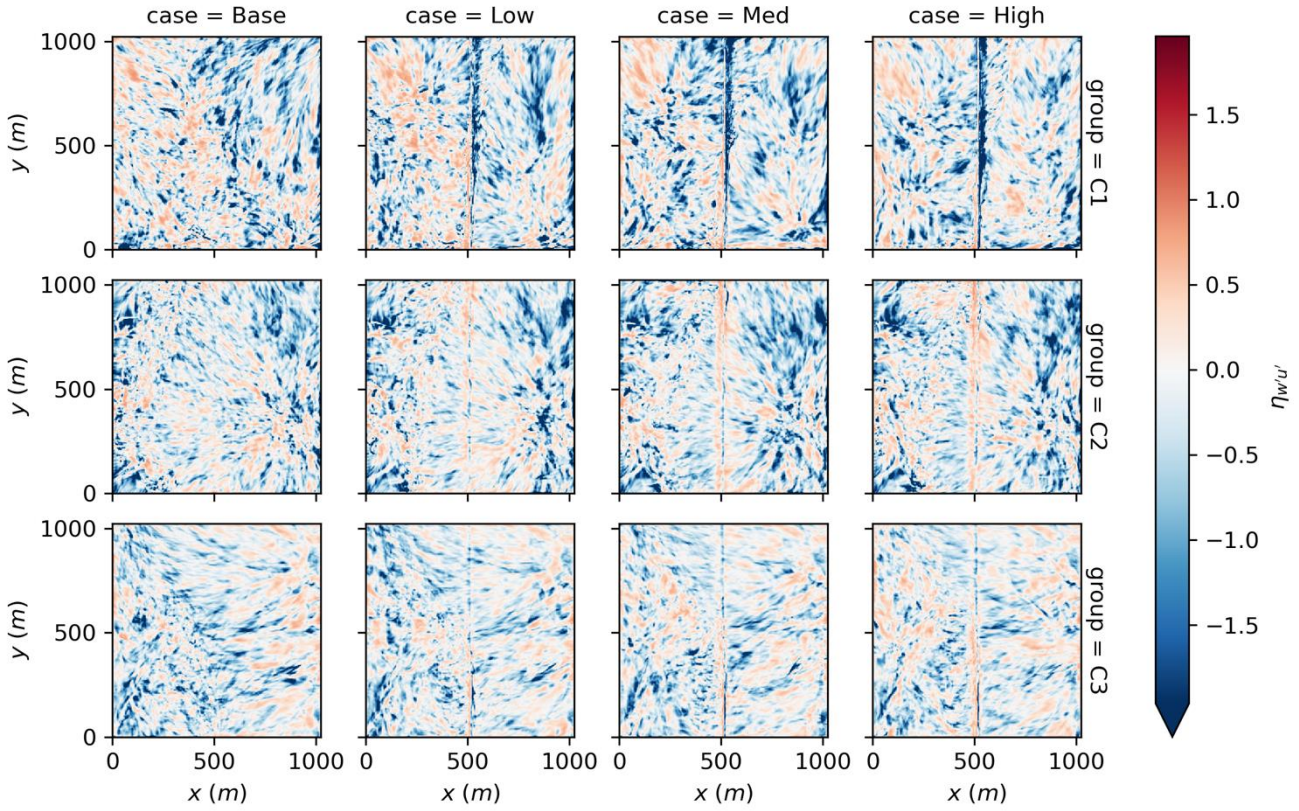

Figure 9. Horizontal cross-section of momentum transport efficiency $\eta_{w'u'}$ at 10m above the surface from all cases during the first 15 minutes of the fire being set up. Each row represents different groups while each column represents either the base cases or the cases with the different fire intensities.

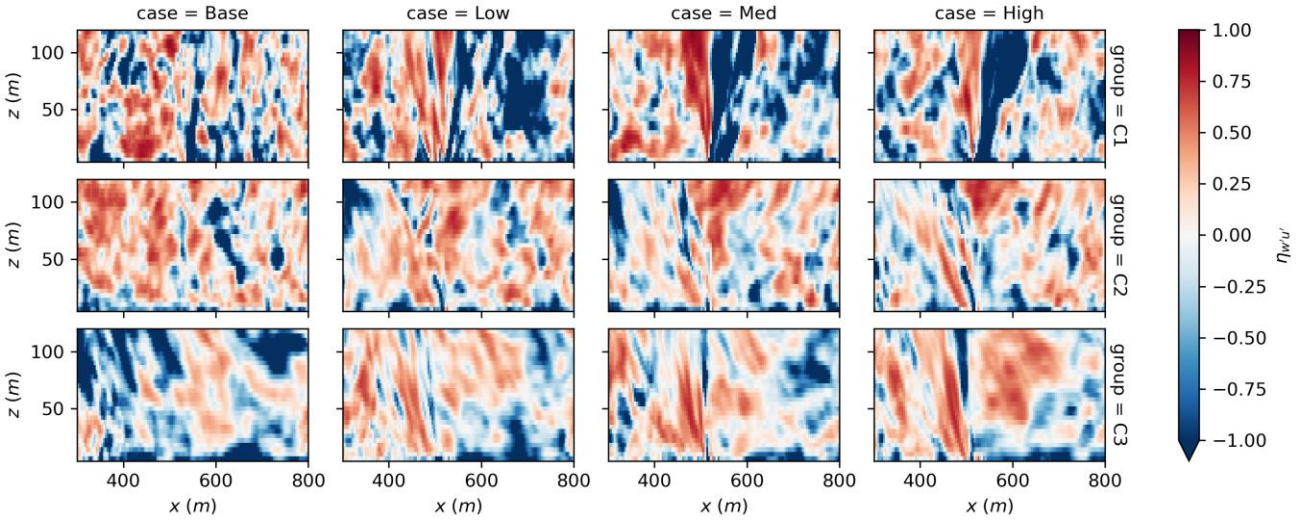

Figure 10. xz cross-section of momentum transport efficiency $\eta_{w'u'}$ at the center of the domain from all cases during the first 15 minutes of the fire being set up. Each row represents different groups while each column represents either the base cases or the cases with the different fire intensities.

4. Discussion and conclusion

The study found that different convective boundary layer conditions will have different impacts in the fire-atmosphere interaction process. In a relatively weak atmospheric CBL (C1 group), our results have shown that the near-surface flow field changed substantially due to the fire-induced flow in all fire cases. The helicity analysis shows an anticorrelation between the ambient atmosphere and the fire-induced flow. The fire-induced temperature anomaly in all cases is spatially confined with a relatively narrower horizontal span compared to

other groups. The horizontal span of the anomaly is consistent with the narrow fire-induced high-efficiency heat transport zone and counter-gradient momentum transport zone. The influence of the fire-induced flow change in heat and momentum transport is extended beyond these zones to the entire near-surface region. This further suggests that fire-induced flow can be substantial in the ambient flow field and reach a large spatial extent. As a result, it would be difficult to predict fire behavior in this scenario without information about fire fuel.

On the other hand, in a stronger buoyancy driven CBL turbulence environment like the C2 and C3 groups, which represent conditions closer to typical midaltitude midday, the ambient flow field remains largely unchanged after the fire initiation. This suggests that, in an ABL with stronger buoyancy driven turbulence, the ambient atmospheric flow can play an important role in fire behavior while fire-induced flow change can be very limited. The strengthening of the vortex structures in the fire cases in the C2 group might also indicate that the ambient vortex structures could contribute to the fire whirl generation process. The fire-induced high-efficiency heat transport zone has a much wider spatial extent which is consistent with the wider extent of the temperature anomaly. The wider heat transport also leads to a weaker buoyancy flow. Unlike in the weak atmospheric CBL, there is no clear buoyancy induced counter-gradient momentum transport zone.

The results might provide guidelines to determine whether ambient atmosphere could play an important role in fire region energy transport and subsequently influence short-term fire behaviors. Future work is needed using either field campaigns or coupled fire-atmosphere models, including detailed physical and chemical processes of fire combustion and spread, to verify our results with moving fire at similar ranges of intensity.

Forest fires, Flame height, Burning rate, Flame temperature, Air velocity profile.

Abstract

The combustion properties of several dead Mediterranean forest fuels were investigated experimentally. Samples of *straw*, *eucalyptus*, *shrubs*, and *Pinus Pinaster* with the same load were placed in cylindrical containers of the same size and were ignited from the perimeter of the container's bottom. A pitot tube and a thermocouple are placed one meter above the fuel surface to measure the airflow induced by the flame and the flame temperature. The main combustion parameters (mass-loss rate, flame height and temperature, and the induced air velocity) seem to evolve according to the same trend regardless of the fuel type. They increase rapidly in the growth phase of the flame then they decrease over a relatively long period characterizing the decay phase. In the crossover period between these two burning phases, the flame is fully developed with a maximum height and burning rate. The time required for the burning rate to attain its maximum value seems to vary only slightly with the fuel type. The maximum flame height and burning rate are found to be the largest for *shrubs* and the lowest for *straw*. The flame temperature and airflow are found to depend on the position in the flame with maximum values near the continuous zone of the flame.

1. Introduction

The increasing number of forest fires around the globe represents a major concern because it endangers seriously the ecosystem by affecting the flora, fauna, the environment, and even human life (Pausas et al. 2008; Vilén and Fernandes 2011). Therefore, a deeper understanding of the combustion dynamics of forest fuels and a better estimation of their combustion characteristics and their correlations are necessary. Many works were already devoted to examining the behavior of these parameters in the case of pool fires (Zabetakis and Burgess 1961; Tarifa 1967; Kung and Stavrianidis 1982; Babrauskas 1983; Koseki and Yumoto 1988; Koseki 1989; Klassen and Gore 1994; Chatris et al. 2001), fire whirls (Martin et al. 1976; Lei et al. 2011; Pinto et al. 2017), and natural fires (Thomas 1963; Dupuy et al. 2003; Sun et al. 2006; Weise et al. 2005).

In this work, an experimental study of the burning characteristics of several Mediterranean forest fuels is realized where the turbulent diffusion flame is subjected only to buoyancy forces. Samples of dead *shrubs*, *Pinus Pinaster*, *eucalyptus*, and *straw* are placed in cylindrical baskets of the same size and ignited to study the effect of the fuel type on fire behavior. The time evolution of the mass-loss rate, flame's height, temperature, and upward air velocity are examined during all the phases of fire development. A systematic comparison between the combustion characteristics and flame properties of these fuels is realized to study their correlations and their role in the flaming combustion behavior.

2. Experimental setup

The samples with the same fuel load (M_f) and initial height ($34\ cm$) are placed in cylindrical containers (with a fixed diameter $d_c = 0.5m$) made of a metallic grid and open on the top. Before each burning experiment, the fuel moisture content is estimated by using a moisture analyzer A&D MX-50 with a resolution of $0.01\ g$. The relative humidity of air and ambient temperature are measured by a thermo-hygrometer. A thermocouple and a Pitot tube are placed one meter above the fuel surface to determine the flame temperature and air velocity at this height respectively (see Fig.1).

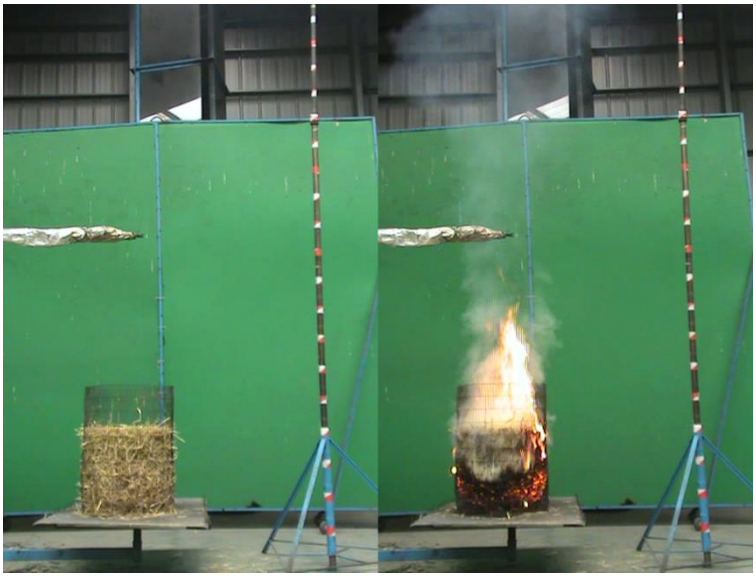

Figure 1. Experimental setup for a straw burning experiment at the Fire Lab of ADAI (Coimbra).

These samples are ignited from the perimeter of the container's bottom under free burning conditions. Three experiments were realized for each fuel to ensure the repeatability of the tests. Each experiment is recorded by an optical video camera Sony FDR-AX53 and a digital camera Canon EOS 550D. The videos are segmented into images by using a Video to JPG Converter software allowing the estimation of the flame heights during the entire duration of flaming combustion. A vertical scale was placed near the container to allow a proper scaling of the flame height values. A digital balance A&D HW-100KGL (10 g resolution) with a frequency of 1 Hz was used to measure the mass evolution of the fuels during their combustion, and its values are recorded on a computer by an RSKey v.1.40 software.

3. Results and discussion

The time evolution of the normalized fuel mass (M_f/M_0, M_0 being the initial mass of the fuel) is shown in Fig.2 for all the fuels considered. The fuel mass decreases towards an asymptotic minimal value M_{fmin}. These curves can be described by the following equation (Drysdal 2011):

$$\frac{\mathrm{d}M_f}{\mathrm{dt}} = -\mathrm{K(T)}.M_f \qquad (1)$$

Where K(T) obeys the Arrhenius law K(T) $\propto$ exp $(-E_A/\mathrm{RT})$. E_A is the activation energy (J/mol) and R the universal gas constant (8.314J /K.mol). This formula is very simple because it accounts only for the water evaporation accompanied by volatiles emission during the pyrolysis of the fuel. It does not take into consideration other mechanisms such as the scission and formation of molecules (David 1975). Equation (1) is also a relaxation equation that leads to an exponential relaxation if the temperature is constant. The curves shown in Fig.2 seem to exhibit two distinct relaxation regimes. For short times, the fuel mass relaxes very rapidly through time and characterizes the growth phase of the fire. Relaxation becomes anomalously slower during the decay phase of the flame (long times). The crossover between these two processes occurs when the flame is fully developed. Moreover, this tendency to equilibrium seems to depend on the fuel type, it is faster for *shrubs* than for *Pinus Pinaster* needles, *straw*, and *eucalyptus* leaves.

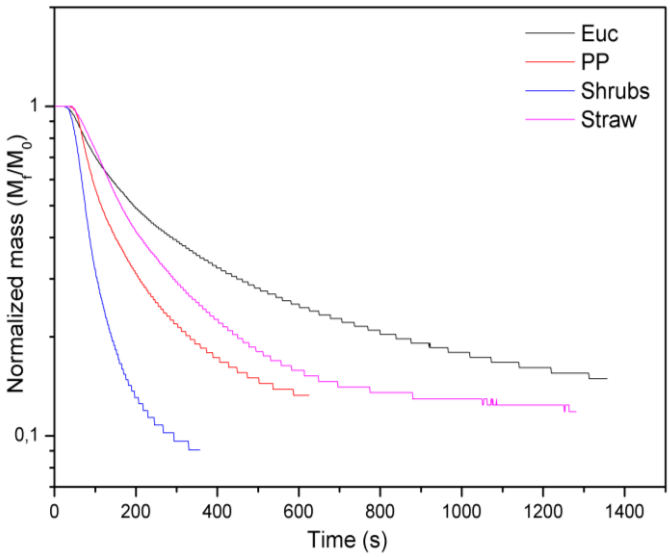

Figure 2. Temporal evolution of the normalized fuel mass for several dead forest fuels.

The mass-loss rate $\dot{M}_f$ is a measure of the rate at which the fuel is consumed, and is a key element to understanding the combustion dynamics. It is deducted from the balance data and its averaged values are estimated at regular intervals (five seconds). The results illustrated in Figs.3 show the same temporal trend for the mass-loss rate, the flame's height, temperature, and the flame-induced air velocity. Fire development is as follows: after ignition, the flame spreads vertically very rapidly along the lateral fuel surface, where a consistent flame begins to form accompanied by a horizontal spread of the flame through the upper surface of the fuel. Afterward, the growth phase begins where the mass loss rate, flame's height, temperature, and upward air velocity increase continuously and the fire uses the available combustible and oxygen to grow until it attains its peak. Then, the flame becomes fully developed and its height is maximum l_{max}. This is followed by a decay of the flame height and mass-loss rate over a relatively long period that characterizes the decay phase. As the thermocouple and pitot tube are placed at the same position to the initial fuel surface, the flame temperature and the vertical motion of gas particles are measured at different relative positions of the flame. Indeed, according to McCaffrey, the flame is subdivided into three regions (McCaffrey 1979):

- The continuous zone that begins at the fuel surface and where the velocity of gas particles increases with height ($v \propto \sqrt{z}$) and the temperature is constant ($T \propto z^0$).
- The intermittent region (the pulsating part of the flame that begins at the end of the first zone) where v is approximately invariant and the flame temperature decreases inversely with height ($T \propto z^{-1}$),
- The thermal plume (situated above the flame) where the gas velocity begins decreasing with height ($v \propto z^{-1/3}$) and the smoke temperature continues falling with height at a faster rate ($T \propto z^{-5/3}$)

Hence, the flame temperature and gas velocity reach their maximum values when the flame is fully developed because they are measured at the closest position to the continuous zone of the flame (see Fig.3a where $l_{max} > 1m$ is much higher than the thermocouple position for all the fuels studied). Since $l < 1m$ in the first part of the growth stage and the last part of the decay phase, the temperatures and velocities measured in these periods are those of the thermal plume and not the flame itself. Therefore, the convection coefficient, which is related to air velocity varies with the vertical position in the flame.

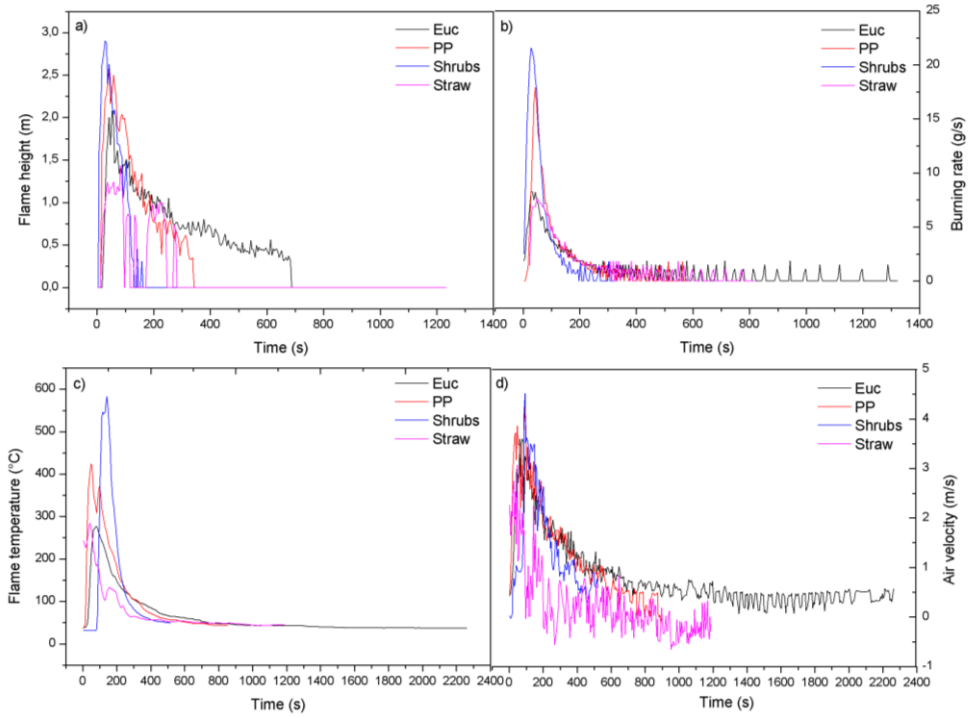

Figure 3. Temporal evolution of: a) flame height (m), b) mass loss rate (kg/s), c) flame temperature (°C), d) air velocity (m/s).

The time t_{max} required for the mass-loss rate to attain its maximum seems to be independent of the fuels $t_{max} = (32.5 \pm 10)$s.There is a time delay Δt between the time at which the burning rate is maximum ($\dot{M}_{fmax}$) and that at which the flame height is maximum (l_{max}). This delay has been found to depend linearly on the fuel moisture content (Sun et al. 2006). The moisture content may not be the only cause of delay since even for completely dried fuels, Δt would still not vanish because of the time required for gas molecules to diffuse through the porous fuel before contributing to the flame. In this work, the moisture content of the samples is around $8 - 10\%$ for all experiments, Δt seems to not change significantly (within statistical errors) for the dead fuels considered (besides a slight increase for straw) as shown in Table 1 where he maximal values of the flame's geometrical and physical characteristics are summarized. The maximum flame height and mass-loss rate are the largest for *shrubs* and the lowest for *straw*. This may be due to the heat flux absorption of the fuel which is related to its optical length, and thus to its packing ratio and surface-to-volume ratio. An extensive analysis of the heat transfer mechanism through the fuels considered is necessary.

Fuel type	Heat of Combustion (kJ/g) [13]	Maximum flame height (m)	Maximum mass loss rate (g/s)	Maximum temperature (°C)	Maximum air velocity (m/s)	Residence time (s)	Δt (s)
Eucalyptus	22.5	1.9 ± 0.3	10 ± 2	292 ± 30	3.9 ± 0.4	845 ± 260	7 ± 6
Pinus Pinaster	13.5	2.5 ± 0.3	18 ± 1	397 ± 19	4.2 ± 0.2	242 ± 83	8 ± 8
Shrubs	16.9	2.9 ± 0.1	24 ± 2	488 ± 78	4.9 ± 0.4	148 ± 35	13 ± 8
Straw	11.7	1.5 ± 0.3	7 ± 1	334 ± 34	3.3 ± 0.4	296 ± 67	25 ± 7

Table 1. Maximum values of some burning characteristics of various forest fuels.

The flaming combustion duration defines the residence time of the flame t_{res}. In Table 1, the maximum flame height (and maximum mass-loss rate) decreases as the residence time t_{res} increases for the fuels considered with a saturation tendency for *Eucalyptus* and *straw*. This is in qualitative agreement with the experimental results found in the case of fire whirls (Pinto et al. 2017). Note the very large residence time of *Eucalyptus*,

which is also characterized by a large heat of combustion. Therefore, the total heat released is much larger for *Eucalyptus* leaves despite their heat release rate being smaller than that of *Shrubs*.

4. Conclusion

An experimental study of the burning characteristics of several dead forest fuels was realized. Samples of dead *Eucalyptus, Pinus Pinaster, straw,* and *shrubs* with the same fuel load were placed in cylindrical baskets and ignited from the bottom. Time evolution of the combustion parameters was found to follow the same trend for all the fuels considered. In the growth phase of the flame, the fuel mass-loss rate, flame's height, temperature, and upward air velocity increase rapidly, then they decrease over a relatively long period characterizing the decay phase. The crossover between these two processes occurs when the flame is fully developed, and the time required for the burning rate to attain its maximal value was found to be the same for all the used fuels. The flame heights and mass loss rate are the largest for *shrubs* and lowest for *straw*. The flame temperature and air velocity seem to depend on the position in the flame, which implies that the heat transfer mechanism varies in the flame.

Keywords

Decision-making; Stress; Training; Biosignals; fMRI

Abstract

Day-to-day we have to make choices. When it comes to critical decisions which may lead to impactful and irreversible consequences, the understanding of the decision-making process is highly relevant but scarcely explored. In the present project, we aim to understand decision-making in the context of firefighting and to study how neurocognitive control and stress management strategies affect decision-making, while also addressing coping responses.

We present here the preliminary results from a cohort of 13 firefighters. We used a functional magnetic resonance brain imaging coupled with biosensors while firefighters played a dilemmatic decision-making task of structural firefighting.

We found brain regions, including the ventromedial and dorsolateral prefrontal cortices and angular gyrus, showing a parametric pattern of activation during the decision phase, i.e. the lower the risk of house collapsing, the higher the neural activity in these areas. This suggests that these regions are processing that risk information and signalling the chances of being successful in the rescue phase. We also found that the power in high frequencies of the pulse rate variability was higher when they decided to enter for the rescue. It is suggestive that deciding not to enter for rescue causes an increase in arousal, which may be related to the expectation about the victims' survival. Concerning coping strategies, we found that active coping used in personal context was significantly correlated with the age and the years of experience of firefighters.

We aim to understand if this pattern of brain activity reflects the coping strategies and if, in turn, it is reflected in the physiological signals we measure. Our results provide here preliminary evidence for a role of specific brain regions in decision-making under critical conditions, with concurrent physiological responses. In the future, we will investigate whether the decision processes in firefighters are different from non-firefighters, and we will address if post-traumatic stress disorder impairs decision-making in this context. Biosignals will also be used in a second phase of the project to inform virtual reality training systems. This may help developing optimal neurocognitive control and better coping strategies to deal with stress.

1. Background

Decision-making implicates making choices based on the balance between associated risks and possible rewards(Shad et al.,2011). This higher order cognition skill involves a complex set of processes that includes different steps of building preferences, choosing behaviours, performing actions and evaluating the outcomes(Ernst&Paulus,2005).

Previous research from our group has pointed out the importance of optimising decision-making and controlling emotions effectively during intensely stressful experiences(Almeida et al.,2015;Banca et al.,2015). This holds particular pertinence in the context of firefighting, wherein poor decisions can bring devastating consequences.

Studies on decision-making during firefighting are scarce despite their potential relevance, mainly in which concerns optimal neurocognitive control and stress management. While some manage to properly deal with these experiences, others adopt maladaptive responses and are at a high risk of developing stress-related disorders and other complications(Sindhu et al.,2020). Dysfunctional coping patterns of response are associated with higher levels of stress and trauma(Fonseca et al.,2020;Skeffington et al.,2017).

Stressful events that are perceived as potential threats can trigger not only emotional but also physiological responses that can be measured by biosensors and functional magnetic resonance imaging (fMRI, an approach that measures in an indirect way the neural activity)(Lee et al.,2022).

It is our goal to study decision-making and stress responses under extreme scenarios of uncertainty in firefighting. We developed a dilemmatic task in the context of strategic decisions considering fire management/victim rescue and self-protection, involving decisions that encompass rational reasoning, risk perception and emotional control. We therefore used fMRI to investigate the neural correlates underlying the decision process and error monitoring in firefighting. Further, we coupled biosensors to measure physiological stress aiming at understanding how different variables influence physiological responses and how they relate with the emotional perception of the firefighter.

We hypothesize that the process of decision in firefighters is associated with specific brain activation patterns and with changes in biophysiological responses to stress, including in pulse rate variability. A further question of our interest is the firefighters' use of coping responses to better understand their resource availability, the level of risk and protection, and the main strategies adopted by these professionals in unpredicted critical scenarios in which immediate decisions and prompt actions are needed.

Here, we provide some preliminary data of our ongoing Project.

2. Methods

This study was approved by the Ethics Committees of the Faculty of Medicine of the University of Coimbra, of the Coimbra Hospital and University Center (CHUC) and of the Regional Health Administration (ARS Centro), and was conducted according with the Declaration of Helsinki. All subjects gave written informed consent.

2.1 Sample characterization

We included a total of 13 right-handed(Espírito-Santo et al.,2017) firefighters (10 males, 3 females), with a mean age of 35.92±9.16 years. Inclusion criteria comprised (1) age between 18 and 75 years and (2) active participation in firefighting. We excluded participants with (1) diagnosed neurological or psychiatric disease, (2) visual or auditory impairments that compromised tasks performance, (3) substance (drugs or alcohol) dependence and (4) contraindications to magnetic resonance imaging. None of the participants reached the cut-off in the Portuguese version of PTSD Checklist for DSM-5 [PCL-5;(Ferreira et al.,2016a)], based on events (identified using Ferreira et al.,2016b;Maia et al.,2016) which ruled out the presence of post-traumatic stress disorder (PTSD). Nine firefighters were volunteer workers and four were professionals, ranging in years of experience from two to 34 years as a firefighter. Our sample worked a mean of 25.15 weekly hours in firefighting activity (ranged from six to 52 hours).

2.2 Coping strategies

The Portuguese version of Brief Coping Orientations to Problems Experienced Inventory [Brief-COPE;(Pais Ribeiro&Rodrigues,2004)] was applied to address dispositional coping strategies to stressful events and problems that occurred, separately, in personal life and during firefighting activity. Scores were obtained with a 4-point Likert scale, ranging from 0 to 3 points in each item, corresponding to lower or higher frequency of actions. In this work, we sought to analyze three distinct coping strategies (subscales Active, Planning and Behavioral disengagement) and three patterns of coping styles [Problem-focused, Emotion-focused and Dysfunctional (Cooper et al.,2008)].

2.3 Functional imaging and biosignals

Magnetic resonance imaging was performed on a 3T Siemens MAGNETOM Prisma Fit scanner (Siemens, Erlangen), equipped with a 64-channel birdcage head coil. Structural images of the brain were obtained with

the Magnetization-Prepared two Rapid Gradient Echo (MP2RAGE) sequence [voxel size=1×1×1mm3; FOV (field-of-view)=256×256mm2; 192 slices]. We acquired three fMRI runs using a multi-band accelerated echo planar imaging (MB-EPI) sequence [multi-band acceleration factor 6; phase encoding: anterior-posterior; TR=1000ms; TE=37ms; FA=68°; voxel size=2×2×2mm3; FOV=200×200mm2; 72 axial slices].

During fMRI, participants were performing a decision-making task following an experimental paradigm with mixed block event-related design [as in Banca et al.(2015)]. An initial scenario (Fig.1) was presented with a burning house, indicating the number of people that were inside the house [1 adult or 1 family], the risk (%) of the house to collapse and the probability (%) of victims saving themselves without external help. Firefighters had to decide, based on these data, if they would enter to try saving the victims, knowing that if unsuccessful, they could also "die". After each decision, the outcome was presented showing what happened to the victims, the firefighter and the house. The stimuli were presented on an LCD monitor and participants selected responses with a Hybridmojo MR-compatible joystick. This was repeated for 20 trials in each of the 3 runs.

Figure 1- Initial scenario of the fMRI trials.

Pulse Rate Variability (PRV) was computed from the blood volume photoplethysmography (PPG) recordings acquired through the Physiological Measurement Unit (PMU) of the MRI scanner with a sampling rate of 400Hz. To reduce noise contamination, the PPG signal was bandpass filtered using a 6^{th} order Butterworth filter with a lower and higher cut-off frequencies of 0.5Hz and 20Hz. The clean PPG signal was then used to compute the PRV by first identifying the PPG pulse peaks, computing the interbeat intervals (IBI), and using a cubic spline interpolation to obtain a uniformly sampled time series with a new sampling frequency of 4Hz. The PRV from each run was then divided into 8s segments, comprising the entry/no entry decision block of the task, and the relative power in the High Frequency (HF) band (0.15–0.4Hz) of the PRV was extracted as a marker for each of the segments using the Fast Fourier Transform algorithm.

2.4 Data analysis

A significance level of 0.05 was adopted in all statistical tests. We did not correct for multiple comparisons due to the preliminary and exploratory nature of these analyses.

Statistical analyses were performed using the IBM SPSS statistics software (v.27). The sociodemographic variables were explored through descriptive analyses. We used Wilcoxon test to investigate within-group differences in coping strategies in life versus firefighting contexts. The correlations between age, years of firefighter activities and workload (hours per week) and coping strategies (used in both personal and firefighting activity contexts) were analysed with Kendall rank correlation coefficient.

FMRI data analyses were fully conducted in the BrainVoyager 22.0 software (Brain Innovation, Maastricht, the Netherlands). We applied pre-processing steps (slices-scan time correction, 3D head-motion correction, temporal high-pass filtering and geometrical distortions correction) and normalized the data to Montreal Neurological Institute (MNI) space. We performed General Linear Model (GLM) analysis for obtaining whole-brain statistical maps at the group level (cluster threshold=20 voxels).

PRV data were analyzed in Matlab (R2021a, MathWorks, USA). Observations were split into enter or not enter, and the balance of the sample sizes was obtained through random elimination of samples belonging to the bigger group. The two conditions were tested against each other using the Wilcoxon signed-rank test.

3. Results and Discussion

We started by evaluating whether the coping style was different comparing firefighters' strategies used in personal contexts and during the activity as a firefighter and found no significant differences ($p>0.05$, $n=12$). Active coping strategies used in personal context were significantly correlated with age ($\tau=0.568$; $p=0.016$, $n=12$) and years of experience as firefighters ($\tau=0.493$; $p=0.034$, $n=12$) (Fig.2). Active coping involves the ability to take active actions to suppress the stressor or to minimize or remediate these effects(Carver et al.,1989). We suggest that older individuals accumulated learning to improve mechanisms of adaptive coping to deal with stress, using active coping as a dispositional tendency in their lives. Concerning coping strategies related to firefighting activity, we did not find any correlation with age or years of firefighting ($p>0.05$). Firefighters are trained to take immediate actions and decisions early in their activities. We hypothesize this growth ability may be transposed to personal events later in life. Also, existing literature suggests the protective effect of resilience in firefighters and experience of personal growth following stress-related events(Sattler et al.,2014).

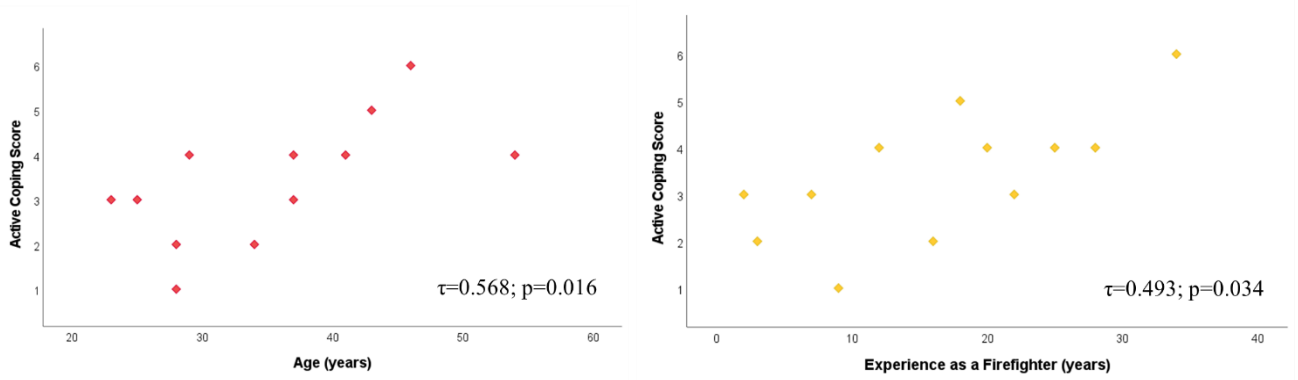

Figure 2- Correlations between active coping score and age (left) and years of experience in firefighting (right).

We studied, with an fMRI task, which brain regions are involved in the decision-making process under the context of firefighting. In Fig. 3 we present brain activity patterns during the decision phase. A parametric analysis showed that the lower the probability of the house collapsing, the higher the activity in the ventromedial prefrontal cortex (vmPFC) ($p<0.05$). We suggest that the activation of vmPFC was related to risk perception, given its association with valuation and risk assessment(Spaniol et al.,2019). The right dorsolateral prefrontal cortex (dlPFC) also showed a significantly greater activation for more favorable probabilities ($p<0.05$), which might possibly be explained by greater risk-taking behavior that was found in the literature to be associated with an increase in the activity of dlPFC(Leota et al.,2021). A role of angular gyrus (AG) in both decision-making, visuospatial attention(Studer et al.,2014) and number processing(Seghier,2013) has been recognized. In this work, the right AG was significantly more active when the risk was smaller ($p<0.05$). We hypothesize that when firefighters have more chances of being successful, they spend more efforts in deciding if they will take the risk.

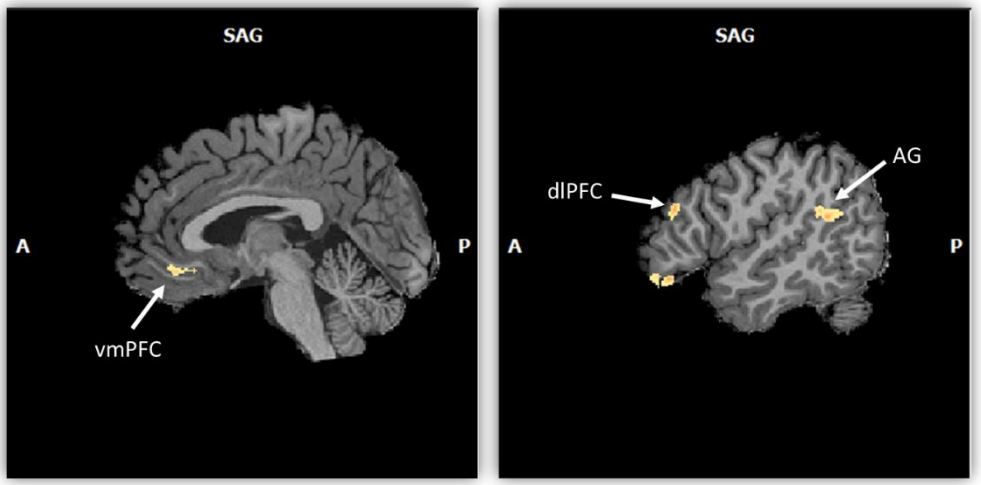

Figure 3- FMRI images showing brain parametric activation associated with lower probability of house collapsing (p<0.05).

The preliminary analysis of the PRV of the participating group of firefighters revealed a significant higher value for the relative power in the HF band of the PRV for the entry decision (median=0.38) compared to the no entry decision (median=0.35), Z=2.59, p<0.01. The distribution of values for this marker for both conditions is represented in Fig. 4.

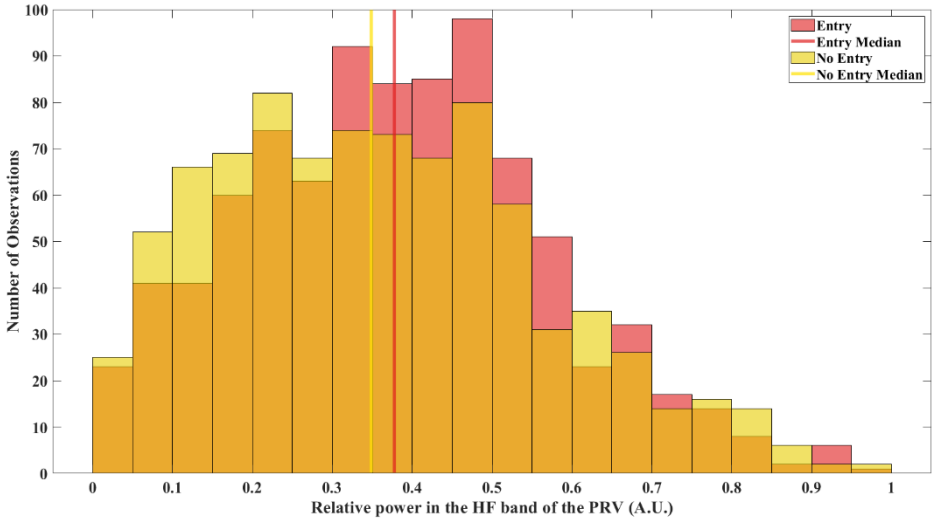

Figure 4- Distribution of values for the relative power in the HF band of the PRV for the entry decision (in red) and no entry decision (in yellow) (p<0.01).

States of stress and anxiety seem to be accompanied by a decrease in HF power(Shaffer&Ginsberg,2017). The lower values found for the HF marker for the no entry decision hint at a decrease in parasympathetic activation and are potentially related to an increase in physiological arousal. A possible interpretation is that choosing not to endanger his/her own life causes a greater expectation in the firefighter to know whether the victims survived or not. Another interpretation, falling in line with Fooken and Schaffner's(2016) suggestion, is that risk aversion in dilemmatic situations is associated with higher arousal, while risk-taking is accompanied by moderate physiological responses. This could suggest that less emotionally involved individuals are prone to taking more risks when confronted with a dilemma.

These results may have potential implications for understanding critical decision processes in firefighters, more directly in structural firefighting contexts. Our findings encourage future works addressing decision-making in different scenarios, such as wildland firefighting.

4. Conclusions

Our results support the relevance of studying decision-making in extreme conditions such as firefighting, from a multimodal approach. These preliminary data suggest an involvement of specific frontal brain regions, that can also be translated into physiological stress and coping strategies. In a future work, we will investigate whether decision processes in firefighters are different from the global community and address if post-traumatic stress disorder impairs effective decision-making. Biosignals will also be used in a second phase of the project to inform virtual reality training systems about the physiological state of the firefighter during firefighting simulation.

Pool fire, Fire Plume, Vegetation, Prescribed burns

Abstract

Prescribed burns are an essential tool of fire management to reduce the impact and occurrence of wildfires. While managing prescribed burns, the smoke trajectory and downwind exposure to smoke are intimately coupled with the smoke production dynamics and the development of the fire plume in the vicinity of the fire front. In turn, the fire plume development is strongly coupled to fire behavior and the flow environment near the fire. This work aims at understanding fire behavior and plume development while interacting with vegetation at the large laboratory scale through experiments and modeling. In order to investigate these coupled processes, initially, flame and plume behavior from a static fire source was characterized. A rectangular pool fire fueled by diesel was used and point measurements of flow, temperature, and heat flux have been recorded. The mass burning rate was measured using a load cell. K-type thermocouples and bi-directional pressure probes have been used for measuring the velocity and temperature, respectively in the flame and plume zones. These data are used for validating a numerical model, the Fire Dynamics Simulator (FDS), for simulating pool fires and the model is subsequently used for predicting the plume interaction with vegetation. A Douglas fir tree, whose properties are well defined in literature, was used as vegetation. The Lagrangian particle model available in FDS was used to model the tree, which was represented with regular shape and size. It had foliage and different classes of wood split based on typical size (diameter) range. The bulk density of the tree was varied to replicate the systematic and controlled variation of the flow obstruction encountered by the plume and to provide realistic predictions of velocity, temperature, and heat flux within the vegetation. In the future, experiments with vegetation located in the plume region will be conducted to validate the numerical predictions.

1. Introduction

Prescribed burns are one of the commonly used fire management tools to reduce the impact and occurrence of wildfires. During prescribed burns, the fire and plume generated from the combustion of the surface fuel (such as pine needles) interacts with the raised vegetation. The fire and plume behavior are influenced by the non-burning raised vegetation through drag and heat transfer and they also have an impact on the raised vegetation when heating it. Similarly, the variability in vegetation also affects the flow, fire, and plume dynamics. In order to analyze such complex phenomena, the fire, which is the source of the plume, must be well characterized. Pool fires were chosen for study as they mimic the fire environment in prescribed burns and are relatively easy to control, while avoiding additional complexities due to fire spread. Generating a volume of smoke at the laboratory scale that is relevant to the field scale requires the use of medium and large-scale pool fires. Several works have been reported earlier on small scale pool fires (Prasad et al., 1999; Attar et al., 2013; Wu et al., 2020), which are typically less than 0.3 m in diameter. However, only limited research has been conducted on medium and large-scale pool fires (Wen et al., 2007; Sudheer et al., 2013; Xin et al., 2005; Wahlqvist et al., 2016; Stewart et al., 2021). These fires fall either in the transition or turbulent regime and are dominated by radiative heat transfer. Wen et al. (2007) conducted experimental and numerical study on medium-scale methanol pool fires. Temperature and velocity measurements were used to validate a numerical model available in FDS. (Sudheer et al., 2013) analyzed the temperature distribution and emissivity of gasoline pool fires with varying pool diameters (0.3 - 1 m). FDS was able to accurately predict the centerline temperature distribution and heat flux measurements for all the cases. Wahlqvist & van Hees (2016) used FDS to predict the mass loss rate of heptane pool fires with the inclusion of heat feedback from external sources, such as walls, and the oxygen concentration near the pool. Stewart et al. (2021) numerically investigated the ability of FDS to predict

medium and large-scale open pool fires of several hydrocarbon fuels including gasoline and diesel. Results showed that FDS predicted the three-step transient burning pattern of: fire growth, quasi-steady burning, and extinction, as observed in the experiments. However, for higher order hydrocarbon fuels such as diesel, when the pan is fully covered with flame, the model overpredicted the burning rate.

It is clear that there is a significant gap in reporting the flame characteristics and dynamics of medium and large-scale pool fires. The transient nature of the flame affects the plume dynamics, entrainment, and mass burning rate. Therefore, it is essential to characterize the pool fires before investigating their interaction with vegetation. Furthermore, the interaction of vegetation with the plume and its impact on the fire environment have not been investigated yet. In this work, point measurements of flow, temperature, and heat flux at various locations in the plume and flame zones were carried out to validate a numerical model for predicting the dynamics of the flame and buoyant plume over a static pool fire. The validated model was then used with raised vegetation to analyze its influence on flow and plume dynamics relevant to a prescribed burn scenario.

2. Experimental methodology

A rectangular pan having a dimension of 68 cm × 63 cm × 6.3 cm was used to generate a diesel pool fire. Diesel flames are highly sooty, and it facilitates the visualization of plume during its interaction with the raised vegetation in the lab and field scale experiments. The rectangular shape has been chosen to allow creating larger fires in the future, by attaching multiple pans together. Figure 1 presents a schematic of the experimental setup. The pan was filled with 2 gallons (7.56 liters) of fuel to provide a steady burning time of 8 to 9 min. The pan was placed over a load cell with an accuracy of 0.1 g for measuring the mass loss rate of the burning fuel. K-type thermocouple with a bead diameter of 0.5 mm were used for measuring the temperature in the flame and plume zones. Velocity measurements were carried out using bi-directional pressure probe. Heat flux sensors (both convective and radiative) were used for measuring the convective and radiative heat flux from the flame. The center of the pool surface was taken as origin. The thermocouples and bi-directional pressure probes were located along the vertical direction (z-axis) 0.5 m from the pool surface and in arrays up to 3.5 m (see Fig. 1.a), while the heat flux sensors were located at 1, 2 and 3 m from the fuel surface and were offset by 1 m in the y-direction (not shown on Fig. 1.a). In the horizontal plane (x-axis), four arrays of thermocouples (a total of seven thermocouples spaced by 15 cm in each array) were fixed at heights of 1, 2, 3, and 3.5 m from the pool surface. Similarly, two bi-directional pressure probes were located on each horizontal plane (8 in total) spaced 15 cm apart from either side of the central probe. Since the boiling point of diesel quite high, a small amount (100 ml) of gasoline was added to the pool prior to ignition in order to facilitate the process. The pool ignited within two seconds when using a propane torch. Figure 1.b shows a flame photographed during the steady burning regime.

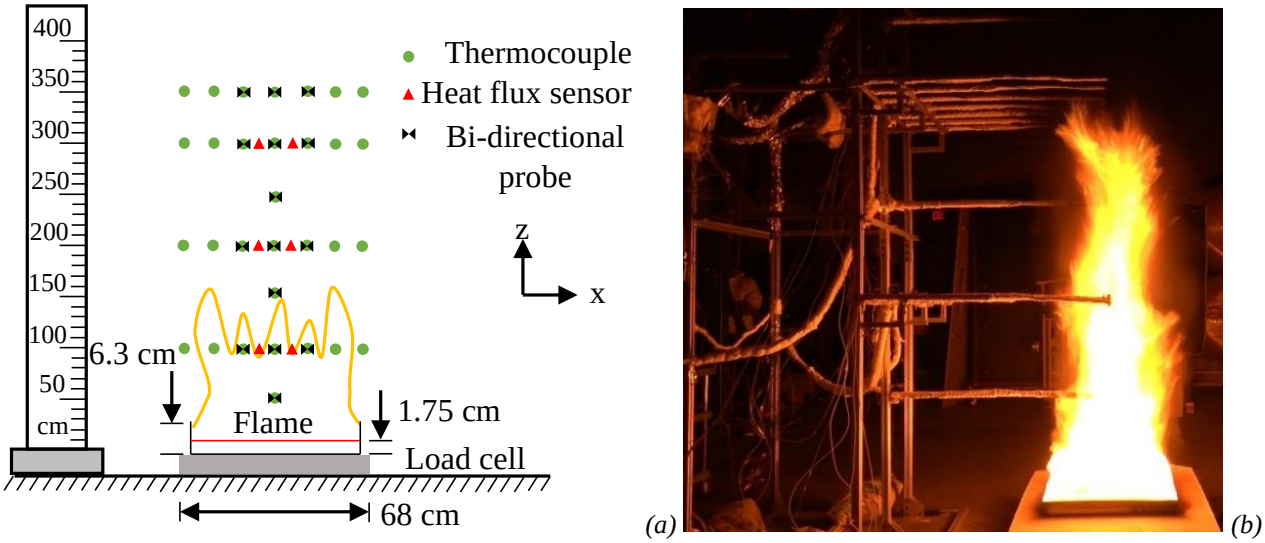

Figure 1- (a) Schematic of the experimental setup (b) flame photograph during steady state burning

3. Numerical approach

3.1. Computational domain

Numerical simulations were carried out using Fire Dynamics Simulator (FDS v6.7.7). Figure 2 shows a schematic of the computational domain used in the simulations. The dimensions of the domain were 6 m × 6 m × 8 m. The bottom boundary was taken as an adiabatic wall. All other boundaries were open to atmosphere. In case of a reverse flow, ambient air (O_2 - N_2: 23.3% - 76.7%, by mass) at a temperature of 20ºC entered the domain through the open boundaries. Dodecane, a surrogate of diesel was used as the fuel. The properties of diesel, adapted from Stewart et al., (2021) were used in the simulations. For simulations with vegetation (Fig. 2.b), the geometrical and thermo-physical properties of Douglas fir tree reported in Mell et al. (2009) were used. The domain was split into several multi-block meshes with uniform grid spacing in the z-direction (within each block). The total number of cells in the domain was around 2.8 million. Numerically, the pool was ignited by giving a constant heat flux of 300 kW/m^2 at the fuel surface to replicate the ignition time observed in the experiments. With this heat flux value, the pool ignited within 3 s.

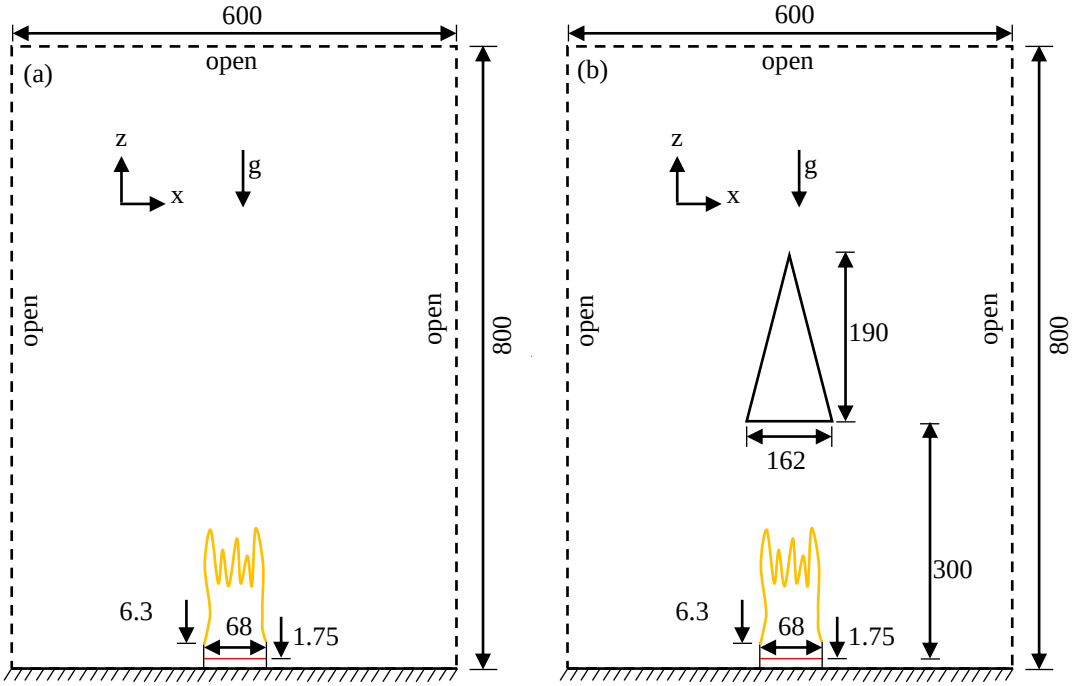

Figure 2- Schematic of the computational domain with (a) a diesel pool fire and (b) a Douglas fir tree located above the pool fire (the trunk was not represented) – Dimensions are in cm

4. Results and Discussion

Figure 3 presents the comparison of the predicted mass loss rate and temperature profiles with the experimental values, along the centerline at different heights above the fuel surface. In the experiments, first gasoline at the surface of the pool ignites and preheats the diesel pool to the boiling temperature. The flame height is low during this stage and the experimental mass burning rate (Fig. 3.a) gradually increases to an average steady state value of around 0.011 kg/s. It takes around 60 s to achieve steady state burning from the start of ignition (t = 0 s) and the average mass burning rate remains constant at 0.011 kg/s during the steady burning regime. It lasts from t = 60 s to t = 580 s, for around 9 min. The burning rate then decreases and the flame extinguishes 2 min after the end of the steady burning regime.

In the simulations, the pool is ignited 3 s after ignition and the mass burning rate quickly reaches steady state (average around 0.0115 kg/s). Then, it slowly increases to 0.013 kg/s with a further increase in time (300 s). After t=300 s, the burning rate rapidly increases to 0.02 kg/s and then steeply decreases until flame extinction. The difference between the experimental and predicted mass burning rate is due to (1) the difference in the ignition process, (2) the difference in fuel properties used in the experiments and in the model (as reported in Stewart et al., 2021), (3) the neglection of internal convection within the pool in the model, while it can be quite

significant in this case because of the adiabatic boundary. The model underpredicts the temperature profiles at z = 0.5 m, however, the experimental trend is captured (see Fig. 3.b). The model accurately predicts the temperature in the flame zone (z = 1 m) and overpredicts it in the intermittent (z = 1.5 m), and plume zones (z = 2.0 and 3.5 m).

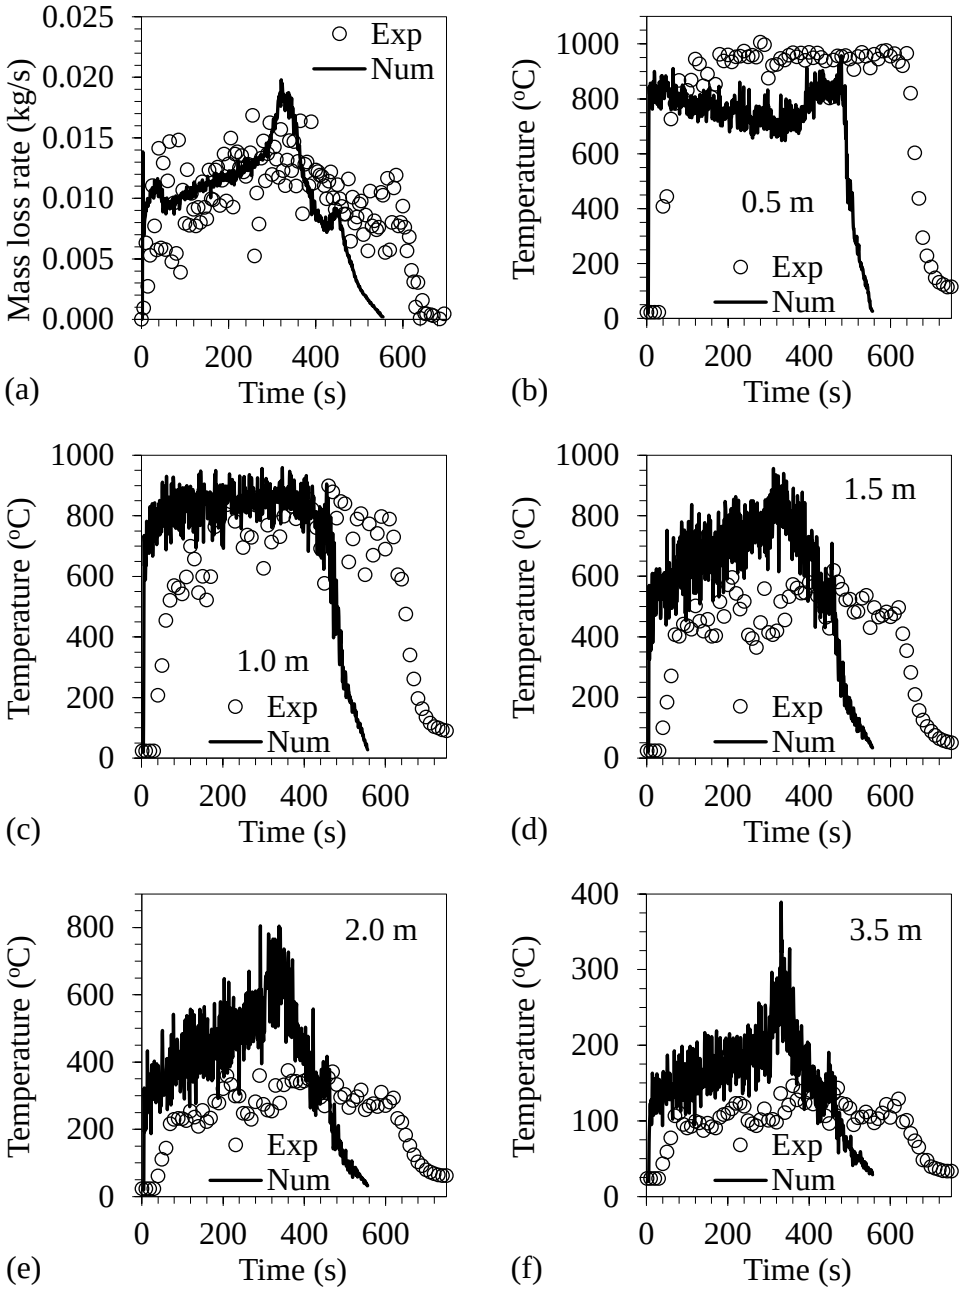

Figure 3- Comparison of predicted (a) mass loss rate and temperature profiles at (b) z=0.5 m, (c) z=1.0 m, (d) z=1.5 m, (e) z=2.0 m, (f) z=3.5 m to experimental data

Figures 4.a and 4.b show the comparison of temperature and water vapor mass fraction contours for cases with pool fire and pool fire with tree. The contours are plotted at 200 s after the start of simulation. The temperature in the flame zone is almost the same in both cases. However, there is a significant difference in the plume temperature above 2.5 m. For the case without tree, the plume temperature reduces to 100ºC - 150ºC above 4 m due to air entrainment and diffusion. On the other hand, for the case with tree, the temperature within the tree is around 250ºC – 350ºC. This results in moisture evaporation (and subsequent pyrolysis of vegetation) as indicated by higher values of water vapor mass fraction contours within the tree (0.02). Figures 4.c and 4.d show the velocity vectors and contours of dodecane and the oxygen mass fraction for these cases. The air entrainment and the acceleration of product gases due to buoyancy in the flame zone are clearly visible. In the vicinity of

the tree, a significant portion of the plume with sufficiently high velocity passes through the tree. Then, the flow velocity reduces due to drag by the fuel particles. Near the edge of the tree (base of the cone), a small portion of the plume is deflected away (as for a flow around an obstacle). However, the drag resulting from this behavior will strongly depend on the packing ratio inside the tree. The oxygen mass fraction within the tree is in the range of 0.16 - 0.23. The oxygen mixes with the pyrolysis gases but will not ignite the tree since the temperatures are not high enough. This justifies the distance chosen for locating the tree above the pool fire, which in this case is 3 m, as the objective of prescribed burns is to avoid burning or harming the trees.

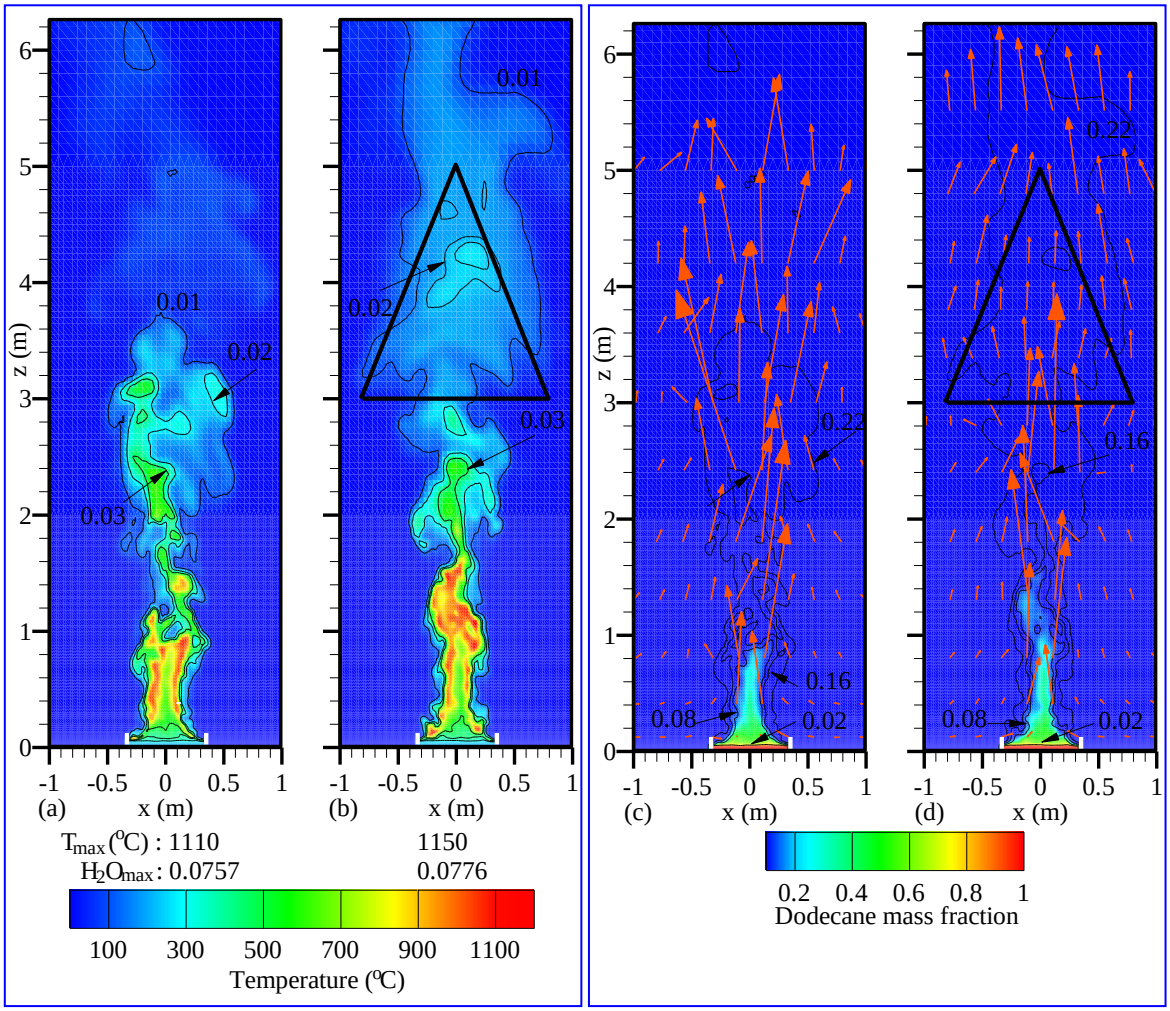

Figure 4 - (a), (b) Contours of temperature (colored) and water vapor mass fraction (lines) (c), (d) Contours of dodecane mass fraction (colored) and oxygen mass fraction (lines) with velocity vectors. The white lines represent the boundaries of the pan, and the triangle represents the Douglas fir tree.

5. Conclusions

An experimental and numerical study has been conducted as the first step of a larger study of the interaction between plume and vegetation during prescribed burns. The predicted mass burning rate and temperature were compared with measurements in a diesel pool fire. The model predicts a higher mass burning rate due to (1) the difference in ignition process, (2) the difference in fuel properties of diesel used in the experiments and that reported in the literature, which was subsequently used in the model, and (3) absence of sub-models to simulate convective heat transfer within the pool. The temperature is overpredicted in the intermittent and plume zones. Even though discrepancies exist, the model reveals some of the key processes such as moisture release within the vegetation which could be difficult to measure due to the presence of water vapor in the plume.

In the future, trees of various size and shape will be placed over the pool fire and point measurements of temperature, velocity, and heat flux will be recorded to model the drag and heat transfer within the vegetation. These sub-models will be included to validate and improve the accuracy of the numerical model.

Abstract

This work presents the preliminary results obtained from the first set of six field experiments conducted within the scope of a project focused on systematically evaluating the reliability of fire pattern indicators used in wildland fire investigation. The field experiments were conducted in the Pinelands National Reserve (NJ, USA) during the conduction of prescribed burns. This allowed studying the generation of fire pattern indicators in a realistic scenario and under controlled conditions. During the experiments, a series of sensors were used to determine the heat exposure that induces the appearance of fire pattern indicators over planted supporting elements. The preliminary results suggest that fire pattern indicators are a valuable and valid tool for the determination of the area of origin of a fire if they are used holistically. Further results and analysis to be presented in the full version of this work include fire spread and the characterization of the heat exposure that generates the fire pattern indicators observed in the complete experimental campaign.

1. Background and Motivation

The increased frequency of catastrophic wildfire events is projected to continue over the next century causing dramatic impacts to human and ecological systems (e.g., loss of life, health impacts, property, and economic losses, lost ecological function, and resilience) (NIFC, 2022; Sample et al., 2022). The rapid expansion of the wildland-urban interface and the effects of climate change have increased the frequency and intensity of these events, highlighting a specific need for fire behavior and effects research, where human and ecological systems intersect to understand anthropogenic roles in unwanted wildland fire ignitions (Maranghides & Mell, 2013; Hammer et al., 2007). Scientific gaps in the basis for standard approaches used for studying ignitions in the field limit our understanding of the reliability and scientific integrity of these approaches and justify a need for new science to either support existing methods or guide improvements.

Field studies of unwanted wildland fire ignitions focus on identifying and evaluating physical fire pattern indicators (FPIs) within a fire's footprint as a forensic means of locating a fire's exact point of origin and ignition source. From this perspective, ensuring the accurate determination of the origin and causes of wildland fires is paramount, and thus standardized methods are provided to fire investigators. In the United States and worldwide, the National Fire Protection Association's Guide for Fire and Explosion Investigations (NFPA, 2021) and the Guide to Wildland Fire Origin and Cause Determination of the National Wildfire Coordinating Group (NWCG, 2016) are the primary documents that provide a systematic method for the conduction of this type of investigation and rely on fire pattern indicators. As per this guide, indicators are commonly divided into two classes: macroscale and microscale FPIs (NWCG, 2016). Macroscale FPIs are associated with large objects and are easily noticeable, for example, the angle of the charring displayed by a tree trunk. On the other hand, microscale FPIs are only observable by getting up close to an object, such as the protection shown behind a

pinecone. The interpretation of microscale FPIs typically becomes more important as investigators work closer to the area of ignition.

Very few scientific studies have attempted to assess the reliability of FPIs systematically, despite their primary importance in fire investigations (Simeoni et al., 2017). To begin addressing this gap, we present a project to develop a novel experiment-based dataset that will be used to assess the reliability of FPIs related to fire behavior and local fire conditions.

To generate a statistically robust dataset, experiments will be conducted in two different settings: field and laboratory. In the field, prescribed burns will be used to study the creation of FPIs in realistic but controlled fire conditions (Mueller et al., 2017). In this setting, it will be possible to observe the generation of most indicators, paying attention to the macroscale FPIs that appear on vegetation and landscape features. Furthermore, microscale FPIs will be identified, and the thermal exposure conditions needed to produce them will be quantified. After the field experiments, laboratory experiments will be conducted using the information gathered in the field. A wind tunnel will be used to study the effects of wind, slope, and vegetation layout on the creation and reliability of FPIs. The combination of the experiments conducted in these two settings will establish a robust and statistically representative dataset centered on the reliability of FPIs within the range of the tested conditions.

The work presented herein showcases the approach and preliminary results obtained from the first set of six field experiments conducted within the scope of this project.

2. Methodology

2.1. Study site and burn plot characteristics

The field experiments were conducted in March 2022 at the Pineland National Reserve (PNR), located in New Jersey, United States. The PNR comprehends an area of ~ 445,000 ha, composed mainly of upland and wetland forests. The basic geography of the area is a relatively flat coastal plain with low-angle slopes and a maximum elevation of 63.5 m, with well-drained sandy loam as the primary soil type (Clark et al., 2015).

As presented by Clark et al. (Clark et al., 2015), the upland forests represent roughly 60% of the forested areas in the PNR, with many closed-canopy stands of approximately 60–90 years of age. In general terms, it is composed of the following three major communities: oak-pine, pine-oak, and pine-scrub oak (Skowronski et al., 2007). For all communities, understory vegetation comprises mainly Scrub oaks and Ericaceous shrubs such as huckleberry and blueberry.

The experiments reported here were conducted in small plots of ~0.5 ha, with low-intensity fires that replicate the conditions near the point of origin of a fire. Supporting elements to study the generation of FPIs were planted in clusters of ~9 m^2 to study the generation of micro-scale FPIs.

To replicate the initial conditions of a fire incident as close as possible, single-point ignition was conducted using a typical isobutane lighter. The location of the point of ignition was varied according to the fire spread scenario to be represented and current wind conditions.

2.2. Diagnostics

2.2.1. Fuel characterization

Vegetation samples were collected from randomly-sampled 1 m^2 destructive harvest subplot areas within each burn unit. As prescribed fires rarely reach the more highly decomposed organic layers of the ground, a collection depth that reaches the litter layer of the forest floor was sufficient (Clark et al., 2015).

The material collected was sorted in-situ as detritus and vegetative material. These materials were then dried for a minimum of 48 hours at 70°C and sorted into fuel particle and time-lag components (e.g., downed wood, stems, fine fuels; 1-, 10-, 100- hour time-lag classes).

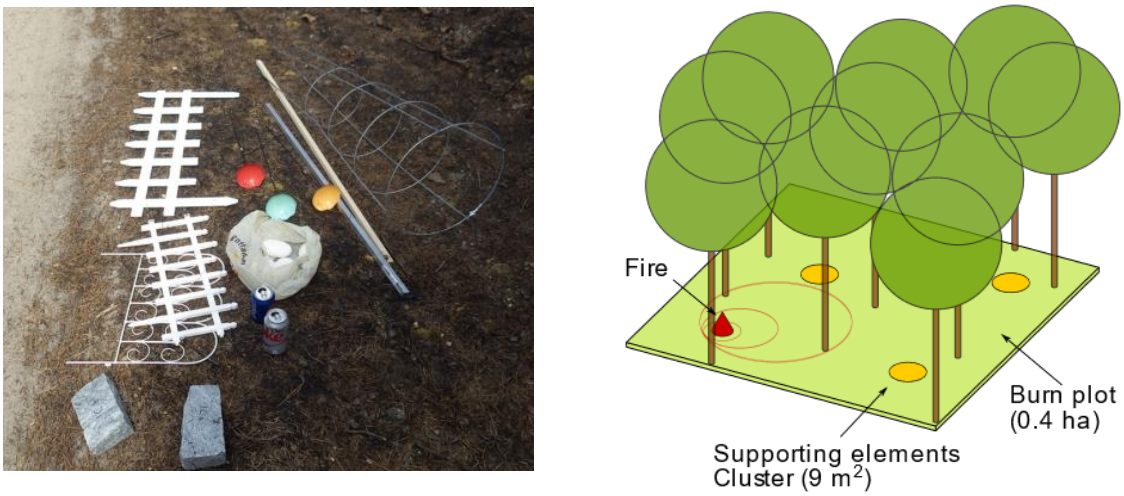
Terrestrial laser scans (TLS) were conducted at each plot before and after the fire to obtain a 3D survey of the vegetation, indicators, and equipment to estimate the initial and final vegetation bulk density and fuel consumption.

2.2.2. Fire spread

Protected conventional cameras mounted at elevated positions inside and in the vicinity of the fire perimeter were used to capture the fire spread from different angles and visualize the fire behavior near the indicators. In addition to these cameras, a weather station and 3D sonic anemometers placed outside the perimeter of the burn plot were used to characterize the environmental and air entrainment conditions before, during, and after the fire.

2.2.3. Generation of fire pattern indicators

Following the approach presented by Simeoni et al. (Simeoni et al., 2017), supporting elements that allow the appearance of microscale fire pattern indicators were used. Fig. 1(a) shows an example of the supporting elements used by Simeoni et al. in the past. As previously mentioned, the supporting elements were planted in clusters comprising an area of approximately 9 m^2 dispersed throughout the burn plot, as shown in Fig. 1(b). The clusters were distributed in the burn plot in a way that allowed to capture head, flank, and backing fire-induced fire pattern indicators.



(a) *(b)*

Figure 1: Supporting items for the generation of micro-scale FPIs. (a) Example of the items used by Simeoni et al., (b) Positioning of the clusters of supporting elements within a burn plot.

Through close post-fire inspection of the supporting elements, the micro-scale FPIs generated were registered. Furthermore, to understand the generation of micro-scale indicators, the heat exposure over the supporting elements was characterized through the following instruments (Fig. 2(a)):

A set of four 1.5 mm-diameter type-K thermocouples (TC) and four thin-skin calorimeters (TSC) were placed near selected supporting elements in different cluster regions. Even though this number of TC+TSC pairs is insufficient to characterize the heat exposure over every planted element accurately, it does allow for an estimate of the time-resolved average effect of the fire within the cluster.

A set of three bi-directional velocity probes and differential pressure transducers were placed at the center of the cluster to register the average 3D wind and gas velocity within the cluster. Additionally, two protected conventional cameras were placed outside the cluster to record the progression of the fire front at perpendicular angles, as shown in Fig. 2(b). The objective of these cameras was to provide a detailed visual record of the fire progression and its effect on the supporting elements.

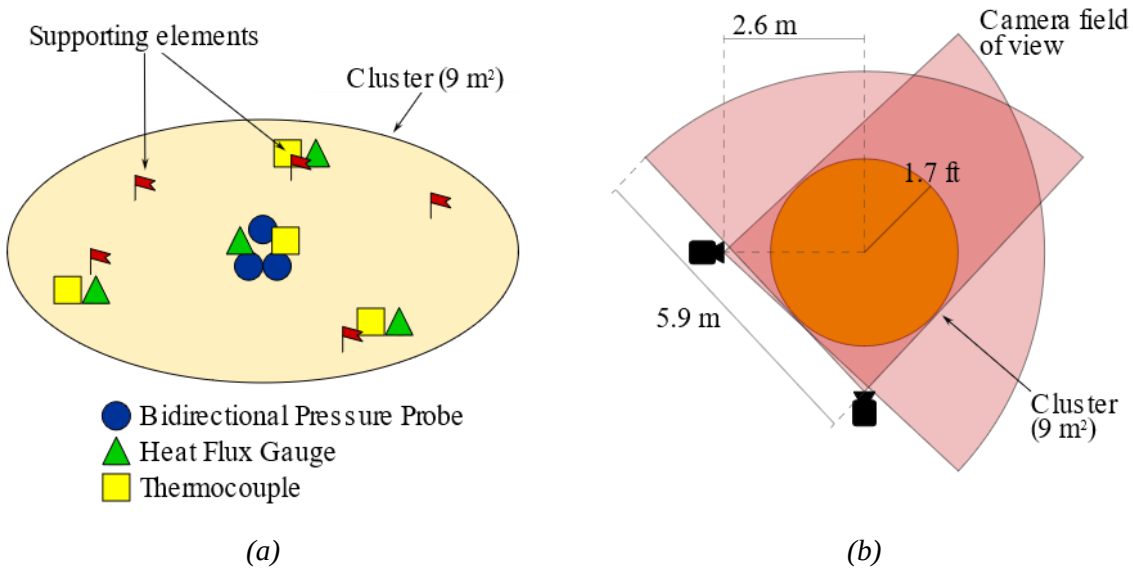


Figure 2: Instrumentation placing within a cluster of supporting elements. (a) Thermal exposure sensors placing, (b) near-cluster camera positioning.

Finally, the generation of macro-scale FPIs was evaluated through visual identification and documentation. Whenever possible, key elements within the burn plot (such as trees or shrubs) were targeted, and a detailed pre- and post-fire analysis (including ground-based LiDAR scanning) was conducted. By using the results obtained from this analysis along with the fire-spread footage registered, it is possible to identify the thermal exposure conditions that lead to the generation of the macro-scale fire pattern indicators observed in these key elements.

3. Results and Discussion

The preliminary results of some experiments are presented to illustrate the approach in practice. Pre- and post-burn TLS scans highlight the ability qualitatively evaluate fuel consumption within the plot as a first step in the approach (Figure 3). In addition to collecting fuel information, this step records the locations of the FPI materials while sonic anemometers collect data from outside the plot (idealized representation in Figure 4(a)). Figures 4(b) and (c) provide a before-and-after comparison of some of the planted elements to provide an example of the FPIs collected; mainly soot deposition and charring. Figure 4(d) displays the overall propagation of the fire derived from visual observations (red contour lines) as well as the propagation direction derived by the individual interpretation of the microscale FPIs (black arrows).

For three of the eight supporting elements, it was impossible to derive a fire propagation direction based on the damage displayed by the supporting element. It is also interesting to notice the apparent contradiction in the propagation direction derived from the FPIs displayed by the two top-most supporting elements, one of them being the galvanized steel cylinder shown in Fig. 4(b). This contradiction was caused by the collapse and the eventual burning of the branch where the supporting element was installed. These preliminary findings support those of Simeoni et al. (Simeoni et al., 2017); the consideration of a single fire pattern indicator can provide insufficient or potentially incorrect information regarding the evolution of a fire. To infer the real behavior of the fire, the information provided by all FPIs identified must be analyzed holistically.

4. Conclusions

The current work presents and demonstrates an approach for systematic studies of fire pattern indicator reliability in wildland fire investigations. The results of this demonstration support the existing idea that fire pattern indicators are a valuable and valid tool for the determination of the area of origin of a fire, but only when they are used holistically. Further results and analysis to be presented in the full version of this work include

fire spread and the characterization of the heat exposure that generates the fire pattern indicators observed in the complete experimental campaign.

Junction forward and backward fires, coalescence fires, parallel fire fronts

Abstract

Merging fires are known as destructive fires resulting in loss of life and houses. Despite growing efforts in the past decade to understand merging fires, there are still many knowledge gaps about their behaviour, especially at the field scale. In this study, we conducted experimental harvested crop burns in Victoria, Australia, in March and April 2021 to better understand thermal behaviour of merging fire fronts. UAVs with visual and thermal cameras were used to capture high-resolution fire propagation and the combustion process of merging fires. During experiments 50 junction fire fronts (32 forward and 18 backward) and 24 coalescence fire fronts were studied. For thermal analysis, 15 forward and 4 backward junction fire fronts, 6 coalescence fire fronts, and 10 parallel fire fronts were considered. Special methods were developed to process IR footages and compare the combustion process of merging fires and linear fire fronts (head and back fires). To do this, regions of interest (ROIs) containing the merging fire and linear fire front were selected in each frame using FLIR Research Studio. The ROIs were then exported using as bitmask images together with radiometric JPEG image containing both fires. Using the R programming platform, we determined the length and shape of the perimeter of fires for each JPEG image and defined buffer zones within the fire perimeter inside the ROI for each fire for further pixel temperature analysis. Thermal analysis showed that for forward junction fires the median temperature of head linear fire fronts was higher than forward junction fires except towards the end of merging. While in backward junction fires, the proportion of pixels with high temperature was much higher than in back linear fire fronts, indicating much larger burning areas. The temperature distributions of coalescence and parallel fires showed a decrease in the number of high-temperature pixels toward the end of the merge for coalescence and throughout for parallel fires. The fire behaviour observed in the field experiments demonstrates the necessity for better understanding of merging of fire fronts and the relationship between fuel, weather and fire line interaction.

1. Introduction

Over the past decade, extreme wildfires have occurred around the world with significant social, economic, and environmental consequences. They threaten the lives of many people and cause billions of dollars in damage. Climate change is further worsening fire seasons by increasing the number of dry and hot days (Bradstock 2010; Parente et al. 2018; Halofsky et al. 2020; Vilà-Vilardell et al. 2020). Longer fire seasons are expected to lead to more frequent and severe fires (Matthews et al. 2012; Di Virgilio et al. 2019). Such predictions were observed during the 2019/20 bushfire season in Australia (Filkov et al. 2020b).

These consequences are mainly the result of dynamic fire behaviours (DFBs) (Werth et al. 2011; Filkov et al. 2018; Tedim et al. 2018; Filkov et al. 2020a), which can lead to rapid increases in fire intensity and rate of spread (Hilton et al. 2017). Merging fires (Viegas 2012; Viegas et al. 2013; Thomas et al. 2017; Hilton et al. 2018; Raposo et al. 2018) is one of them. The convergence of separate individual fires into larger fires is called coalescence, and the merging of two lines of fire intersecting at an oblique angle is termed junction fire or junction fire fronts (Viegas 2012). Fire coalescence, junction and parallel fire fronts are all examples of merging fire fronts.

Most of experimental studies of merging fires have been conducted in the laboratory (Viegas et al. 2013; Oliveira et al. 2014; Sullivan et al. 2019), and only a few in the field (Raposo et al. 2018). Filkov et al. (2021) have demonstrated that the fire behaviour associated with merging fires in the field can be different and there remain ‘scale-gaps’ in the experimental data used to inform model development. Moreover, information about

thermal behaviour of merging fires and burning depth is unknown. Therefore, the aim of this study was to develop materials that provide a better understanding of the dynamic nature of fire line merging.

1.1. Methods

Two experimental burns (Shelford and Lake Burrumbeet) on harvested wheat fields were conducted in Victoria, Australia, in March and April 2021. During experiments, junction fires, spot fire coalescence and parallel fire fronts were investigated.

Automatic Weather Station (AWS, 30 min temporal resolution) was used for air temperature and relative humidity measurements. Davis cup anemometer sensor in the Shelford burn (ICT International) and 2-dimentional DS-2 sonic sensors in the Lake Burrumbeet burn (Decagon Devices, Inc., Pullman, USA) with one min temporal resolution were used for wind direction and speed measurements. The terrain in both burns was relatively flat with minimal undulations. Fuel properties and weather condition are presented in Table 1.

Table 1- Fuel properties and weather characteristics

Burn name	Fuel height, cm	Fuel load, kg/m^2	MC, %	Wind speed, m/s	T, C	RH, %
Shelford	18.6±3.8	0.11±0.03	36±3	3.4±1.1.	27.4	44
Lake Burrumbeet	51.4±2.6	0.65±0.12	17±4.5	5.4±1.2	16	62

MC is the fine fuel moisture content (wet basis), T is the air temperature at 15:00, RH is the relative humidity at 15:00, ± is the standard deviation

Two UAVs, a DJI Mavic Pro (Shelford burn) and DJI Matrice 210 (Lake Burrumbeet burn) were used to capture high-definition video imagery of fire propagation. DJI Mavic Pro is equipped with visual camera (3840×2160 pixels, 30 Hz). The camera model used with the DJI Matrice 210 was the XT2 payload with dual visual (3840×2160 pixels, 30 Hz) and thermal (640x512 pixels, 30 Hz) video capability. XT2 payload allows to film simultaneously both visual and thermal (radiometric) videos. The post processing phase was completed for each separate visual and thermal video and metadata file using the Full Motion Video (FMV) toolbox within the ArcGIS Pro 2.8.0 software (Macdonald 2017). The result is a video file with each frame georeferenced. The multiplexed video file was then used to identify and spatially define fire fronts at set time intervals.

After starting the ignition line, the fire front produced fire tongues. When the fire lines of two neighbouring tongues naturally merged together, we identified it as junction fire fronts (forward junction fire fronts) and the angle between them as an initial angle. If the junction fire fronts were spreading opposite to the direction of the head linear fire front, we identified them as the backward junction fire fronts. Two spot fires spreading toward each other were identified as coalescence fires. Two fire fronts burning parallel to each other and propagating towards each other were identified as inward parallel fire fronts. We measured travelling distance of the merging fire fronts every 2-5 seconds to calculate ROS. To estimate the effect of merging fire fronts on fire propagation we compared them with head and back linear fire fronts. The ROS of the linear fire front was measured in the vicinity to each merging fire front for their entire duration.

To analyse the effect of merging fire fronts on fire behaviour and thermal energy release, we compared the temperatures above 200 °C on thermal images of merging fires and linear fire fronts. Since the junction and linear fire fronts are very different in length and shape of the fire perimeter, we required a method for their relative comparison. To do this, we compared the temperature of pixels inside the buffer zones for each fire. In order to define them, we had to delineate linear and junction fires and determine their perimeters on thermal images. This process is different for each type of merging fires. For junction fires, we first manually created two regions of interest (ROIs) containing a junction fire and a section of a linear fire front on the thermal video (head and back linear fire fronts for forward and backwards junction fire fronts, respectively) using FLIR Research Studio 2.0.0. For parallel fire fronts and coalescence fires, we created one ROI containing both parallel fire fronts (their sections) and coalescence fires (complete fires).

The ROIs were then exported using FLIR Research Studio 2.0.0 as bitmask images together with radiometric JPEG image containing both fires. All images were exported at 2-, 4- or 5-second intervals, starting from the formation of the merging fire to its transition to a linear fire front for junction fires (180-degree junction angle) or to the moment of joining parallel or coalescence fires. Using the R programming platform 4.1.0 (R Core

Team 2021), we determined the length and shape of the perimeter of the merging and linear fires for each JPEG image. Using this information and the st_buffer function in R (sf package), we defined buffer zones within the fire perimeter inside the ROI for each fire for further analysis. We then analysed the temperatures of pixels, after which we calculated the temperature distributions for each time step. Due to different time duration of each merging fire, we converted time steps to percentages of final time.

2. Results and discussion

The use of a drone with a dual visual and thermal camera showed that the thermal camera was able to detect all active hot spots and fire fronts even through dense smoke, which was a significant constraint in our previous study (Filkov et al. 2021).

Thirty-four videos were filmed and multiplexed. Seventy-four merging fire fronts (42 in Shelford and 32 in Lake Burrumbeet burn) were identified: 50 junction fire fronts (32 forward and 18 backward) and 24 coalescence fire fronts. For thermal analysis, 15 forward and 4 backward junction fire fronts, 6 coalescence fire fronts, and 10 parallel fire fronts were considered since the amount of available thermal video footage was limited.

The combined ROS of forward, backward and head linear fire fronts had the highest median ROS for forward junction fires (2.02 m/s), followed by head linear and backward ROS, 0.67 m/s and 0.18 m/s, respectively. The ROS of the head linear fire fronts changed mostly in the range 0.1-2 m/s during the lifetime of the merging fires. A comparison of the median ROS values for forward junction fires and head linear fire fronts between the two burns showed that the difference was very consistent. Forward junction fires were 3 times faster than head linear fire fronts, 3.02 and 3.11 times faster for the Shelford and Lake Burrumbeet burns, respectively. The ROS of backward fire fronts is consistent between the two burns, 0.17-0.2 m/s. Although the average ROS of forward junction fires was 3 times that of head linear fire fronts, it was up to 18 times higher than head linear fire fronts in some cases.

The pixel temperature distribution within the buffer zones for merging fires is presented on Fig. 1. Data analysis for forward junction fires showed that the median temperature of head linear fire fronts was higher than forward junction fires except towards the end of merging (Fig. 1a). In backward junction fires, the proportion of pixels with high temperature was much higher than in back linear fire fronts (Fig. 1b). For example, the difference in median temperature between the two ranged from 100 to 200 °C, indicating much larger burning areas in the backward junction fires. Non overlapping notches in all groups indicate with a 95% confidence level that the temperature medians for junction fires and linear fire fronts are different.

Analysis of temperatures above 500 ºC in forward junction fires, representing flaming combustion in wildfires (Wotton et al. 2011), showed that the density of high-temperature pixels (above 500 °C) increases, and the temperature peak shifts toward higher temperatures during the merging process. Whereas for head linear fire fronts, the temperature density and its peak remain practically unchanged. It was expected that the density of "hot" pixels should be higher for forward junction fires compared to head linear fire fronts during the merging process. Higher ROS should have resulted in more fuel burning simultaneously and larger "deep flaming" areas. However, we found that only in the last stage of merging (75% and 100% time) was the median temperature and temperature range higher and larger. It is assumed that the “deep flaming” is a consequence of the forward junction fires and not a mechanism of their propagation. Liu et al. (2021) in their literature review discuss potential mechanisms of fire merging and point to interacting air entrainment fields and enhanced heat feedback to fuels. In our study, we did not have the opportunity to study convection, but it will be addressed in future studies.

Unexpected results were also received for coalescence fires (Fig. 1c). Although, the ROS increases over time, its value decreases as the distance between two spot fires decreases. At this point, we have no explanation for these results. The temperature distribution also showed a decrease in the number of high-temperature pixels toward the end of coalescence. One possible explanation for this is that in our analysis we assumed that the end of coalescence is the time when the two fires joined together, but not the time when they completely merged to form one fire. Additional experiments and analysis are needed to explain the above results.

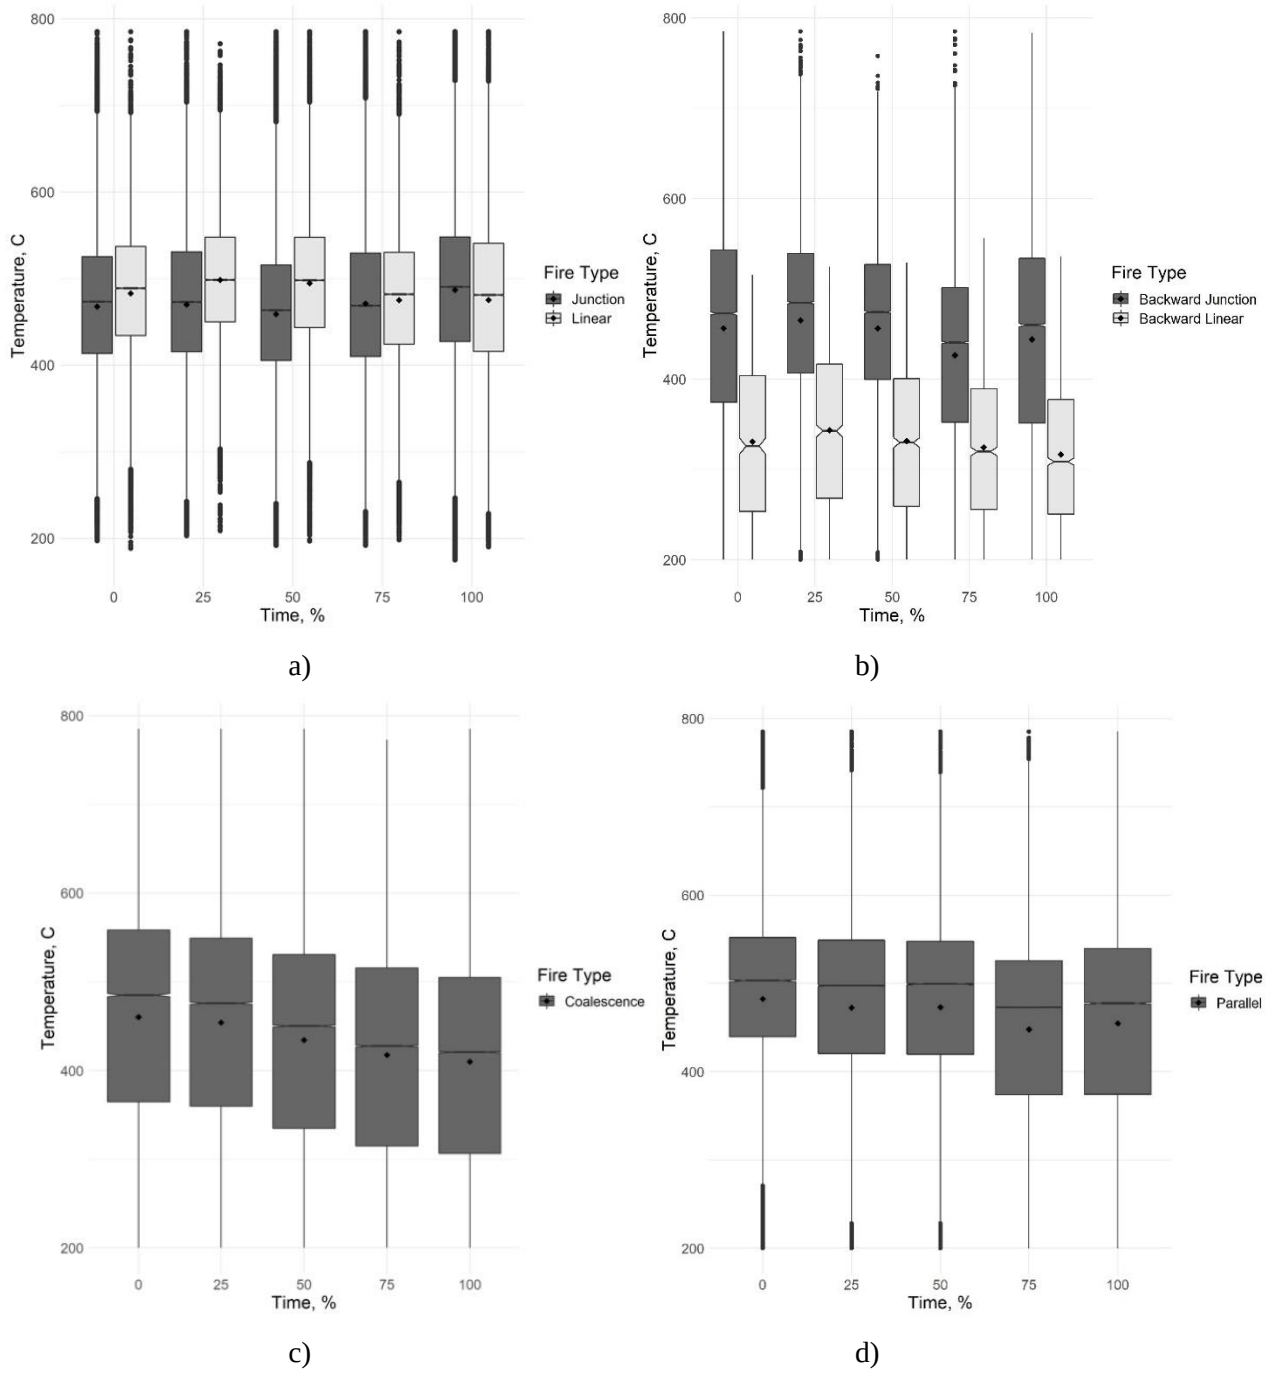

Figure 1- A notched box plot of the distribution of pixel temperature in the buffer zone of the merging fires: a) the forward junction fire (Junction) and head linear fire front (Linear) for the duration of forward junction fire; b) the backward junction fire (Backward junction) and back linear fire front (Back linear) for the duration of backward junction fire; c) the coalescence fires; d) the parallel fires. Time is dimensionless. Zero percent is the moment of formation of the merging fire, 100% is the moment of transition to the linear fire front (180-degree junction angle) or to the moment of joining parallel or coalescence fires. Boxes contain 50% of data. Dots represent outliers. Line is the median and rhombus is the mean.

Parallel fire, opposite to forward junction fires, had a decrease in the number of high-temperature pixels by the end of merging.

Our study has a few limitations. The drone thermal camera is factory calibrated to 550 °C. Values above this value are extrapolations in the FLIR software. They should be analysed with caution. In our future study we are going to use a thermal filter to extend the temperature range. Also, comparing thermal pixels within buffer zones of merging fires and linear fire fronts may not be the best option.

3. Conclusion

Conducted field experiments have confirmed that merging fires behave differently than regular fires (linear fire fronts), and standard operational models will underestimate fire behaviour when merging occurs. In some cases, the forward ROS of forward junction fires can be up to 18 times higher than the head linear ROS. Analysis of the thermal footages revealed that a greater number of pixels with higher temperatures were observed at the end of fires merging in forward junction fires and during the entire merging time in backward junction fires compared to linear fire fronts. These results indicate the danger that junction fires can pose to firefighters and communities and the need to incorporate them into fire behaviour models. Further research is needed to better understand the unexpected temperature behaviour of coalescence and parallel fires.

Abstract

Safety zones are fundamental tools that can be used by wildland firefighters to avoid injury or fatality when engaging in wildland fire operations. The National Wildfire Coordinating Group (NWCG) recommends that a safety zone be defined as a pre-planned area of sufficient size and suitable location that is expected to prevent injury to fire personnel from known hazards without using fire shelters. Currently, safety zones are primarily designated by fireline personnel as part of daily fire management operations. Though critical to safety zone assessment, the effectiveness of this approach is inherently limited by the individual's ability to accurately and consistently interpret vegetation conditions, topography, burning conditions and spatial characteristics of potential safety zones (e.g., area and geometry of a forest clearing). Regardless, effective safety zones provide safe separation distance (SSD) from surrounding flames, ensuring that the surrounding heat cannot cause burn injury. We introduce a new online tool for mapping SSD based on vegetation height, terrain, wind speed, and burning conditions: the Safe Separation Distance Evaluator (SSDE). The new tool allows users to draw a potential safety zone polygon and estimate SSD and the extent to which that safety zone polygon may be suitable, given the local landscape, weather, and fire conditions. The SSDE tools calculates separation distance based on vegetation height, wind and slope adjustment factors and burning conditions. Fuels layers are imported for LANDFIRE Existing Vegetation Height. Slope is calculated from the Shuttle Radar Topography Mission (STRM) digital elevation model. Winds are derived from the local fire weather forecast. Burning conditions are based on fuel moisture, relative humidity, and temperature. The Safe Separation Distance Evaluator (SSDE) algorithm is built and applied in Google Earth Engine (GEE), a cloud-based platform for processing and analyzing GIS and remotely sensed data, using JavaScript application programming interface. SSDE is a tool that can provide valuable safety information to wildland fire personnel who are charged with the critical responsibility of protecting the public and landscapes from increasingly intense and frequent fires in a changing climate.

1. Introduction

Wildland firefighters are tasked with a wide variety of fire management duties, many of which place them in close proximity to flames. One of the primary tasks is the removal of fuels and construction of containment lines to limit the potential damage to lives, property, and other critical resources (Wei, 2019; Silva, 2020; Connor, 2017). Particularly when engaged in a direct attack, whereby firefighters may be working within a few meters or less of that flaming zone, the potential risk for safety incidents is elevated (Cheney, 2001). Sudden or unexpected changes in fire behaviour can have devastating effects to vulnerable fireline personnel on the ground (Page, 2017). Events such as the Yarnell Hill fire in 2013, which claimed the lives of 19 firefighters and the South Canyon fire, which resulted in 14 firefighter fatalities, demonstrate the tragedy that can occur in the wildland fire profession (Arizona State Forestry Division, 2022; Butler, 1998; Alexander, 2015). Beyond these well-known, high-fatality events, there is an additional and significant background level of mortality that occurs among on-duty wildland firefighters (Butler, 2017). The causes of death are varied, and include heart attacks, vehicular and aircraft accidents, falling trees, and smoke inhalation, to name a few. Between 1990 and 2020, there were 525 documented wildland firefighter fatalities in the United States (National Interagency Fire Centre,

Wildfire Today). The causes of fatalities vary greatly (Figure 1), with nearly one fifth (19%) of which were due to burnovers or entrapments. This category is the direct result of fatal exposure to excessive heat, fire, and/or smoke. Burnover results from fire rapidly overtaking firefighting personnel before they can move to a safe area, and entrapment indicates that firefighters' ability to move to a safe area is compromised (National Wildfire Coordinating Group, 2017). As wildland fires increase in frequency, extent, and intensity, wildland firefighters may be put at heightened risk while working in the increasingly complex fire environment (Abatzoglou, 2016; Abatzoglou, 2021; Dennison, 2014; Balch, 2017; Westerling, 2016).

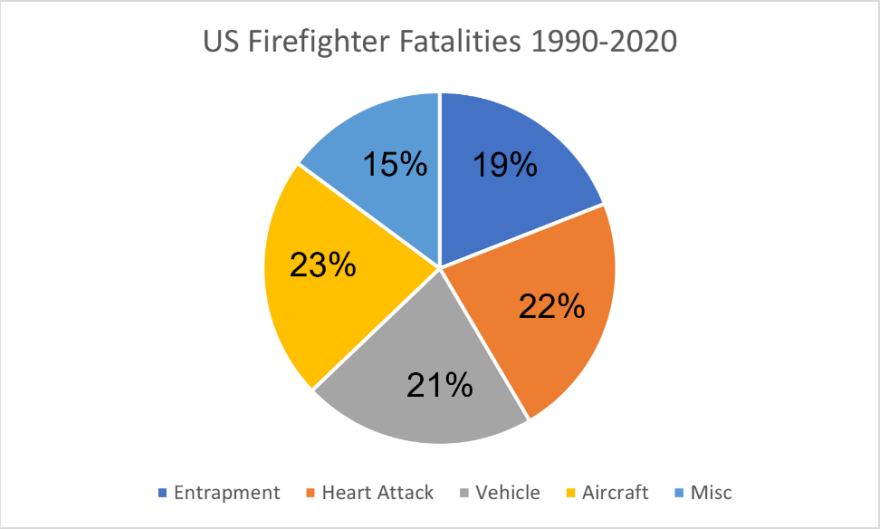

Figure 1- Firefighter fatalities by category from 1990-2020. Total wildland fire fatalities during that time span were 525.

Gleason (1991) proposed a system of interdependent safety measure to reduce firefighter risk of burnover and entrapment: lookouts, communications, escape routes, and safety zones (LCES). Safety zones are a critical component of this system, essentially areas large enough to allow firefighters to escape the harmful effects of fire (Beighley, 1995). Safety zones must be large enough to hold firefighting personnel and equipment and should provide a safe separation distance (SSD) between vegetation and these assets (Figure 2). The SSD must be large enough that heat from the wildfire is reduced to the point that a fire shelter is not necessary to prevent firefighter injury.

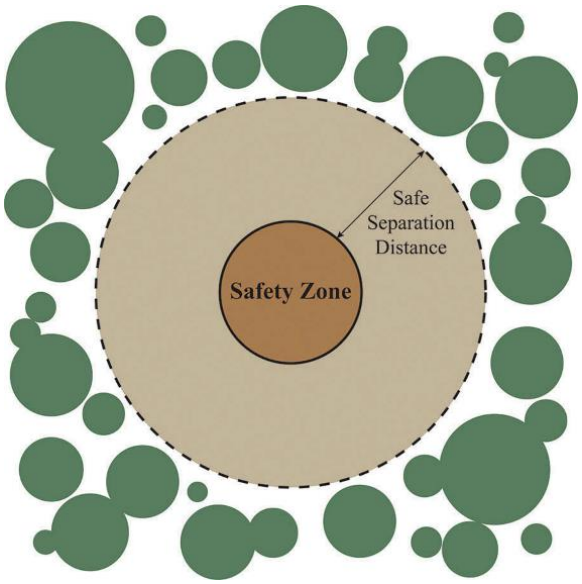

Figure 2 – Basic safety zone example diagram depicting Safe Separation Distance (SSD)

The current NWCG guideline for estimating SSD comes from Butler and Cohen (1998a), who determined, based on radiant heat modelling, that SSD should be equal to or greater than four times flame height. This

guideline assumes flat terrain and does not account for convective heat transfer, which can strongly contribute to firefighter heat exposure (Butler, 2014). Although this guideline has since been widely adopted (National Wildfire Coordinating Group, 2022), the research that underlies it is based solely on one heat transfer mechanism: radiation. Heat transfer by convection is also a major—sometimes dominant—force, particularly in the presence of steep slopes and high winds (Dupuy, 2011; Frankman, 2013; Parsons, 2014). In the presence of such convective heat, particularly if a fire crew is upslope and/or downwind of flames, SSD will increase (Page, 2017, Butler, 2014). Thus, the four times flame height rule is likely insufficient in these conditions. Recent work by Butler et al. (Butler, 2017) has sought to update this guideline with the inclusion of a "slope-wind factor", which adds a multiplicative term to the SSD equation to account for the effects of convective heat transfer (Page, 2017, Butler, 2014; Parsons, 2014; Page, 2018, Campbell, 2022). In addition, given that safety zones should be designated prior to, rather than during, the presence of flames, the four times flame height rule requires firefighters to predict how tall the flames might eventually be, which is a challenging endeavour. Accordingly, the newly proposed guidelines assume that, in a crown fire, flame height is approximately equal to twice the vegetation height (Campbell, 2022). As a result, the new SSD equation is defined as:

$$\mathbf{SSD = 8 \times VH \times \Delta,}$$

where VH is vegetation height and Δ is the slope-wind factor. Butler recently defined these slope-wind factors seen in Table 1, based not only on slope and wind speeds, but also on the burning conditions, as dictated by fuel conditions (e.g., moisture) and weather (e.g., relative humidity) (Campbell, 2022).

Table 1. Slope-wind factors (Δ) from Butler, coloured on a scale from blue (low Δ) to while (moderate Δ) to red (high Δ) (Campbell, 2022).

		Slope				
		Flat (0–7.5%)	Low (7.6–22.5%)	Moderate (22.6–40%)	Steep (>40%)	
Wind Speed	Light (0–4.5 m/s)	0.8	1	1	2	Low
		1	1	1.5	2	Moderate
		1	1.5	1.5	3	Extreme
	Moderate (4.6–8.9 m/s)	1.5	2	3	4	Low
		2	2	4	6	Moderate
		2	2.5	5	6	Extreme
	High (>8.9 m/s)	2.5	3	4	6	Low
		3	3	5	7	Moderate
		3	4	5	10	Extreme

Burning Condition

Although guidelines for use on the ground are valuable, they still require the firefighters themselves to make the calculation of SSD on the ground while engaged in other fire management activities. This requires the ability to accurately estimate vegetation height and terrain slope and anticipate wind speed and fire intensity. Moreover, even if these difficult interpretations and predictions can be made, an even more challenging endeavour is to identify an area on the ground cleared of vegetation that provides the calculated SSD in all directions.

To resolve these limitations and improve wildland firefighter safety, we introduce a new, interactive, web-based, open-access mapping tool for estimating SSD and evaluating potential safety zone effectiveness through geospatial analysis. The Safe Separation Distance Evaluator (SSDE) tool uses LANDFIRE Existing Vegetation Height data, which is both nationally available in the contiguous US and is updated every few years. Additionally, instead of only assessing SSD-driven suitability on clearings that already exist, this tool allows users to draw their own safety zone polygon to evaluate the potential suitability of a safety zone in any environment (Figure 3). The SSDE algorithm is built and applied in Google Earth Engine (GEE), a cloud-based platform for processing and analyzing GIS and remotely sensed data, using the JavaScript application programming interface (Gorelick, 2017).

2. Methods

2.1. Algorithm Description

The Safe Separation Distance Evaluator (SSDE) algorithm is built and applied in Google Earth Engine (GEE), a cloud-based platform for processing and analyzing GIS and remotely sensed data, using the JavaScript application programming interface (Campbell, 2022). GEE was selected a for few reasons: (1) it enables the

production of user-facing applications that can be widely accessed by anyone with an internet connection; (2) it hosts an immense catalog of geospatial data, including datasets necessary for the analysis of SZ suitability; (3) its cloud computing capabilities provide for rapid execution of complex geospatial functions, allowing users to quickly assess SZ suitability.

SSDE evaluates SSD through the analysis of proportional SSD (pSSD) within potential SZ polygons (Figure 3). pSSD quantifies the extent to which a potential SZ polygon provides SSD from surrounding vegetation/flames, considering the average per pixel SSD contained within a series of segments (or clusters of contiguous pixels) around the SZ polygon. Measured in percent, a pSSD of 100% or greater for a given pixel would mean that, factoring in vegetation height surrounding the polygon, slope, wind speed, and burn condition, the pixel's location should provide sufficient SSD, should fire personnel opt to use this location as a SZ. Conversely, a pixel with a pSSD of less than 100% would indicate that firefighters located within that pixel may risk injury from burning vegetation outside the boundary of the polygon.

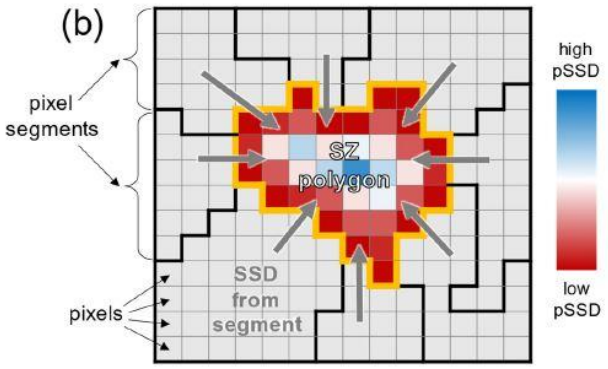

Figure 3: Conceptual depiction of that SSDE calculates SSD within a safety zone (SZ) polygon.

To calculate pSSD at the SZ polygon level, the user can define a potential SZ using the polygon drawing tools in SSDE, guided by the conditions both within the polygon and surrounding the polygon. The best SZs are those that contain no flammable material within, naturally or otherwise, so ideally this SZ polygon would be drawn in an area with low fuel loading, such as short or sparse grasses or litter. Alternatively, a SZ polygon could also be drawn in an area that has recently burned, or an area that would be targeted for fuel removal to create a SZ.

pSSD within a SZ is dependent upon the slope and vegetation height of the surrounding landscape. As discussed in the introduction, heat transfer from flames generally increases with increasing vegetation height and terrain slope. Accordingly, a SZ in the midst of steep terrain and tall vegetation will require a larger SSD than a SZ in the midst of flat terrain and short vegetation. If we assume that the SZ itself contains little or no flammable material, then the primary concern for SZ evaluation is the area surrounding the SZ. Accordingly, to calculate pSSD within the SZ polygon, slope and vegetation height need to be evaluated within a "buffer" surrounding a SZ (Campbell, 2017; Dennison, 2014).

3. Results and Discussion

The SSDE was developed in GEE and a free, open-access, web-based application can be viewed at https://firesafetygis.users.earthengine.app/view/ssde. The full publication can be viewed at https://www.mdpi.com/2571-6255/5/1/5/htm.

We envision the SSDE being of broad interest to the wildland fire community, from fire scientists to incident management personnel to wildland firefighters. Its open-access nature allows anyone to explore, examine, and interact with the concepts of SZs and SSD. Even if not used in an operational context, there is great value in being able to quickly and easily examine the conditions that define potential SZ suitability on a broad spatial scale. Wildland firefighters designate SZs on a daily basis as a part of their fire management

duties. Built into this designation process is an inherent degree of subjectivity that can result in differences in the interpretation of SZ suitability between and among crews. By using an objective tool for SZ suitability analysis that can be broadly applied in the US, fire crews across the country can increase the consistency and

reliability of the SZ evaluation process. However, given that this is a web-based platform requiring an internet connection, that also does not translate well to a mobile environment, we do not envision this as a real-time decision-making tool that firefighters could use on the ground. Instead, operational use of SSDE could be at the incident command level, for daily or more frequent evaluation of potential SZs for crews working on a fire. Given the dynamic and fast-paced nature of fire management, it is essential to be able to make rapid assessments of SZ suitability, particularly as fire conditions change. For example, cross-referencing near-real time data representing the current fire perimeter with SSDE can enable the evaluation of whether or not previously burned areas can provide SSD from nearby unburned fuel. Additionally, our SZ suitability driver analysis revealed the strong influence of wind on maximum within-SZ pSSD. This highlights the need to continually re-evaluate SZ suitability not only as the fire evolves, but as local weather conditions change as well.

Wildland fires, litter fires, measurements, Rate of Spread, Heat Release Rate

Abstract

This work presents the results of laboratory experiments, focused on the characterization of surface wildland fires propagating in a litter fuel bed. A series of fire tests are conducted using an inclinable combustion table, measuring 2 m x 2 m, aiming to identify the effects of several important operational parameters on the characteristics of the developing fire. The parameters studied are the slope angle and the fuel load. A broad sensor network is installed, including 52 thermocouples, 3 bi-directional velocity probes, 2 heat flux sensors, a weighing system, 2 optical cameras and a real-time gas analyser. The obtained measurements are used to determine the time evolution of several characteristic parameters, such as position of the flame front (that yields the mean rate of spread), heat release rate, heat flux, axial velocity, as well as the mass loss. The construction of a 2D temperature field from the thermocouples that rest on a plane parallel to the propagation axis, illustrates several interesting flame characteristics. It is found that the rate of spread increases with slope angle and fuel load, whereas the heat release rate increases with slope and, dramatically, with fuel load.

1. Introduction

Wildland fires draw a large attention from multiple fields of science and engineering, due to the broad range of interacting physical and chemical phenomena that develop in multiple temporal and spatial scales. Understanding the wildland fire behaviour aims in acquiring in-depth scientific knowledge that will enable to adequately predict several key characteristics, such as flame rate of spread. The main parameters affecting the behaviour of wildland fires are the characteristics of the flora fuel, the atmospheric conditions, and the local topography.

Laboratory experimentation on wildland fires is broadly used to investigate various aspects of their characteristic behaviour (Rothermel and Anderson, 1966; Viegas and Pita, 2004). Although laboratory-scale experiments cannot incorporate the full spectrum of length scales observed in real-scale wildland fires, they still offer some significant advantages, since they facilitate controllability, repeatability and instrumentation management. In this context, small-scale fire tests may provide significant insight to the spread rate of surface wildland fires, thus providing valuable information to further understand and analyse more complicated wildland fire scenarios, e.g., crown fires (Scott et al., 2014).

A broad range of physical quantities has been proposed to describe the behaviour of a wildland fire. Undoubtedly, the most widely studied quantity, of both academic and practical value, is the Rate of Spread (ROS); knowledge of a wildland fire's spatio-temporal evolution is required to effectively coordinate fire suppression and civilian evacuation activities. In terms of the fire's combustion characteristics, the Heat Release Rate (HRR) is the most common quantity used to describe the thermal power and, thus, the severity of the fire; estimation of the HRR is usually performed in a laboratory environment by means of the oxygen consumption calorimetry method.Other measured quantities like the fuel mass loss rate, the radiative heat flux and the temperatures inside and above the fuel bed, can potentially reveal significant information regarding the underlying phenomena (e.g. convection, radiation) that affect the fire behaviour. .

In this work, a series of surface (litter) fire tests are performed on an inclinable combustion table, aiming to investigate the impact of several operational parameters on certain significant quantities that describe the fire behaviour. The investigated parameters are the fuel bed slope and the fuel load, and the measured properties are the mean Rate Of Spread (ROS), the Heat Release Rate (HRR), the mass loss rate, the heat flux, the axial velocity profile as well as the temperature spatial distribution, above and "inside" the fuel bed.

2. Experimental apparatus and experimental method

The experimental apparatus used is an inclinable combustion table, where fuel beds of Pinus Halepensis needles are evenly distributed. The table has an area of 2 m x 2 m and it can change its slope angle from 0 to 30 degrees (c.f. Figure 1). The table is located under an exhaust hood, which is used to collect the combustion product gases; a continuous gas analyser is employed to estimate the instantaneous HRR, using the oxygen consumption calorimetry method (Thornton, 1917; Janssen, 1991). The combustion table is equipped with a broad network of measuring instruments, i.e., a grid of 52 thermocouples distributed on a vertical plane along the direction of fire spread, near the middle of the fuel bed's width (y = 40 mm); 3 bi-directional velocity probes and 2 heat flux meters (one located vertically, at the downstream end, and the other located horizontally, at the level of the fuel bed surface) are also installed. To measure mass loss, the inclinable table rests upon three load cells. The positions of the instruments on the table are presented in Figure 2.

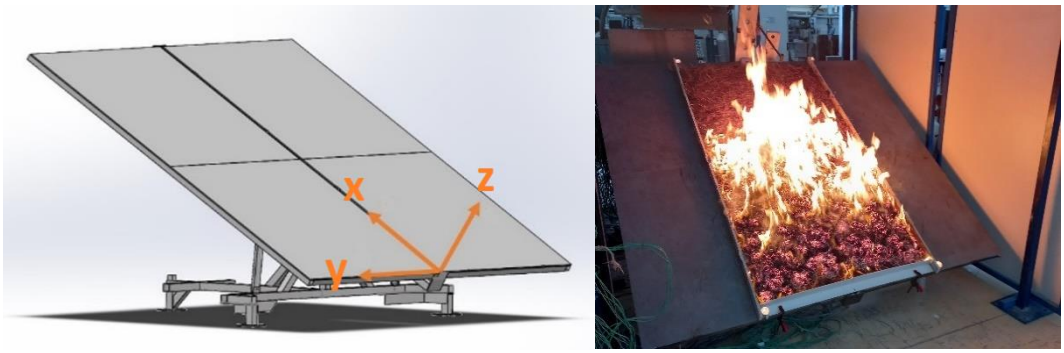

Figure 1: Model representation of the combustion table and its coordinate system (left) and indicative view of the experimental apparatus during a fire test (right).

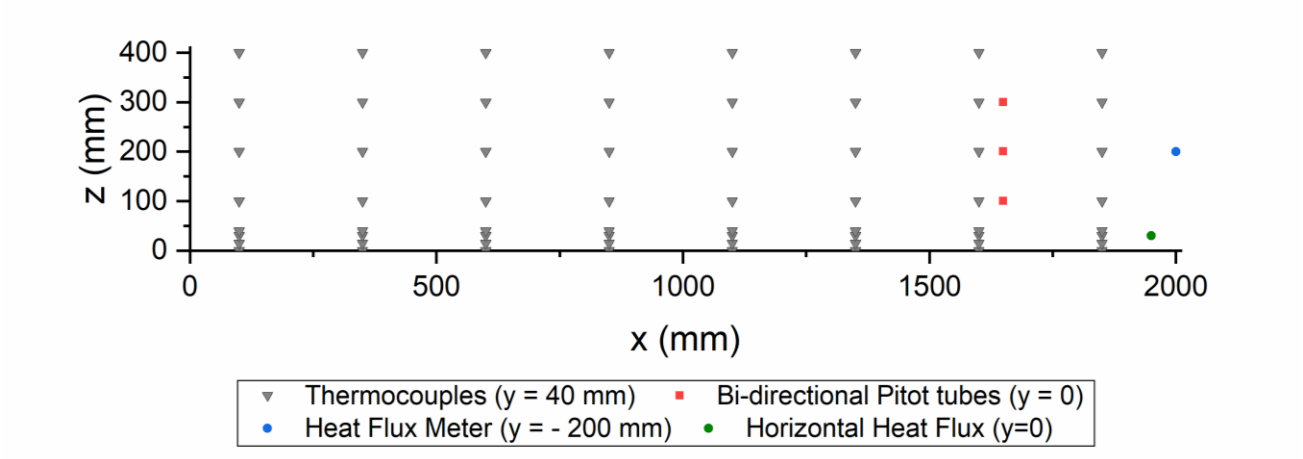

Figure 2: Locations of the measurment sensors (the coordinate system is defined in Figure 1).

The performed parametric study investigated the impact of two operational parameters, which are known to affect the characteristics of the developing fire, i.e., the fuel load and the slope angle. The specific characteristics of the 5 experimental test cases are presented in Table 1. For all the fire tests conducted, the fuel bed dimensions were 1.0 m (width) x 1.9 m (length). The Fuel Moisture Content was measured with a moisture analyser, yielding for all the experiment a value around 9% (in dry basis). The fire was linearly ignited at the upstream edge of the fuel bed (x = 50 mm) with the help of a paper string soaked in ethanol. Each test case was repeated 3 times; the presented results are averaged values.

Table 1- Characteristic parameters, and results of the 5 investigated test cases.

Test case	Slope angle, S (deg)	Fuel load (wet basis), m'' (kg/m^2)	Fuel bed height, δ (mm)	Rate of Spread, R (mm/s)	Fire duration, t_{end} (s)	Peak HRR, HRR_{max} (kW)
S00-M0_50	0	0.50	30	3.7	515	31
S00-M0_25	0	0.25	15	3.0	627	17
S20-M0_50	20	0.50	30	9.8	194	69
S30-M0_50	30	0.50	30	40	48	205
S00-M0_25	30	0.25	15	36	53	126

The ROS was estimated using temperature measurements from thermocouples located at the top surface of the fuel bed. More specifically, the first time that the second derivative of the temporal temperature recording was zero was assumed to be the time that the flame front reached that specific thermocouple. The rate of spread, R (mm/s), was estimated via linear interpolation of the resulting points of time and x position for the eight thermocouples in the array. The time the fire front required to reach the end of the fuel bed, t_{end} (s), was calculated by dividing the length of the fuel bed with the respective R; this value was used in each test case to define a dimensionless "flame propagation time", $\tau = t / t_{end}$, which is used in subsequent plots, allowing better comparison of the temporal evolution of the measured properties.

3. Results and Discussion

The temporal evolution of the flame front position is presented in Figure 3; the respective mean ROS values are given in Table 1. The ROS is found to increase with increasing slope as well as with increasing fuel load, in agreement with the existing literature (e.g. Tihay et al., 2014; Campbell-Lochrie et al., 2020). It is interesting to note that for the cases of 30° slope, there is a rapid increase of ROS. For all test cases, the instantaneous R appears to be relatively constant, thus suggesting the establishment of "steady-state" fire spreading conditions.

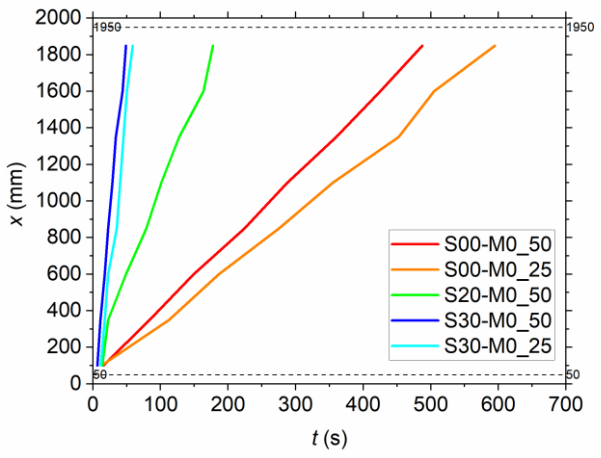

Figure 3 – Estimated temporal evolution of the flame front position.

The temporal evolution of the estimated HRR and the dimensionless mass loss are illustrated in Figure 4. Regarding the HRR (Figure 4, left), a similar trend to the temporal evolution of ROS is observed; more specifically, the HRR is found to increase with increasing slope and fuel load (Tihay et al., 2014). The effect of fuel loading seems to be stronger for the HRR, compared to that observed for the ROS, which is not surprising, since an increase in the fuel load results in a corresponding increase in the total amount of energy available for combustion. As far as the HRR temporal profile is concerned, it appears to reach a prolonged "plateau", for the test cases where the slope was less than 30 degrees. On the contrary, for the S30 test cases, the HRR exhibited a dramatic increase, showing a rather instantaneous "peak" before decreasing again. For all test cases, the HRR started to decrease roughly at $\tau = 1$. From that point on, it seems that the higher the peak value (HRR_{max}, c.f. Table 1), the longer the combustion processes continued to evolve behind the flame front. The continuation of the combustion process after $\tau = 1$ is also evident by the temporal evolution of the dimensionless mass loss

(Figure 4, right), where the mass continues to decrease for test cases S20 and S30, whereas it essentially ceases for test cases S00. Additionally, it is noted that with increasing the slope and the fuel load (while keeping the bulk density, $\rho_b = m''/\delta$, constant) the remaining fuel mass increases. This is mainly owed to the non optimal ventilation of the lower part of the fuel bed when its depth is increased as a consequence of the fuel load increase; in addition, the high ROS values observed with increasing slope, lead to reduced flame front residence times over the fuel bed, thus resulting in a prolonged combustion process.

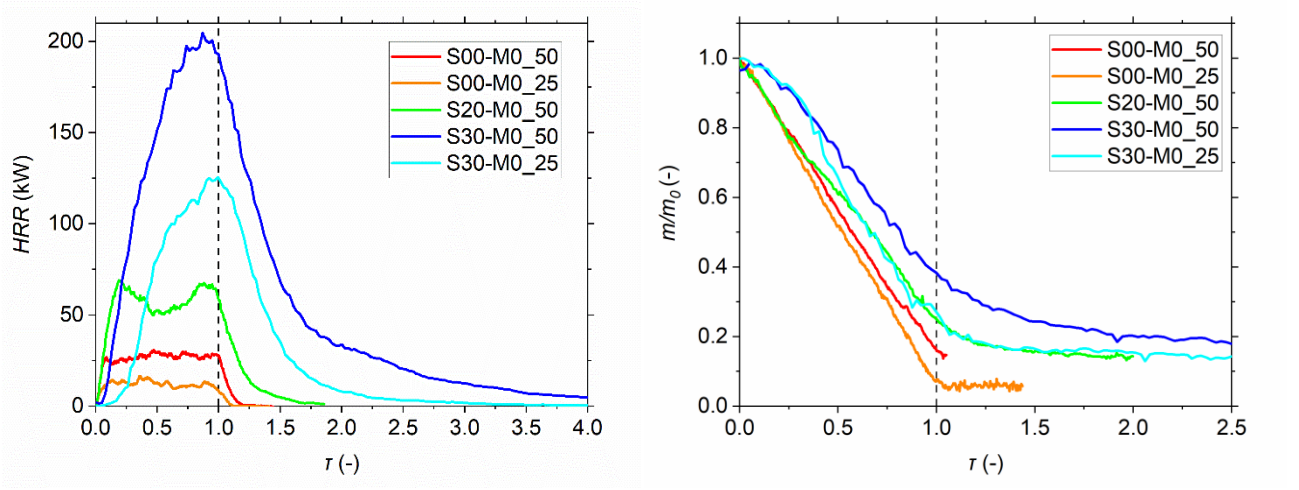

Figure 4 – HRR (left) and "normalised" mass loss (right) as a function of dimensionless time, τ.

The developing temperature fields above and inside (the dashed line corresponds to the fuel bed thickness, δ), the fuel bed, at three characteristic dimensionless times (0.25, 0.50 and 0.75) are presented in Figure 5 for all test cases. Increasing the slope results in a general increase of the temperature of the flame front, in agreement with relevant observations in the literature (Morandini et al., 2001); the same trend is observed when the fuel load is increased. The inclination angle of the flame toward the plane of propagation is increased with increasing slope angle. In addition, as the slope angle increases the flame front "depth" increases as well.

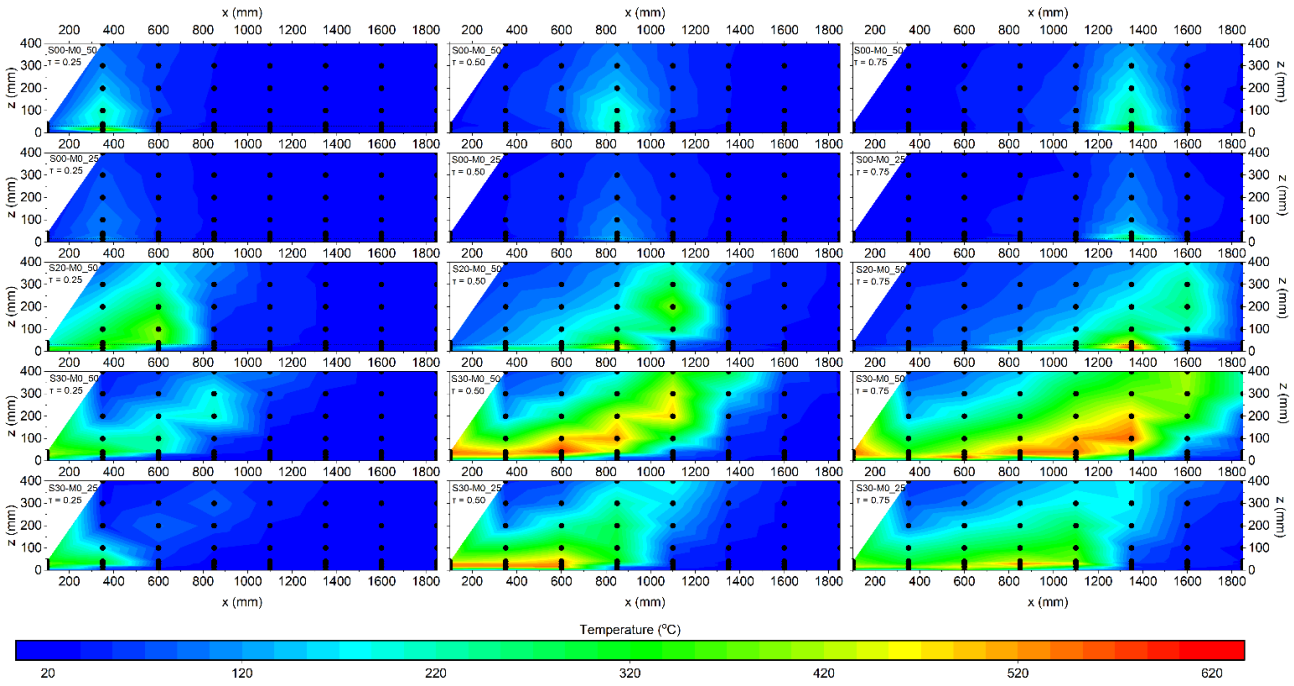

Figure 5 - Temperature contour plots for all test cases, at three characteristic dimensionless time values.

The temporal evolution of the horizontal heat flux at the downstream end of the fuel bed is presented in Figure 6. Again, increasing the slope and the fuel load result in an increase of the heat flux from the flame front. This is due to the fact that increasing the fuel load results in an increase of the flame height, while increasing the

slope decreases the flame tilt angle (the angle between the flame front and the combustion table). Both trends results in an increase of the radiative view factor which enhances the measured radiative heat flux. The latter is additionally enhanced by increased temperatures (as a result of increasing fuel load), as well as by increased emissivity (due to the increase of the flame depth).

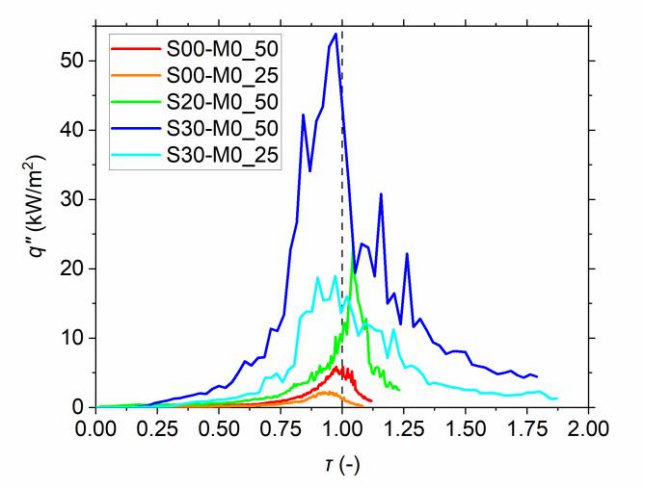

Figure 6: Temporal evolution of horizontal heat flux at the downstream end of the fuel bed.

The temporal evolution of the axial velocities near the downstream end of the fuel bed (x = 1650 mm) at three different heights (z = 100, 200 and 300 mm) are presented in Figure 7. At the height of 100 mm, close to the fuel bed surface, the negative velocities prior to the flame front's arrival indicate a downstream entrainment of air. After the passing of the flame front the axial velocities turn positive with a trend to increase with increasing slope. The magnitude of that upstream velocity seems to be unaffected by the fuel load (test cases M0_50 and M0_25), in contrast to the downstream velocity. At higher levels (200 mm and 300 mm), downstream air entrainment appears mainly in the non-sloped test cases (S00); additionally, the effect of fuel load seems to be stronger for test cases S30. As expected, the axial velocity magnitude decreases with increasing height.

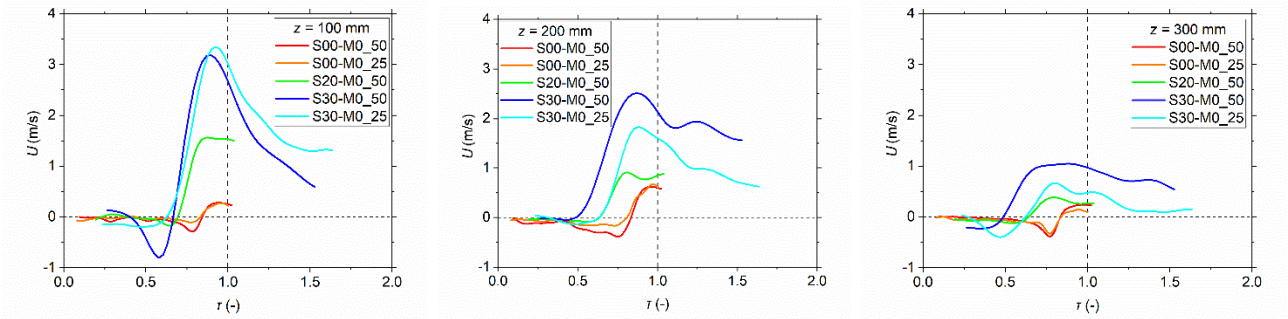

Figure 7: Axial velocity measurements at z = 100 mm (left), 200 mm (middle) and 300 mm (right).

4. Concluding Remarks

A parametric investigation regarding the effects of slope angle and fuel load on the characteristics of surface wildland fires has been conducted on a laboratory-scale combustion table. The trends observed are generally in agreement with respective findings reported in the literature. ROS increases with increasing slope angle and fuel load; a rapid increase is observed for a 30º slope angle. HRR follows a similar trend; the fuel load has a stronger influence on HRR compared to ROS. After ignition, the HRR seems to reach a plateau for all test cases, except those with a 30º slope, where HRR exhibits a continuous increase until a peak value is reached and then a gradual decrease. The remaining fuel mass increases with increasing slope, due to the appearance of incomplete combustion conditions at the lower parts of the fuel bed. The spatio-temporal evolution of gas temperatures reveals that the flame depth increases with increasing slope and fuel load, while the flame tilt angle is decreased. Moreover, increasing fuel load and slope result in increased flame front temperatures; the same observations appears to be true also for the heat flux. Finally, axial velocity measurements reveal the magnitude

and the direction of the upstream and downstream air entrainment flows and how they change with slope and fuel load.

Forest waste valorization; Generation of synthesis gas; Biofuels

Abstract

The aim of this project is to valorize forest biomass wastes (and then prevent their occurrence as a fuel source in forests) into bioenergy, more precisely, production of 2nd generation synthetic biofuels, such as biogas, biomethanol, bio-DME, etc., depending on the process operating conditions, such as pressure, temperature, and type of solid catalyst used. The valorization of potential forest waste biomass enhances the reduction of the probability of occurrence of forest fires and presents a major value for local communities, especially, in rural populations. Biogas produced can be burned as biofuel to produce heat and/or electricity, for instance, in cogeneration engines applied for domestic/industrial purposes. After the removal of forest wastes from the forest territory, this biomass is dried, grounded to reduce its granulometry, and liquified at temperatures between 100-200 ºC. Then, using the electrocracking technology, this liquified biomass is mixed with an alkaline aqueous electrolyte located in an electrolyzer (electrochemical reactor which performs an electrolysis process), using a potential catalyst, in order to produce syngas (fuel gas, mainly composed of CO, H2, and CO2). In a second reaction step, the syngas produced can be valorized in the production of synthetic biofuels, in a tubular catalytic reactor. The whole process is easy to implement and energetically, shows significative fewer costs than the conventional process of syngas gasification, as the energy input in the conventional pyrolysis/gasification process is higher than 500 ºC, with higher pressures, while, in the electrochemical process, applied in this project, the temperatures are not higher than 70 ºC, with 4 bars of pressure, at maximum. Besides that, the input of energy necessary to promote the electrolysis process can be achieved with solar energy, using a photovoltaic panel. In the production of biogas in the catalytic reactor, there is another major value from this process, which is the co-production of water, as Sabatier reaction converts CO2 and H2 into biomethane (CH4) and steam water, at atmospheric pressure, with 300 ºC of temperature, maximum, with a high selective solid catalyst. Finally, it is expected to produce a new bio-oil from this kind of biomass, with properties closer to a fossil fuel than wood bio-oils, which can be used as a fuel or as a diolefins/olefins source and, also, to produce, from forest biomass wastes, pyrolytic bio-oils with complementary properties and valorized characteristics. This can be used in the wood treatment or as a phenol source, for several industrial applications. A new and valorized application can be found for forest biomass wastes, which can be incorporated into the biorefinery concept.

1. Project background

Over the past years, Portugal has been affected by wildfires resulting in the degradation of natural resources and human life. The increased agriculture and forest lands that are unmanaged are one of the main contributions to wildfires. The present project intends to contribute to the reduction of wildfires by collection and valorization of the forest biomass growing in lands of higher wildfire susceptibility. The first step for biomass valorization passes through a detailed characterization (anatomical, chemical, physical and thermal properties) in order to establish the best platform for their transformation into energy or chemicals. Liquefaction and syngas production are two processes where the biomasses can be transformed into added-value products. Biomass liquefaction is a recent method that converts biomass into bio-oil. In the last years, there was an increase in the number of published works related to this technology (Huang, 2017), in particular, using forest biomasses (e.g. eucalypt, cork residues) (Mateus, 2016). Generally, this process has three main steps: depolymerization, decomposition, and recombination of biomass compounds at higher temperatures. The biomass is decomposed into bio-oil,

solid, and small gas components. The critical process parameters, such as temperature, residence time, repolymerization process, condensation, and compound decomposition of the different phases can change (Gollakota, 2018). The biomass liquefaction was applied first by Mateus et. al. (2016), using cork dust from the cork stoppers rectification process. The dust was dried at 120 ºC, and mixed under a glass reactor, with a mixture of organic solvents, and an acid catalyst at 160 ºC (90 min). The bio-oil was recovered after a purification process and, the solid waste obtained was dried. Hydrogen can be produced by water electrolysis, an electrochemical process, where it's needed to supply energy, from an electric source, producing also, oxygen, half the quantity of hydrogen (Carmo et al., 2013). It uses electric current through two electrodes: the anode (oxygen production) and the cathode (hydrogen production) (Guerra, 2015).

The natural gas, coal, and biomass can be converted into biofuels and chemical products, like biodiesel by the Fischer-Tropsch process, methanol/DME, hydrogen, and ammonia, all of them used as raw-material, syngas, depending on their quality, operating conditions, etc., through thermochemical processes, like, reforming, pyrolysis, partial oxidation, and gasification. Due to the higher energetic input costs, these processes are only economically feasible at large scales (Venvik, 2017). Besides that, it's possible to produce syngas ($CO/CO_2/H_2$), by water co-electrolysis with a carbon source. Today, syngas is indispensable in the chemical industry, crude oil, and energy industries. It is considered an attractive raw material in the chemical synthesis, as well, as in the production of clean fuels, like biofuels (biogas, methanol, DME) (Nguyen, 2015) (Khodakov, 2007). The main production processes result from the reforming process, especially used in the crude oil and petrochemical industries. The methanation reaction is called the Sabatier process. Recently, the methanation of carbon dioxide gained interest due to its application in the Power-to-Gas technology, as well, as the biogas upgrading, into natural gas. Hydrogen reacts with carbon monoxide and carbon dioxide and they are transformed into methane and, water as co-product. The methanation of carbon monoxide/dioxide is an overall exothermic chemical process (Stangeland et al., 2017).

The GreenSynFuel technology, patented by GSYF, a small Portuguese company that has been working with ISEL and IST-ID partners, with the purpose of producing syngas in only one reaction step, through an innovative electrochemical process of water alkaline electrolysis, using graphite as electrodes and, with electricity supply. The design of the electrolyzer used in this project is a quite differentiating point since the produced gas isn´t separated, as there is not a physical separation of the hydrogen and oxygen gases. This electrolyzer presents a significant reduction in costs, from the conventional electrolyzer technology (alkaline, PEM, and SOEC). This process can be used to produce renewable synthetic biofuels, as alternatively to fossil fuels. Biofuels obtained from forest biomass, are considered environmentally friendly and sustainable ones, if the electric source is a renewable one, like solar or wind energy (Guerra et. al, 2015) (Guerra et. al., 2018a) (Guerra et. al., 2018b). GSyF technology belongs to this category. The production and utilization of these biofuels will play an important role in the decarbonization of the energy mix, maximizing the utilization of renewable sources, like the forest biomass, going to meet the Energy Roadmap 2050 objectives of the EU, also defined in the National Script of Low Carbon.

A preliminary step, already performed at ISEL, was the built-up of a lab prototype, to test/validate this technology. Then, it was possible to build a pilot plant of this electrolyzer (with modules of 1 kW power) applied to produce syngas, with posterior production of biomethane and biomethanol, through water electrolysis with steel electrodes and liquified biomass, as the renewable carbon source. The valorization of biogas produced can be used, also, to produce heat/electricity, for the off-grid market, with special emphasis on the rural electrification. After technology validation, it's our purpose to perform the scale-up for modules with more power (megawatts), where the potential clients are the network management of low voltage, storage of renewable electric energy, and production of synthetic fuels. In this project, the main purpose is to produce biogas with this renewable process, valorizing the liquified biomass from the forest wastes, to prevent the probability of occurrence of wildfires.

2. Project preliminary results

2.1. Sampling and fractionation

Residues from *Acacia melanoxylon* were collected with the cooperation of Parques de Sintra - Monte da Lua, in Sintra, Portugal. Three types of residues were collected: i) chips (composed of wood and bark); ii) Crown

residues (composed of branches and leaves); and iii) a Mixture of the first two types of residues (chips and crown residues). The samples were air-dried in the laboratory for 1 month and then milled in a Retsch SM 2000 knife mill, sieved in a Retsch ISO 9001 vibratory screen, and the 40-60 mesh fraction was used for chemical analysis.

2.2. Chemical analysis

Forest residues from *Acacia melanoxylon* (chips – wood and bark; crown residues – leaves and branches; a mixture of both) were collected and characterized by pyrolysis analysis (PY-GC/MS). The extractive-free samples were milled to a fine powder and around 0.10mg pyrolyzed at 550ºC for 1 min. The content in carbohydrates ranged from 42.6% (crown) to 52.4% (mixture), while lignin ranged from 19.6% (mixture) and 24.0% (chips). The monomeric lignin composition was similar between the samples, with a predominance of syringyl units (S, 15.2%, 11.1%, and 12.6%), followed by guaiacyl units (G, 7.8%, 7.1%, and 5.5%), and a minor percentage of *p*-hydroxyphenyl units (H, 0.3%, 0.7%, and 0.3%). This agrees with the literature since the Acacia species belongs to hardwoods, and in this group, the S and G-units prevail.

2.3. Bio-oils production and characterization

Several materials were used as feedstock for theprocess, such as heartwood, sapwood, bark, and branches from the burnt remains of a tree caught in the fires in Leiria national park, and pinewood sawdust was used as the standard feedstock material. Besides the shredding of some of the samples, such as the heartwood, sapwood, and bark samples, to increase the contact surface area between the solvent and the feedstock, no further treatments were done to the feedstocks. The standard chemical used as a solvent in the process was 2-Ethylhexanol, but studies were done utilizing pork lard (PL) and glycerol carbonate(GC). Regarding the catalyst, it was used p-Toluenesulfonic acid (PTSA) primarily, although some tests were done using sulfuric acid (SA). Also, a liquefaction procedure was tried which consisted of a moderate acid-catalyzed liquefaction process. The liquefaction of lignocellulosic material occurs through a solvolytic reaction under acid catalysts to form smaller fragments, with the further possibility that these fragments continue reacting with either themselves or with the solvent to form higher molecular fragments or solvent-derived compounds. The types of biomass used in the liquefaction processes were tested to find out their water and ash content, and the elemental analysis as well.

The studies performed on the solvent showcased the problem of using either PL or GC as a solvent, with the first producing low conversion rates and the second-highest viscosityproducts that are difficult to work with at an industrial scale. As for studies done about the catalyst and temperature, the best results using PTSA were produced when it was fed in higher amounts to the reactor, and whilst the SFA showed better conversion yields for reaction temperatures below 170 ºC, as the temperature increased the conversion gap between the two catalysts tested decreased. Some of the lignocellulosic samples, heartwood, and sapwood, produced consistently higher conversion yields for the type of feedstock used, showcasing similar behavior. At the same time, the reaction times increased, with thestandard pine trailing behind them. As for the bark and branches samples, their conversionrates were mostly lower than those of other samples, similar to the increasing liquefaction time. Some bio-oil samples, produced from heartwood,sapwood, and bark, had their excessive solvent removed and their TAN and OHN calculated through titration, with both of those values following opposite trends to the ones expected by the literary research. The OHN of the samples was also mostly lower than the lowest limit necessary for rigid and semi-rigid polyurethane production. As a whole, the tests conducted showed that the samplesfrom burned wood, especially samples of heartwood andsapwood, can be used in liquefaction processes and produce high conversion yields that originate in final products, such asbio-oils, that have a higher HHV and can be used in several industrial processes as fuels. This indicates that liquefaction is a possible way to somewhat reduce the economic impact felt by landowners who suffered due to the fires that raged through the country last summer and autumn, by using the valueless waste resulting from the burnt wood and creating a value-added product that can be used as fuel.

Also, bio-oil production was performed by the thermochemical liquefaction method. Different species of woody biomass such as burnt pine heartwood, Acacia Melanoxylon bark wood; 2-Ethylhexanol was used as a solvent and p-Toluenesulfonic acid was used as a catalyst. The procedure consisted of a moderately acid-catalyzed liquefaction process., and it was applied under different conditions in accordance with MODDE 12.1 Pro® software program to obtain the model. After numerous trials, optimal results showed a bio-oil yield of 86.03% at 160 ºC for 180 mins of reaction time and by using 5.5% p-TSA catalyst concentration overall mass and an HHV of 36.41 MJ/kg, energy densification ratio of 1.96 times greater than the HHV of burnt pine heartwood.

In addition, the liquefaction conversion of the bio-oil from acacia bark wood was 83.29% at 170 ºC for 30 mins of reaction time and by using 10% p-TSA catalyst concentration overall mass. A reaction surface methodology (Box-Behnken design) was applied for liquefaction reaction optimization. The obtained model for the liquefaction of Burnt Pine heartwood offers an ideal correlation with the experimental data as R^2= 0.988. The model predicts accurate responses with a probability of 98.8%. Furthermore, the software offers relatively more accurate responses with a probability of 99.8% (R^2=0.998). In the proposed model for Burnt pine heartwood, the most effective coefficient was temperature, while the most effective was the catalyst concentration for acacia bark wood. The liquefied products were characterized by Fourier Transformed Infrared (FTIR) and thermogravimetric analysis (TGA); Scanning electron microscopy (SEM) was also performed to confirm the effect of the morphological changes on the surface area of the solid samples.

Fire-spotting, Flame geometry, Atmospheric stability, Climate classification, Climate change

Abstract

The aim of the present study is to provide a simple yet complete addition to operational fire spread models for representing the random behavior of fire-spotting in various climate classes through simple inputs related to the wildfires. Results from different test cases highlight the sensitivity of the proposed simple physical parametrization in simulating different scenarios of the generation of secondary fires by fire-spotting under different climatic conditions. Since climate change may cause extreme conditions that contribute to the high fire intensity and larger wildfires, the parametrization here proposed allows us to model the fire-spotting process in various climatic zones and to adjust the existing operational model to the climatic changes.

Fire-spotting involves aspects among scales: from the combustion chemistry in microscale, to fire-atmosphere interaction in macroscale. At the meso-scale level, fire-spotting is affected by the mean wind and fireline intensity, which is found to be in a strong interaction with the surrounding factors, such as fuel and local orography. At the macroscopic level, the atmospheric stability conditions impact the fire-spotting pattern. Both, meso- and macro-scale factors are taken into consideration in the proposed probabilistic model devised to provide a physical meaning to the spread of fire by virtue of firebrands, which allows the integration of the diversity of all these parameters into a few differentiable regions. For this purpose, the classification based on the Köppen-Geiger map is considered, as it is done in the study of complex natural systems in a broad range of topics in hydrology, agriculture, biology, and many others.

Preliminary studies show as well that fire-spotting is a vegetation-dependent phenomena, since not all types of vegetation can generate sufficient combustion energy or produce the firebrands. In order to represent the vegetation component of the fire-spotting generation, the biome world map is incorporated, resulting in the integrated climate-biome classification for the fire-spotting generated fires.

1. Introduction

In present study we are aimed to integrate the diversity of climate-dependent parameters of the fire-spotting into a few differentiable regions basing on an integrated climate-biome classification. For that purpose, ***RandomFront2.3*** routine described in Truccia et al. (2019) is considered to perform the calibration of the fire-spotting parameters to different climate classes by applying the statistical study and simulations. In the considered approach, the effect of the fire-spotting is incorporated into the main fire-front model by adding features related to the statistical description of the firebrands transport, which depends on flame structure and local weather, aerodynamics around firebrands, combustion and heat transfer of firebrands during flight. Since ignition of the fuel at the landing position involves heat exchange over a sufficient period, a delay effect due to "heating-before-burning" is taken into account by the model proposed in Trucchia et al. (2019).

The proposed multi-scale physical parametrization for the fire-spotting phenomena points out the impact of atmospheric stability and fuel moisture on the fire-spotting. This fact motivates us to improve the probabilistic model by including the local climate characteristics. Moreover, since climate change may cause extreme conditions that contribute to the high fire intensity and larger wildfires, the proposed parametrization allows for modelling fire-spotting phenomenon in various geographical zones and adjustment of the existing model to the

climate changes. Thus, we focus on the calibration of the fire-spotting parameters to different climate classes by applying the statistical study and simulations.

2. Integrated climate-biome classification

Despite a growing body of literature that recognizes the interaction between climate and wildfires, much less is known about the climate impact on fire-spotting. However, the amount and bark type of fuel determine the energy available for combustion, while wind and hot air are the primary drivers of the fire-spotting. Locality of these factors cause the possible geographical variations of the fire-spotting patterns. Previous studies reported different spotting distributions, number and distances of the secondary fires in various geographical zones, see Storey et al. (2020).

In present research, we integrate the diversity of climate-dependent parameters of the fire propagation into a few differentiable regions basing on climate-biome classification. For the biome, the Walter's vegetation classification by Breckle (2002) is considered, while for the climate the Köppen-Geiger climate classification by Peel et al. (2007) has been applied. This classification distinguishes five climate groups, depending on seasonal precipitation and air temperature and their seasonality. These groups are:

A: Tropical, that is characterized by average temperature ≥ 18◦C with significant precipitation.

B: Arid, where the average temperature is around 20◦C with little precipitation.

C: Temperate, that has the coldest month averaging between 0◦C and 18◦C and at least one month averaging above 10◦C.

D: Cold (continental), where at least one month averaging ≤ 0 ◦C and at least one month averaging ≥ 10◦C.

E: Polar, that includes tundra and ice cap, and characterized by every month average temperature ≤ 10◦C.

Hence, there have been chosen several climate classes with the parameters given in Table 1. The integrated climate-biome parametrization is incorporated to the operational code LSFire+ via ***RandomFront2.3*** post-processing routine, see Trucchia et al. (2019). In the considered probabilistic model, depending on the climate class the ambient temperature, the ABL height and mean biomass are chosen. Rest of parameters are fixed in order to emphasize the impact of the climatic factors. Table 1 connects and systematizes various classifications, such as Köppen-Geiger climate classes, biomes and NFFL fuel models. The flame geometry is found to be proportional to the mean biomass. It is important to notice that the parameters may vary within the same climate class due to season and location.

Table 1. Climate dependent parameters for the wildfire propagation modelling

Climate Class	Biome	Mean biomass, tons/ha	NFFL Model	H_{ABL}	Localization
Af	Tropical rainforest	500	6	1200 / 350	South America, Amazonia
BSh	Savanna	27	3	3500 / 2500	South-East Australia
BWh	Desert	4	1	2700 / 550	South-East Australia

In present study, for the simulation of the fire front propagation, we use the NFFL fuel model Scott and Burgan (2005), which allows the consideration of the fuel characteristics in accordance with the chosen climate class. Thus, the climate characteristics are incorporated not only through the parameters of the fire-spotting distribution but also through the parameters of the underlying fire-spread model. Moreover, one of the key vegetation characteristics, net primary productivity, impacts through the fire intensity on the flame length and the maximum loftable height.

3. Multiscale parametrization

The described above climate-biome parameters are incorporated into the fire-spotting probabilistic model of Trucchia et al. (2019). The firebrand landing distribution $q(\ell)$ is here assumed to be lognormal distributed following

$$q(\ell) = \frac{1}{\sqrt{2\pi}\sigma\ell} e^{-\frac{\left(\ln\frac{\ell}{\mu}\right)^2}{2\sigma^2}}, \tag{1}$$

with median μ and mode $\mu e^{-\sigma^2}$.
At the macroscopic scale, fire-spotting is affected by atmospheric conditions. In particular, we plug the depth of the atmospheric boundary layer (ABL), that is related to the atmospheric stability, into the estimation of the smoke-injection height including the uplift against the atmospheric stratification and the plume widening due to entrainment of the surrounding air. Then, it holds

$$\mu = H_{max}\sqrt{\frac{3\,\rho\,C_d}{2\,\rho_f}},$$

where H_{max} is the maximum loftable height, ρ is the air density, ρ_f is the fuel density and C_d is the drag coefficient. In fact, H_{max} depends on the fire intensity and atmospheric stability, the detailed study of this parameter and the impact of the atmospheric stability conditions are provided in Egorova et al. (2020).

The parameter σ is defined in Egorova et al. (2022) as follows

$$\sigma = \frac{1}{z_p}\ln\left(\sqrt{Fr} + \beta\sqrt{\frac{2\,\rho_f U^2}{3\rho C_d g\,L_f}}\right),$$

where Fr is the Froude number, $\beta = 0.945$ is a correcting factor, g is the gravitational acceleration, and L_f is the flame length written in terms of the fireline intensity I_f and some surrounding factors as follows

$$L_f = \beta_0 I_f^{2/3} = \frac{I_f^{2/3}}{\cos\theta\,\left(2g\left(\rho c_p T_a\right)^2\right)^{1/3}},$$

where c_p is the specific heat of air at constant pressure, T_a is the air temperature and θ is the tilting angle in the simplified model of the flame geometry presented in Figure 1.

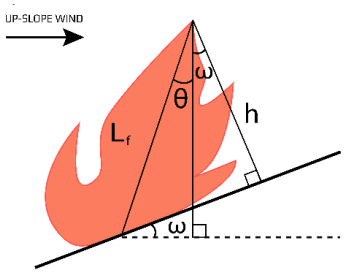

Figure 1: Flame geometry

Considered parametrization of the downwind landing distribution admits the consideration of climatic factors and their impact on fire-spotting, and, consequently, on the fire front propagation, which will be discussed further.

4. Simulations

The simulations show that by using the considered physical parametrization of the fire-spotting distribution different fire-front patterns can be obtained. We focus mainly on the climate classes with registered fire-spotting events, such as South-Eeastern Australia (BSh and BWh classes) and Mediterranean zone (Csa class).

For BSh and BWh climate classes (see Table 1), which can be considered as a pattern for the South-East Australia, as well as Csa class (Mediterranean class), the stable and unstable atmospheric conditions are considered to compare the fire-spotting patterns not only between the classes but also within the chosen class. The simulated fire fronts are plotted in Figures 2, 3 and 4, respectively.

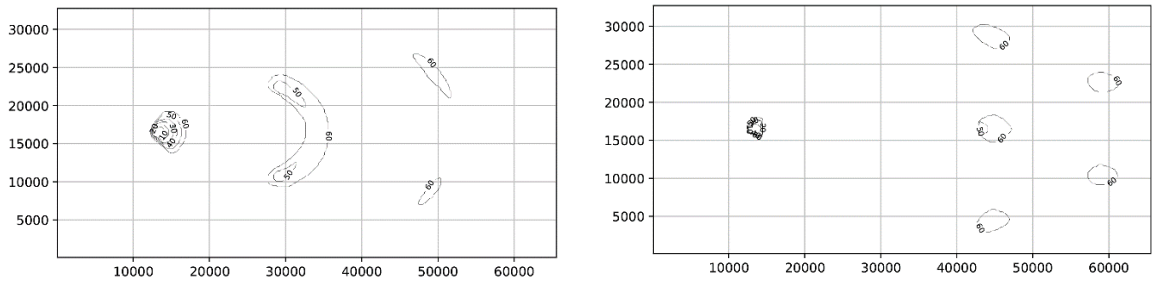

Figure 2: Fire-spotting pattern in the BSh climate class (South-Eastern Australia) during the unstable (left) and stable (right) atmospheric conditions

In the case of BSh, the fire-spotting is observed in both modes: unstable and stable atmospheric conditions. However, with unstable atmosphere, which corresponds to the daylight period, the secondary fires merge, while during the stable conditions the fire-spotting pattern is characterized by longer travel distance of the fire brands and higher number of new independent ignitions.

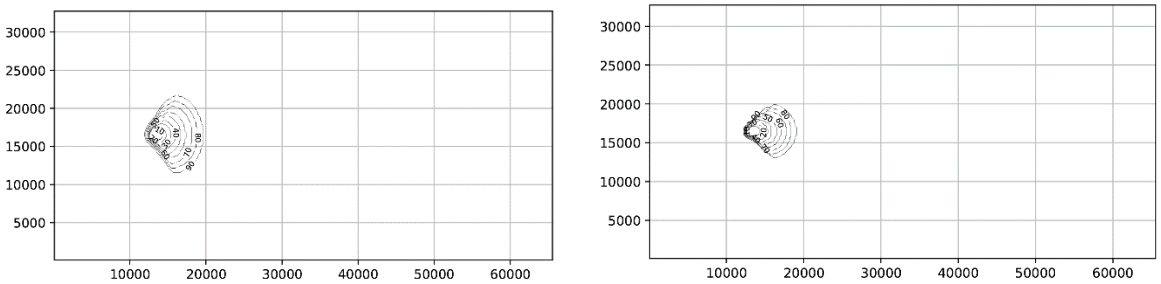

Figure 3: Fire front without fire-spotting in the BWh climate class (deserts in South-Eastern Australia) during the unstable (left) and stable (right) atmospheric conditions.

In contrast, for the BWh class, which represents deserts located in the South-Eastern Australia, fire-spotting is not observed, exposing the effect of the climate factors of the model. Moreover, the main front under the unstable atmospheric conditions is larger due to the turbulence effect, see Egorova et al. (2020) for details.

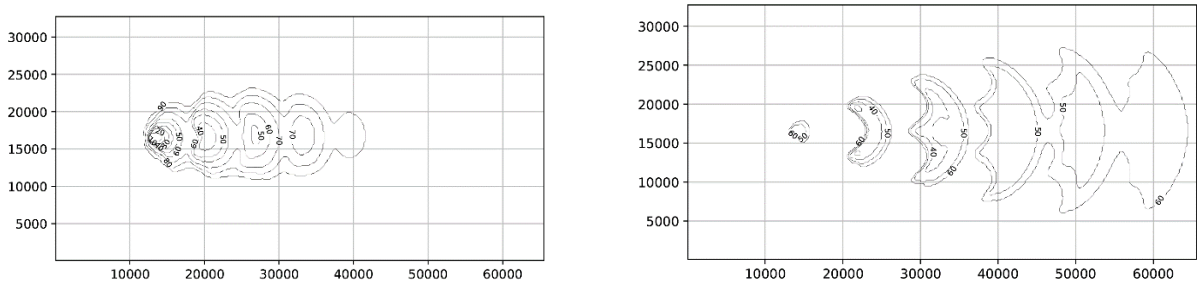

Figure 4: Fire-spotting patterns for the Csa climate class (Mediterranean Area) during the unstable (left) and stable (right) atmospheric conditions

Slightly different patterns can be obtained for the Mediterranean climate class Csa in Figure 4: during unstable conditions fast merging leads to one large fire, while during the stable atmosphere several spotting fires can be observed. Hence, the structure is like for BSh class, but the form of the fire front is completely different.

The performed simulations reflect qualitatively the reality: in different climate classes different fire-spotting patterns are observed. Unfortunately, validation though the comparison with historical data is not feasible. In fact, we cannot get sufficient statistical information about fire-spotting generated fires from wildfires worldwide from satellites' data collected using NASA Fire Information for Resource Management System (FIRMS).

Actually, data are taken from two satellites: MODIS with resolution 1 km and VIIRS with resolution 375 m, which means that VIIRS can capture smaller fires.

The observation horizon is chosen from 2012-01-20 to 2021-08-31. The data were collected for BSh and Csa climatic zones, BWh class is omitted since there is no fire-spotting. Due to this lack of data, we oversimplify the framework by assuming that fires captured by MODIS are primary fires, while the rest "small" ones could be secondary, or spot fires. The results for various climate classes are reported in Table 2. Thus, in order to estimate the proportion of the fire-spotting generated fires, we calculate the percentage of these larger fires and then estimate the number of possible secondary fires for one primary fire.

Table 2. Approximate number of small independent fires for one large fire in various climate classes.

	BSh class	***Csa class***
Total	3.77	4.31
Day fires	2.69	2.19
Night fires	6.50	12.31

The proposed model of fire-spotting with integrated climate-biome classification reflects qualitatively real patterns: during the night the number of small independent fires is higher. In the case of BSh climate class the number of small fires is doubled, see Figure 2, which agrees with the performed simulations where the doubled number of secondary fires is observed during the stable atmosphere conditions comparing to the unstable ones. For Csa class the difference between patterns in unstable and stable atmospheric conditions is rather significant, see Figure 4, which is also reflected by the simulations. Beside these, we remind the case of the BWh class where actually, for the corresponding set of the parameters, no fire-spotting generated fires appear consistently with the property of the class: these also can be considered as a kind of first validation test of the model since simulations reflect the fact that in desert there is no fire-spotting, see Figure 3.

5. Conclusions

In this study, we propose a multi-scale physical parametrization for the fire-spotting phenomena, which includes such climate-dependent factors as atmospheric boundary layer, fuel type, vegetation, in order to adjust the existing model to the changing conditions. Analyzing the different parameters, the integrated climate-biome classification has been proposed for the various climatic zones. The simulations show that by using the proposed parametrization of the fire-spotting distribution different fire-front patterns can be obtained. We focus mainly on the climate classes with registered fire-spotting events, such as South-Eastern Australia, and Mediterranean zone. The South-Eastern Australia is represented by two climate classes with completely different fire-spotting patterns: in the case of desert, the fire-spotting is not observing in the simulations, which agrees with reality. This fact shows the sensibility of the proposed classification for the probabilistic fire-spotting model.

The adjustment of the fire-spread model to the climate class becomes more and more urgent due to the climate change. In other words, the prediction of the wildfire propagation may vary not only in space but also in time. Some parameters, mainly climatic, which are usually considered as constant for a given location may change and the fire will propagate in different manner.

Critical heat flux for ignition, dead fuel, live fuel, moisture content, *Pinus halepensis* needles.

Abstract

Wildland fire spread has been shown to exhibit unexpected behaviors depending on the fuel roughness, wind and land topography. Fire outbreak has attracted for a long time both wildland fire scientists and operational. The critical heat flux for ignition is one of the most important parameters used in fire safety. For example, it may be used for the fuel breaks estimation at Wildland Urban Interface. The critical heat flux for ignition of dead and live Pinus Halepensis needles (moist and dry) is investigated using a cone calorimeter. It is determined by using a recently developed method based on the phase transition theory where ignition time behaves according to a power-law trend near threshold. Compared to the usual deterministic methods, this method accounts for the probabilistic ignition behavior observed for porous fuels. The determined critical heat flux for ignition seems to be independent of the state of the fuel (live or dead) and of its moisture content within the errors. A heat transfer analysis is realized using the steady temperature which is related to the absorbed incident heat flux. From this analysis it is concluded that surface temperature at ignition does not change for fresh or dry live and dead fuels.

1. Introduction

Every year, a very large number of wildfires raged across the globe (Martin et al.2016), causing human misery and damage to properties. In the last decade, wildland fires become more intense and prolonged in time. The wildland fire safety has drawn the interest of scientists and operational in the effort to overcome fire outbreak and spread. Wildland management and Wildland Urban Interface (WUI) are among the main topics requiring fire risk reduction. This may be realized either by including fire breaks or by planting less flammable fuels. The critical heat flux for ignition is the parameter investigated for this end. Usually, the critical heat flux for ignition has been estimated by deterministic methods like ASTM 1534 standards (ASTM, 2017). However, such methods do not account for the probabilistic behavior of ignition that occurs near the critical heat flux. Recently, a new method based on phase transition theory (Stanley, 1971; Yeomans, 1992) has been proposed for the estimation of the critical heat flux for ignition applied to porous fuels (Sabi et al., 2021). The critical heat flux obtained by this method appears much smaller than those using deterministic ones. This is due to the probabilistic behavior occurring at lower heat flux intensities. Phase transitions are ubiquitous in nature, they can be observed in various fields like conductor/insulator or percolation (Stauffer and Aharony, 1992), liquid/gas (Blundell and Blundell, 2006), paramagnetic/ferromagnetic transitions (Stanley, 1971), etc.

The flame is a gas phase phenomenon (Drysdale, 2011), and emitted volatiles can be either in the flame state if ignition occurs, or remain in gaseous state if ignition does not. Ignition/non-ignition phase transition is referred to the different states of the gas phase: flame (ignitable) or gas (non-ignitable) (Sabi et al. 2021). Sabi et al. (2021) have studied analytically the ignition time behavior using a simple model based on conservation energy, where ignition temperature was the only ignition criterion. This analysis led to a logarithmic divergence of ignition time while this divergence has been found experimentally to be power-law. The power-law divergence has been recovered by considering the critical rate of flammable gas emission. The critical heat flux for ignition may depend on various fuel parameters like moisture content, porosity, and its live or dead state. Terrah et al.

(2020) have found that there is no critical moisture for ignition; they suggested that for any moisture content there is a critical flux for ignition because of the difficulty igniting of fresh live fuel. Jervis and Rein (2015) have shown that the most flammable fuels are fresh dead and aged needles followed by dry live needles, the least flammable are the fresh live needles. Recently, it was found that the rate of spread is higher for dried live *Pinus Halepensis* needles (with maximum flame height) than for fresh live ones (with smaller flame heigh) which indicates the existence of moisture threshold for fire spread (Aizeti, 2021). According to such a flammability difference, it is expected that the more the fuel is flammable, the more its critical heat flux for ignition is smaller. For instance, it can be reasonably thought that a moist fuel has a larger critical heat flux than a dry one. In this work, the influence of the state of the fuel (dead or live) and moisture content on the critical heat flux for ignition of *Pinus Halepensis* needles is investigated using a cone calorimeter.

2. Experimental setup and sample preparation

The ignition process is realized through a cone calorimeter with an electrical resistance of a power of $3000\ W$ used as a heat source. The heat source provides to the sample an incident radiation heat flux of magnitude ranging from 5 to $25\ \mathrm{kW/m^2}$. The received heat flux is varied by changing the distance of the top surface of the sample to bottom of the cone calorimeter. The heat flux at the top surface position of the sample is calibrated by using a water-cooled heat flux sensor of type Hukseflux SBG 01 working in the range 0-200kW/m². The experimental setup and calibration are shown in Fig.1. The ignition is controlled by a pilot flame located *2 cm* above the sample top surface. Although the distance to pilot is slightly greater than the $1\ cm$ required by ASTM 1354 standards (ASTM 2017), it allows avoiding the contact of needles with the pilot. The cone calorimeter is further equipped with a K-type thermocouple measuring surface temperature (placed perpendicular to the needles at the top surface of the sample). The time evolution of temperatures provided by the K-type thermocouples is recorded via a data acquisition station Graphtec midi-LOGGER GL 840 connected to a personal computer. The steady temperature is realized by exposing the samples to a sufficiently low heat flux to avoid ignition. In this case, both surface and gas temperatures become nearly constant at a maximum value within a steady period (around 50 min). As will be shown below, the maximum steady temperatures are related to the absorbed incident heat flux.

Pinus halepensis needles are harvested from the Campus of USTO University. The fuel is in three (3) states: dead, fresh live and dried live. The live fuel is completely dried using a micro-wave oven for $3\ min$. This device allows a short drying time to maintain the fuel it is live state before ignition. The micro-wave oven provides the same drying quality as the other devices (Terrah et al, 2020). Live fuels of $10\ g$ mass are either ignited directly (moist fuels) or completely dried (moisture content of 50% in wet basis) before ignition. Dead fuels of $5.5\ g$ mass (moisture content of 10% in wet basis) are considered for ignition. The samples are placed in a cylindrical holder of $10\ cm$ diameter of a mesh shape. The mass was weighted using a Kern PCB 350 balance with $1\ mg$ resolution. The ignition test is considered as succeeded and recorded if the flame persistence time is greater than $4\ s$ (sustained ignition). It is considered as failed if smoldering combustion is observed instead of flaming, with complete oxidation of the fuel in its solid phase (Rein, 2016).

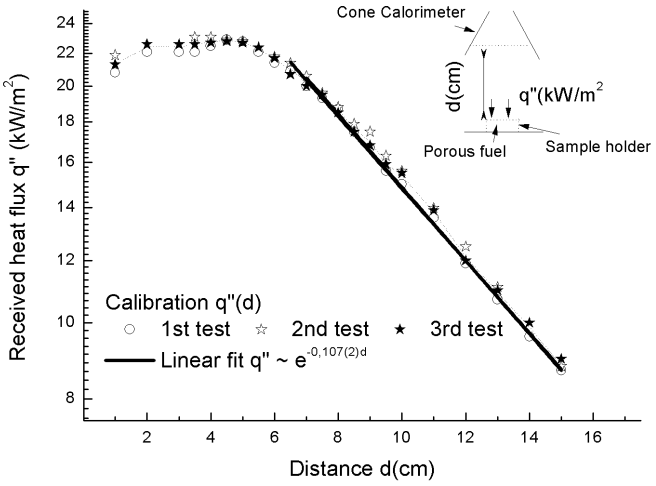

Figure 1- A schematic representation of the calibration flux and the experimental setup

3. Results and discussion

As mentioned above, recently a new method based on phase transition theory (Yeomans, 1992; Stanley, 1971) has been proposed to estimate the critical heat flux for ignition of porous fuel (Sabi et al. 2021). Compared to the usual methods, this method has been shown to account for the ignition probabilistic behavior occurring near the region of the critical heat flux for ignition. Sabi et al. (2021) have shown that ignition time t_{ign} diverges as a power-law as $q"_{inc} - q"_c$ as

$$t_{ign} \sim (q"_{inc} - q"_c)^{-\gamma} \quad (1)$$

The critical exponent γ is related to the kind of ignition. The estimation of the critical heat flux consists in varying $q"_c$ until the power-law trend appears of t_{ign} as a function of $q"_{inc} - q"_c$ (i.e. until the best linear fit of the plot in logarithmic scale is obtained).

Fig. 2 shows ignition time as a function of $q"_{inc} - q"_c$ in logarithmic scale for the 3 states of *Pinus Halepensis* needles (fresh live, dry live and dead). The critical heat flux for ignition $q"_c$ is obtained as to have the best linear fit. The uncertainty is estimated by estimating the critical flux within 5 % reduced correlation coefficient. It is found that the critical heat flux for ignition is the identical within uncertainties for the 3 states (dead fuel, fresh live fuel and dried live fuel), despite that the ignition process takes a longer time for moist live fuels than dried ones or dead fuels. The critical heat flux for ignition is independent of moisture content contrary to Terrah's suggestion (Terrah et al. 2020). The lines representing the three states of the fuel in Fig.2 (logarithmic scale) appear nearly parallel, corresponding to nearly constant a critical exponents. This suggests that ignition process is similar for the three states of the fuel.

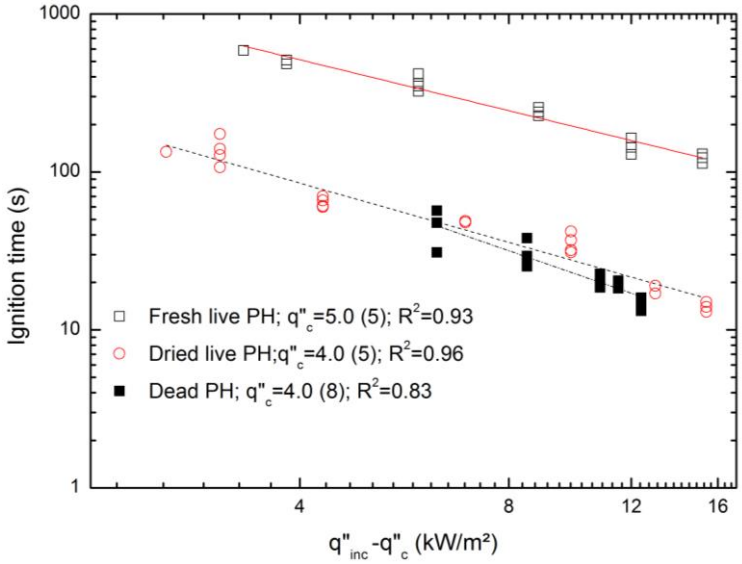

Figure 2: Ignition time vs. $q"_{inc} - q"_c$ for dead and live fresh and dried live fuls

To interpret this result let us analyze the heat transfer mechanism involved in ignition process. When the fuel bed of mass $m = m_{dry} + m_w$ is submitted to an incident heat flux $q"_{inc}$, it is heated to a temperature T, and the net absorbed heat flux by the fuel $q"_{net}$ is related to the absorbed incident heat flux $aq"_{inc}$ and the lost flux. Neglecting conduction heat transfer, and vapors emission, this is described by the following equation:

$$q"_{net} = aq"_{inc} - h(T - T_0) + \sigma\varepsilon\left(T^4 - {T_0}^4\right) = \left(m_{dry}{c_p}^f + m_w{c_p}^w\right)\frac{dT}{dt} \qquad (2)$$

Here h is the convection coefficient, σ is the Stefan Boltzmann constant, ε is the emissivity of the fuel, T_0 the ambient temperature, and ${c_p}^f$ (${c_p}^w$) is the specific heat of fuel (water). As surface temperature T increases with time, the lost heat flux increases, which decreases the net absorbed heat flux until it vanishes asymptotically (for a sufficiently low heat flux with no ignition), leading to a steady (maximum) temperature T_{max}. Therefore, the absorbed incident heat flux is related to the maximum temperature as:

$$aq"_{inc} = h(T_{max}-T_0) + \sigma\varepsilon\left({T_{max}}^4-{T_0}^4\right) \qquad (3)$$

In Fig.3 time evolution of temperature is presented for the parameters of moist and dry *Pinus Halepensis needles* used in (Sabi et al., 2021). The maximum temperatures seem to fluctuate within $10° C$. Within this temperature interval, both moist and dry fuels maximum temperatures seem to collapse. At the critical heat flux for ignition, the maximum temperature coincides with ignition temperature. This means that the fuel bed surface temperature reaches ignition (T_{ign}) asymptotically at $t \to \infty$. Replacing T_{ign} in equation (3) The critical heat flux for ignition reads thus:

$$aq"_c = h\left(T_{ign}-T_0\right) + \sigma\varepsilon\left({T_{ign}}^4-{T_0}^4\right) \qquad (4)$$

As a consequence of the results shown in Fig.2, it appears that ignition temperature does not vary with moisture content, and is identical for dead and live fuels within the uncertainty.

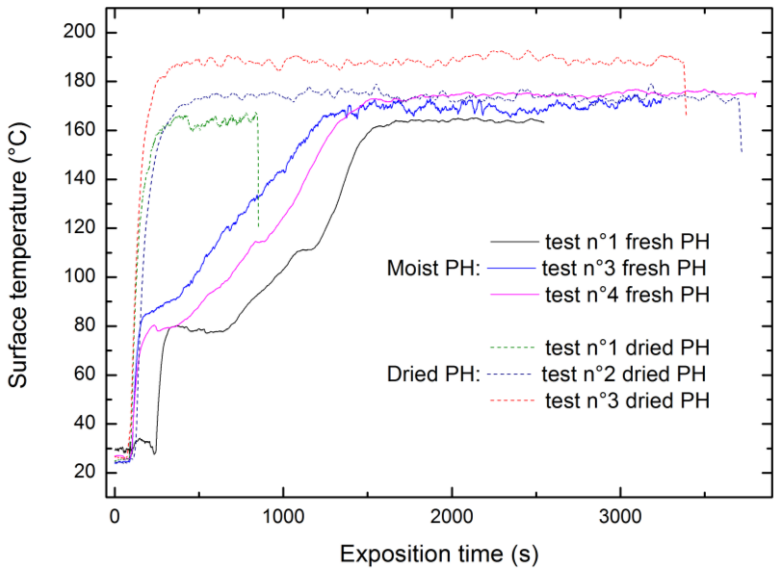

Figure 3: Steady surface temperature as a function of exposition time for moist and dried Pinus Halepensis

4. Conclusion

The estimation of the critical heat flux for ignition based on phase transition theory is used to compare the ignition for three states of *Pinus Halepensis* needles: dead, live fresh and live dried. The critical heat flux for ignition seems identical for the three states, although ignition time is very different for each state. A heat transfer analysis led us to conclude that surface temperature at ignition is identical for these states of the fuel bed within statistical errors.

Drone swarm technology as a competitive alternative to traditional aerial firefighting

Ágoston Restás

University of Public Service, Institute of Disaster Management. 1101 Budapest, Hungary, krt. 9-11., {restas.agoston@uni-nke.hu}

Keywords

Aerial firefighting, drone, swarm, effectiveness, water flow

Abstract

Aerial firefighting is effective however very expensive solution to suppress forest fires. Drone application as a most developing branch of the aviation industry can be a complement, or perhaps even a competitive solution with the traditional aerial firefighting. Based on the input data drone swarm technology can be not just an effective but also an efficient solution suppressing forest fires. In this study author used both practical and theoretical approach to investigate the possibility of drone usage delivering suppressant to fire front. Firstly, the required width of wetting strip and the required amount of water per unique area were investigated; practical experience shows that based on the flame length first responders can estimate both the effective width of the fire brake and the amount of water required per a unique area. As a second part of this paper, the transport capability of a drone was investigated during its life cycle that is specially optimized for firefighting. In the example author took a 100 kg transport capacity that is easy to transfer to other drone design; in case of 0.3 MWm-1 fire intensity 100 kg water is enough to make 100 m long fire brake, in case of 3.4 MWm-1 fire intensity 100 kg water enough to create only 2.5 m fire brake. Even if this latest results can be seen a bit short we have to take into account the swarm technology. In 10 km distance 30 drones can built a 5 m long fire brake per a minute that means 300 m per hour. This result is no worse than what large or very large air tankers can built averagely in this fire intensity. Expecting the technological development in the near future the length of the fire brake will raise drastically meaning that drone swarm technology will be not a complement but a competitive solution to the traditional aerial firefighting.

1. Introduction

Due to climate change, forest fires are an increasingly serious problem in the developed world. Fires will become more frequent, more widespread, and more difficult moreover the suppression costs are raising very dynamically. One of the most effective, but certainly the most expensive ways to suppress fires is by using aircraft. In doing so, planes or helicopters release various extinguishing agents, especially water or retardants, at the burning front line. Drone applications, as the most dynamically developing branch of aviation (Tsiamis et al. 2019) raises the question of whether the use of drones makes sense, has a professional or an economic advantage in firefighting tactics. Attempts have been made to use drones for fire detection (Yandouzi 2022), surveillance (Alexis 2009, Kumar 2011), and even to ignite controlled fires (Goldammer et al. 2012), but the possibility of extinguishing large-scale front lines has been investigated very limited (Ghamry et al. 2017; Ausonio et al. 2021).

There are more and more literatures dealing with drone technology (Tsiamis et al. 2019) moreover the latest time appeared even videos and reports, mostly in the social media, presenting the possibility of drone technology in the fight with different kind of fires (Gabbert 2019; Steffen 2020; Tech Insider 2021; Aydin et al. 2019). Forest fire requires much more extinguishing material than closed area fires so the drone technology due to its limited transport capacity seems to be not reasonable for this purpose. However, the swarm technology might compensate the limited transport capacity of single drones. As an example, a large air tanker (LAT) carrying 12,000 litres suppressant to 100 kilometres and it can takes 2 circles per hour means that the flow rate is 400 litres per minute at the fire front. The distance that is 100 kilometres seems to be long in normal case however this value is normal in case of LAT service. The flow rate can be the same if a fire engine with 12,000 litres capacity transports water for 10 kilometres distance with 2 circles per hour frequency. The fire does not mind about how far the water comes from or how it gets there, the main condition for extinguishing the fire is the amount of water flow. At the current level of technology, one drone is assumed not to be able to provide an efficient flow of water, but with their mass application, that is swarm technology, this might be ensured even today. The purpose of this paper is to investigate the possibilities of drone swarm technology to suppress fires.

2. Methods

The author used the relevant literatures dealing with drone swarm technology and firefighting however there are only some that focusing specially on this topic (Ghamry et al. 2017; Ausonio et al. 2021). Therefore, this study uses some assumptions that is adapted basically from other technology and practical experiences however the data regarding forest fires calculating with comes from the practice that confirmed by literatures as fundamentals (Byram 1959; Bel 1986/87). The author used in this research even his practical experience in both the application of drones and the extinguishing of forest fires, and he used also simple mathematical methods and logical conclusions to present the results.

3. Results

Knowing or estimating the intensity of a fire is important to be able to calculate how much suppressant we need to extinguish it. Low fire intensities can be extinguished with fewer extinguishing agents, while in the case of a higher fire intensity, the maximum amount of suppressant that can be used is not enough. The minimum and maximum amount of extinguishing agent required for successful suppression is known from laboratory measurements and practical experiences. The minimum effective amount may vary depending on the literature, usually between 0.2 and 0.5 kgm^{-2}; in this study, the author calculates a value of 0.5 kgm^{-2}. The maximum amount of suppressant does not exceed 5 kgm^{-2}, even in a mature forest. Knowing the length of the flame is needed to determine the width of wetted strip in front of the front line. Based on practical experience, a wetted strip of 2 to 2.5 times the flame length effectively counteracts the thru-burn, i.e., it prevents the spread of fire. The lower width value is sufficient at lower fire intensities, the higher value is at higher fire intensities. In the study, the author calculates a 2-fold value.

Based on the above, we have to choose the amount of extinguishing agent required per unit area by the intensity of the fire or by the height of the flame. The minimum effective amount of water is 0.5 kgm^{-2} and the maximum is 5 kgm^{-2}. In the study, the amount of water that the author assumed is delivered to the fire front with the drone was 100 kg. Figure 1 shows the amount of water that is sufficient to wet this area as a function of fire intensity.

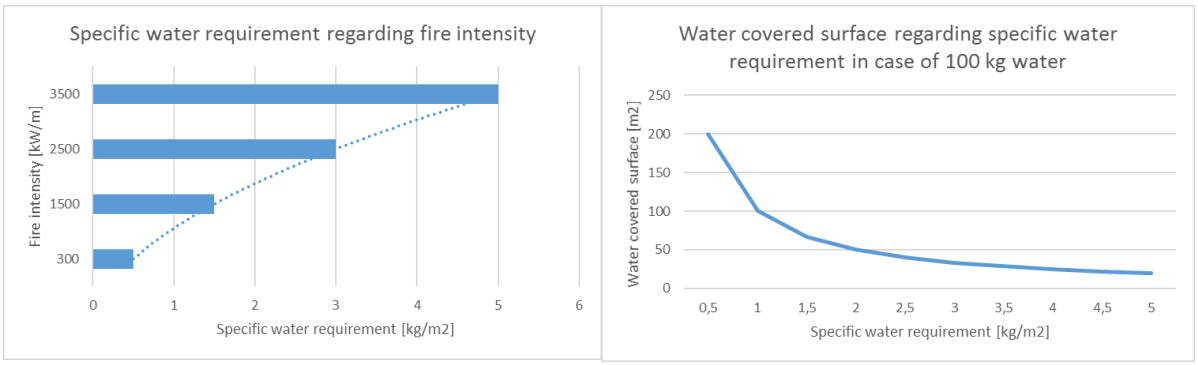

Figure 1. The amount of water that is sufficient to wet the area as a function of fire intensity (left) and the water covered surface depending on the specific water requirement (right)

The author assumed that the average life cycle of a drone optimized for firefighting is about 2,000 hours. It is possible if we count with the life cycles of brush less electric engines (Brando et al. 2022), that is a main critical part of the drone. The average speed during the service life is calculated with 80 kmh^{-1}, so the distance covered during the life cycle is about 160,000 km, in one half of which it carries a fire suppression materials to the fire front that can be water, short or long term retardants. In the other half of life cycle drone flies back to the charging station empty. The shape of the drone is aerodynamically optimized due to continuous long-range flights, so it also produces buoyancy with its surface design. This allows the specific energy consumption to be lower than e.g. at spray drones of the same power. When flying back, the weight of the drone is significantly less, so its flight speed can be higher than average, which can result in time savings that compensate for the loss of time caused by charging at the base and releasing time at the fire front. Using the above assumptions, the life cycle time is halved, so the transport time of the suppressants, as well as the return time is 1,000 to 1,000 hours. Besides the flight hours the time of suppressant release at the fire front and the refuelling time at the base site is considered negligible.

The load capacity of a drone developed for firefighting is assumed 100 kg. Based on this, the transport capacity of the drone is 8,000,000 kg.km (1000 h x 80 $km.h^{-1}$ x 100 kg) during its life cycle. This can be modified in the same way as the other data, following the logical principle of the calculations to obtain the efficiency characteristics for the given values.

Based on the first assumption (A), the distance between the refuelling base and the front line of the fire is taken to be 10 km on average. In this case, the drone can make 4 turns in 1 hour, so the delivered quantity is 400 kg. The distance and the delivered quantity are inversely proportional, i.e. the smaller the distance, the more the delivered quantity, and vice versa. Assuming individual cases, as the distance increases, the quantity that can be delivered decreases (200 kg per hour for 20 km) and increases as the distance decreases (800 kg per hour for 5 km). During the life cycle of the drone, that is about 2,000 hours, and taking four missions per hour cycle, 800,000 kg of suppressant can be applied at a distance of 10 km (2,000 h x 4 mission per hour x100 kg per mission). With this process at a distance of 5 km carried 1,600,000 kg water, at a distance of 1 km carried 8,000,000 kg water by only one drone. Based on the above we can multiply the transported value of the water depending on the number of the drones included in the swarm.

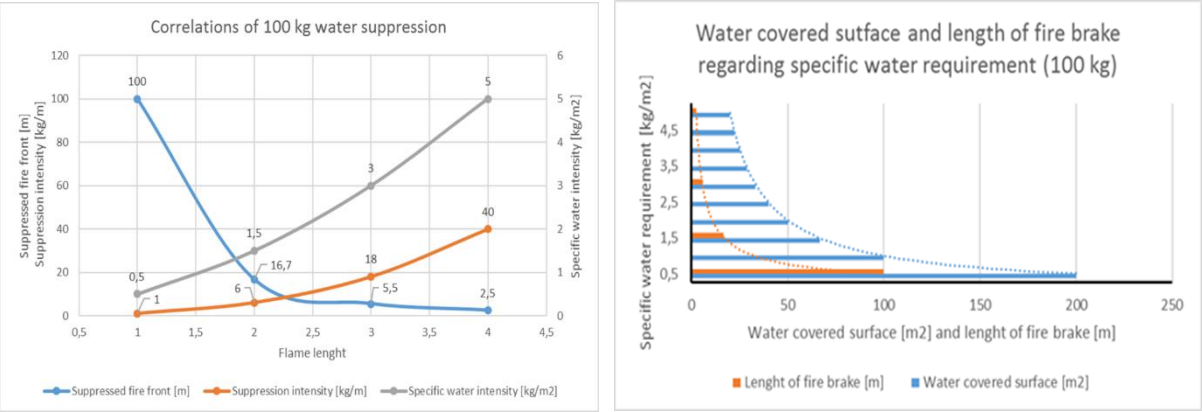

Figure 2. Different calculations of effectiveness with 100 kg water delivered by drone

4. Conclusions

Aerial firefighting is effective however very expensive solution to suppress forest fires. Drone application as a most developing branch of the aviation industry can be a complement, or perhaps even a competitive solution with the traditional aerial firefighting. Based on the input data drone swarm technology can be not just an effective but also an efficient solution suppressing forest fires. In the example author took a 100 kg transport capacity that is easy to transfer to other drone design; in case of 0.3 MWm^{-1} fire intensity 100 kg water is enough to make 100 m long fire brake, in case of 3.4 MWm^{-1} fire intensity 100 kg water enough to create only 2.5 m fire brake. Even if this latest results can be seen a bit short we have to take into account the swarm technology. In 10 km distance 30 drones can built a 5 m long fire brake per a minute, that means 300 m per hour. This result is no worse than what large or very large air tankers can built averagely in this fire intensity.

Pine forest, Ignition Characteristics, Fire spread, Smoke Toxicity, Smouldering (FT-IR)

Abstract

The mechanisms of fire and smoke spread in forest and vegetation fires have not been fully investigated. Most numerical models often only consider the topography of the area and climatic influences such as wind and temperature. There is a need to understand the fire behaviour of specific vegetation in order to predict how the fire and smoke will spread during a fire incident. Understanding the mechanisms and behaviour of fire is therefore important for both, preventing and fighting fires. The European research project DRYADS and the associated German pilot project "Fire research in forest fires and derivation of safety measures" deal with these problems. Therefore, several measurement campaigns were carried out to study safety-relevant parameters, fire behaviour, fire spread and spontaneous combustion processes of specific German vegetation and soil samples. The research objectives of the studies focused on the characterisation of fire development and spread as well as smoke composition.

1. Introduction

Common pine vegetation (Pinus sylvestris) is involved in approximately 75% of wildfires in Germany. Over the past five years, the German regions of Saxony-Anhalt and Brandenburg have been particularly affected, with an increase in the number, severity and area affected by fires. It is essential to understand the mechanisms of vegetation-specific fire behaviour and smoke production in order to develop effective fire fighting measures. To achieve this, fire experiments are conducted on 0.25 m² soil samples to characterize the ignition proteries and fire spread in ground fires. In addition, self-ignition amd smouldering tests of the local soil and vegetation samples were conducted in a DIN tube furnace and the resulting smoke gases were measured and analysed by FT-IR spectrometry. Furthermore, the self-ignition behavior of soil samples was investigated by thermal storage tests, performed in the SEDEX-oven. Also here the smoke gases were measured by FT-IR. The results provide an comprehensive overview of typcial fire behavior and smoke compositions and characterize essential factors influencing ground fires.

Previous studies (Huand & Rein, 2014; Morandi & Silvani, 2010; Martin et al, 1993; Tihay et al, 2016) (selection) already show characteristic processes of fire spread in forest soils; the present series of experiments is intended to determine regional characteristics. In addition the results provide the basis for large-scale tests and numerical simulations within the DRYADS-project.

2. Small-Scale Fire Tests

2.1. Experimental Setup

The small scale (real scale) fire experiments were conducted in 25 x 50 x 50 cm plexiglass boxes outdoors. Samples were taken from natural vegetation (52°23'04.8"N, 11°14'11.8"E) and dried under ambient conditions, to obtain low moisture levels. The ignition was performed by placing a heat-conditioned metal cylinder (approximately 650°C, pre-heated in the Muffeloven) on the dry litter layer of organic material. Temperatures were measured at different locations and depths of the sample to characterize the intensity of the ground fires. The fire spread was recorded with a thermal imaging camera, and mass loss was tracked using a burn scale. To

measure the temperatures, thermocouples were mounted at a depth of 5 cm (TC 2 to 10) and 10 cm (TC 11 to 14). As the intensity of the fire tests was significantly influenced by the wind, the prevailing wind speeds were recorded with a weather station.

Figure 1 – Burning Soil Sample

2.2. Results

Due to the high dryness (soil moisture <15%), the organic litter layer ignited when the cylinder was placed on top. The dry components of the upper layer burned with the appearance of flames. After 5 minutes, a smouldering fire is established on the entire surface of the specimens. Horizontal and vertical heating of the entire sample occurs. Selected measured temperatures and the mass lass of one specimen are shown in Figure 2.

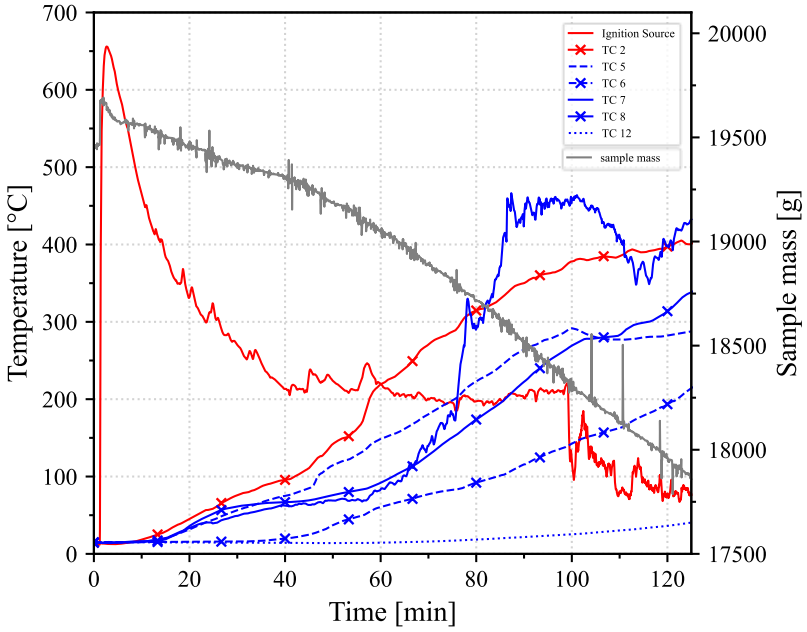

Figure 2 - Temperature curves and mass decrease of pine soil sample

The smouldering fire led to the slow combustion of the organic material of the soil, also recognizable by a steady mass decrease. Furthermore, the classical combustion processes of forest soil (preheating, drying, pyrolysis, oxidation), as described by Huang & Rein (2013) among others, could be observed. The smouldering fire is

maintained by the heat generated in the reaction zone. It also provides energy to fuel the drying, preheating and pyrolysis processes. It was also shown that previously ignition-resistant components (e.g. mosses) could be thermally conditioned by the addition of heat, and if sufficient pyrolysis gases were produced, flaming combustion could be initiated at a later stage. The heat of the metal cylinder just only delivers the initial energy, to start the tests. The thermocouple (TC 1) under the metal shows a constant temperature after about 40 minutes, so it could be stated, that from this point on the combustion is no longer influenced by the energy of the ignition source.

The studies show that all of the ground fires investigated spread independently and persistently after initial ignition. All tests showed fully developed smoldering fires, which constantly heated the soil samples to over 300°C (also up to 400°C) after two hours. Figure 3 shows typical temperature curves (measurement 5 cm below litter layer) of different soil samples. It can be seen that the samples from the coniferous forests show a much faster and significantly more severe temperature rise over the experimental time.

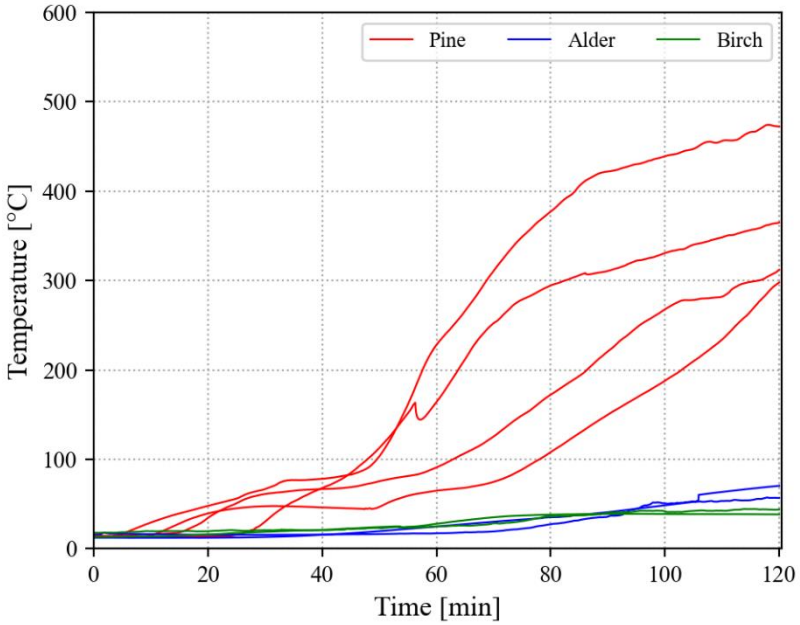

Figure 3 - Comparison of maximum soil temperatures of different samples

The intensity of the fires varied with the composition and moisture of the soils, the possibility of air entry into the soil layer and the duration of the tests. In general, the test stand is very suitable for investigating the characteristic fire behaviour of certain soil samples and the inter-soil fire spread. It should be noted that as the scale is increased, the influence of fire thermic increases (e.g. radiant heat, greater turbulence) and affects aboveground fire behaviour. The experiments show the danger of the rapid horizontal fire spread and the intensive heating of the soil layers, which pose major challenges for the firefighters during large-scale forest fires and can irreversibly damage the vegetation.

3. Experiments on Smoke Toxicity

3.1. Experimental Setup

The DIN tube furnace is suitable for creating optimal and reproducible smouldering conditions. This is to be understood as thermal oxidative decomposition without flame formation. For the tests in the DIN tube components (5g each) of the organic litter layer were taken. In another test series a thermal storage furnace (SEDEX-oven) was used to study spontaneous ignition behaviour. Heterogenous samples of soil (100g) were heated until the pre-set maximum temperature was reached. By measuring the temperature with a thermocouple, it is possible to detect any spontaneous ignition.

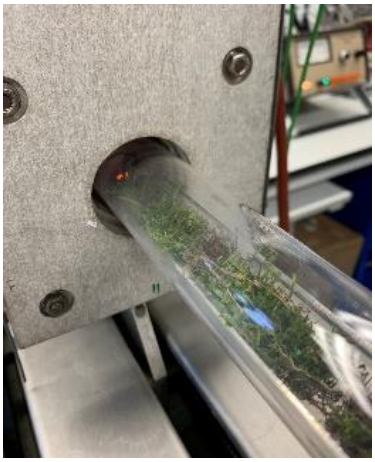

Figure 4 – DIN tube furnace with 5g soil sample

Figure 5 – SEDEX-Oven with 100g soil sample

Both, the DIN tube furnace and the SEDEX-oven were coupled with an FT-IR spectrometer to determine combustion products of the smouldering fires. The FT-IR were calibrated to different typical smoke components, which can be identified and quantified in respect to their concentration. By this determination, approaches to the evaluation of the hazard from smoke in regional ground fires should be made.

3.2. Results

3.2.1. Smouldering Test in the DIN Tube Furnace

In the comprehensive series of experiments, samples of moss, leaves, needles, bark, branches, soil, wood fragments, sand and pine cones in different compositions were investigated. Due to the heterogeneity of the samples, the composition of the smoke gases also varied.

The displayed sample in figure 4 contained small branches, as well as a proportion of sand, moss, needles and bark. Figure 6 and 7 show typical measured concentrations of this specimen 1.1 of hydrogen cyanide and sulfur dioxide, which are classified as toxic gases. The black line shows the medium concentration of two trials of a measurement series while the red line shows the average concentration during the whole experiments.

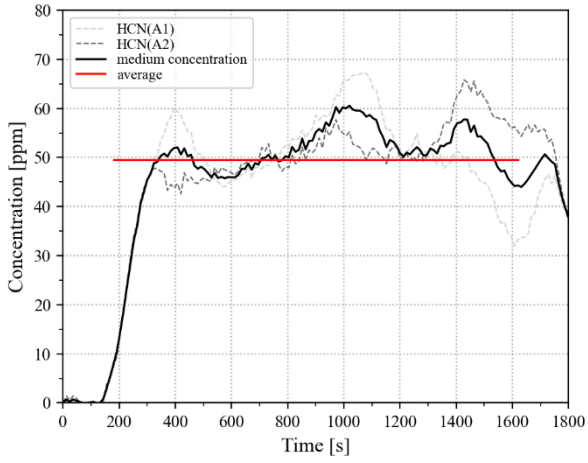

Figure 6 - Concentration of hydrogen cyanide (sample 1)

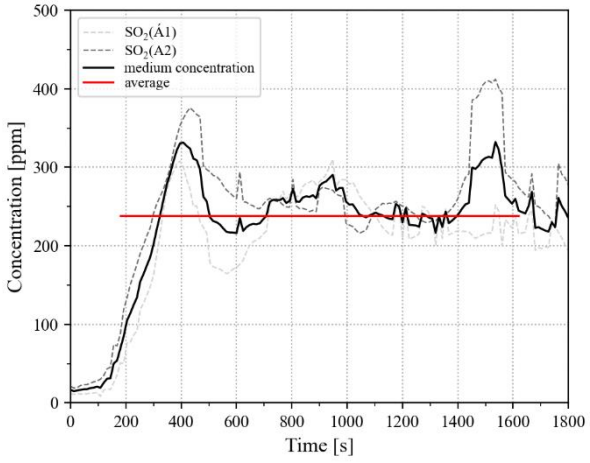

Figure 7 - Concentration of sulfur dioxide (sample 1)

The graphs rise continuously at the beginning when the heating ring of the DIN tube furnace initiates smouldering. During the course of the experiment, a relatively constant release of the toxic gases is established. The averaged released values are 50 ppm for HCN and 240 ppm for SO_2. The following table presents the average concentrations of typical measured product from different experiments.

Table 1 – Average concentrations (medium of two tests each) of different samples in [ppm]

SOIL SAMPLE	HCN	SO_2	C_3H_4O	C_2H_6O	CO	NH_3	CH_4
A	48	236	24	77	2940	13	640
B	45	276	29	79	3095	22	958
C	99	217	9	58	4280	25	545
D	36	301	54	86	5818	16	1064
E*	21	417	120	364	4316	10	4524

*(only needles)

The comparison shows the similar magnitudes of concentrations for different samples. The experimental setup makes it possible to measure the different components of the smoke gases. In additional experiments, the concentrations will be further quantified and the sources of the hazardous combustion substances can be determined by specific analyses.

3.2.2. Self-Ignition test in the SEDEX-oven

The samples in the SEDEX furnace were heated up to 400°C for 24 hours. Typically, spontaneous combustion occurred after 9-10 hours at temperatures of 180°C. The self-ignition of the organic material leads to a sudden increase of the temperature up to 440°C and initiates a burning process inside the oven.

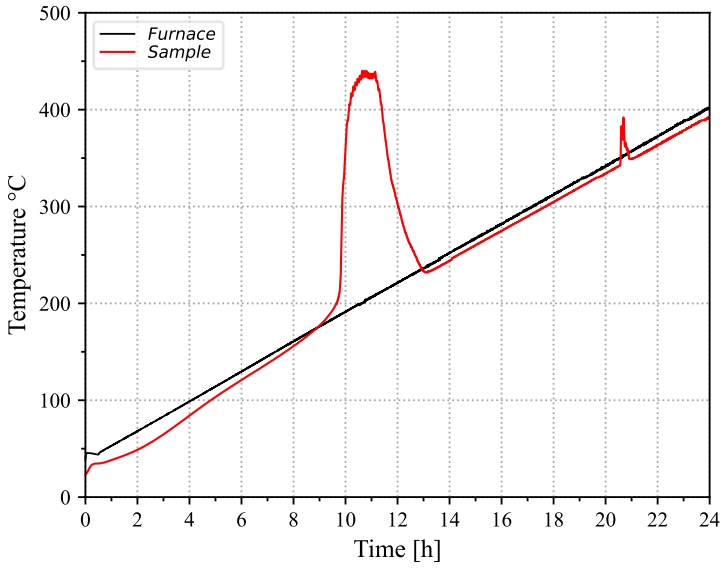

Figure 8 – Self-Ignition of sample from organic pine vegetation

During the experiments, analogous to the smoldering tests, the composition of the smoke was analyzed. The combustion products in the smoke are the similar to those of the other determination. The emissions of the

By the end of the self-ignition tests, complete combustion of the organic material can be assumed, leaving behind non-combustible components, such as heavy metals. Both the amount of mass loss and the level of concentrations of smoke depend on the composition of the sample. Due to the heterogeneity of the samples, further test series will be carried out to compare the values in order to determine a generally valid quantification of the hazards.

3.3. Evaluation of the smouldering tests

The inhalation of the harmful substances contained in the fire smoke can represent a not inconsiderable health hazard for people at the appropriate concentration. The experimental setup offers the possibility to determine the smoke compositions of different samples and to quantify them by comparison. The experiments provide knowledge in the area of basic research on the concentration of pollutants in fire smoke under smoldering conditions typically encountered in ground fires. The study of local vegetation provides specific insights into hazards from fire smoke, which must be considered in terms of fire suppression.

4. Conclusions

The fire tests and smoldering experiments are to be used to investigate the vegetation-specific fire behavior of local forest soils. The measured temperatures in the soil und the detected smoke compositions show the possible, high damaging effects of soil fires. Furthermore, the rapid and extensive spread of fire can spread to above-ground vegetation and lead to severe fires. The experiments will be expanded to include other vegetation types and in number to provide quantitative information on specific hazards.

Small and medium scale experiments are the basis to develop a numerical model capable of predicting the fire propagation. The combination of experiments and numerical investigation allows a quantitative assessment of the influence of the different heat transfer modes and therefore will significantly improve the understanding of fire propagation in these fires. In addition, by analyzing possible combustion products in the smoke, hazards for first responders and further, for the civil population can be determined and protective measures can be derived.

Firefighters; leadership; well-being; rural fires; virtual reality.

Abstract

In this study, we analysed the effects of team leadership style on the well-being of firefighter teams operating under conditions of a simulated rural fire. Twenty teams of firefighters (composed of five elements each) took part in a computer-based fire-fighting simulation task and were randomly assigned to one of two conditions (leadership style: directive vs. empowering). Our results showed that directive leadership style was negatively associated with team members levels of stress and anxiety, while an empowering leadership style did not have a significant effect on team members levels of stress and anxiety. The distinct effects of team leadership style remain unchanged when we controlled for the levels of stress and anxiety before the simulation. Through moderated regression analyses we observed that the effect of directive leadership styles in reducing stress and anxiety was stronger for participants with higher levels of previous stress and anxiety. Implications for theory and practice are discussed.

1. Leadership and well-being among firefighters

Firefighters have a high-strain occupation, since physical danger and psychological stress are part of their daily lives (Prati, Pietrantoni, & Cicognani, 2010). In this study, we draw from the theory of leadership, defined as a social influence process where leadership behaviors affect followers' outcomes, to build an understanding of the different ways firefighters react to the constant disruption and ongoing strain involved in their work, focusing specifically on responses that lead to positively adaptive outcomes. We have considered leadership a contextual variable that can explain this positive result because leaders have the potential to be a buffer against work stressors (Harms, Credé, Tynan, Leon & Jeung, 2016), thus we expect to contribute to the literature, by empirically investigating leadership behaviors that explain when and how firefighters positively adapt to stressful situations.

2. Virtual reality

The development of virtual environments and computer game technologies made it possible to create scenarios in 3D graphic environments and new learning contexts based on virtual simulation tools for the training of incident commanders (Wijkmark & Heldal, 2020). The scenarios can have different levels of complexity and firefighters can move and interact in the virtual environment, make decisions, and observe the consequences of decisions taken.

Virtual reality scenarios challenge firefighters and make them feel involved and react as if they were in real events (Reis & Neves, 2019). Virtual reality simulation enables to create large-scale events that would be extremely difficult and even dangerous to recreate in a live exercise (Boosman, Lamb & Verhoef, 2015).

3. Hypothesis

In this study, we wanted to verify which leadership style contributed better to the well-being of subordinates, and therefore raised the following hypotheses:

1) the empowering leadership style is negatively associated with stress and anxiety levels during intervention action in a simulated rural fire situation.

2) the directive leadership style is positively associated with stress and anxiety levels during an intervention in a simulated rural fire situation;

3) the effect of the empowering style (3.a) and the directive style (3.b) is stronger in relation to firefighters who at the beginning of the intervention had higher levels of stress and anxiety when compared to those who at the beginning of the intervention had lower levels of stress and anxiety.

4. Procedure and sample

Twenty teams of firefighters (composed of five elements each) participated in the simulation exercise where they hat to confront a simulated rural fire scenario. Simulation studies enable us to manipulate contextual conditions difficult to access in real environments (*e.g.* extreme conditions in a rural fire) and to measure their impact on the deployment of participants well-being.

We used a simulation exercise similar to the ones used in firefighters' training and participants were randomly assigned to teams of five individuals to fight a massive extent rural fire. Teams were also randomly distributed through 2 experimental conditions in which leadership style [i.e. empowering leadership; directive leadership] was manipulated.

To induce a high-demand situation, we presented participants with disruptive conditions in the scenario. To manipulate leadership behavior, participants in each team answered a questionnaire to measure their style as leaders (empowering vs. directive), and the participant with the higher score on either empowering or directive style was assigned the leading role (team leader). Next, the leader was given a script with the behaviors considered to be the most effective according to the condition he was assigned to (directive or empowering). Each team was assigned to one of the two leadership style conditions.

Pre and post simulation stress and anxiety were measure with 6 and 5 items, respectively, from the Portuguese version (EADS-21; Pais-Ribeiro, Honrado & Leal, 2004) of the Depression Anxiety Stress Scales (Lovibond & Lovibond, 1995).

5. Results

To test our hypothesis that directive and empowering leadership have a different impact on subordinates' levels of stress and anxiety in a firefighting situation, we conducted a regression analysis. In addition, to test the hypothesis that the behavior of the leader has more impact when subordinate levels of anxiety and stress before the situation were high, we conducted a moderated regression.

Table 1. Direct and interaction effects of leadership style and previous stress and anxiety levels on stress and anxiety after the simulated firefighting episode.

Variable	Model 1 Stress as outcome	Model 2 Anxiety as outcome
Empowering leadership	.278	.394
Directive leadership	-.494*	-.578**
Previous stress	.251*	
Previous anxiety		.417**
Directive leader X Previous stress	-.258**	
Directive leader X Previous anxiety		-.234*
R2	.170**	.277**

* $p < .05$; ** $p < .01$

As we can see in Table 1. team leader's directive leadership style had a significant direct negative effect on subordinates' levels of stress and anxiety after the simulated firefighting episode. A directive leadership style

seems to be associated with reduced levels of stress and anxiety in subordinates, measured immediately after they engaged in firefighting simulated with a VRX simulator used to train firefighters. Opposite to our expectations, team leaders empowering leadership style did not have a significant effect on the levels of stress and anxiety of individuals after the simulated firefighting episode.

In Figure 1. we plotted the interaction between team leader's directive leadership style and subordinates stress levels measured before the episode of simulated firefighting. As shown in Figure 3, individuals led by a directive leader exhibited lower levels of stress after the performance than they reported before. Moreover, this stress-reducing effect was stronger for subordinates with higher stress levels in the beginning, thus supporting Hypotheses X.

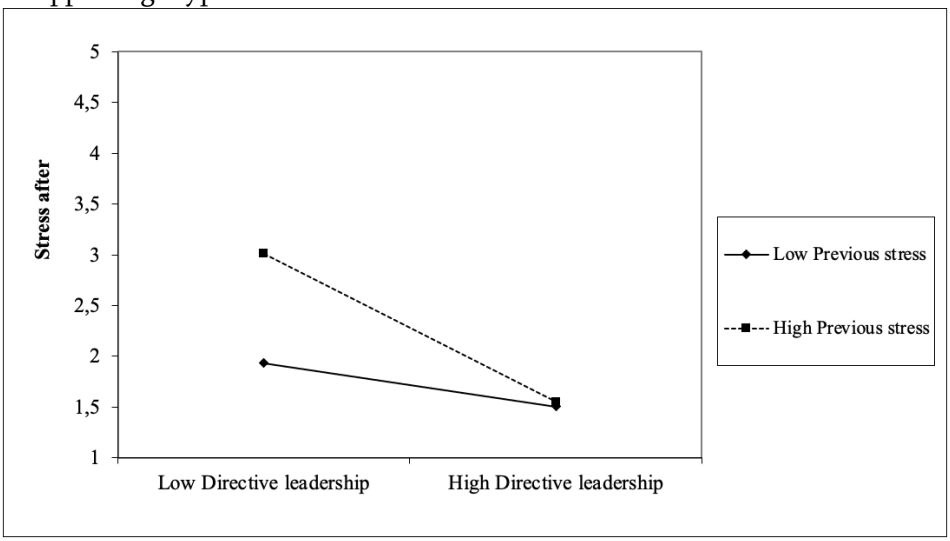

Figure 1. Interactive influence of previous stress and directive leadership style on stress after the firefight.

In Figure 2. we plotted the interaction between team leader's directive leadership style and subordinates' anxiety levels measured before the episode of simulated firefighting. As shown in Figure 3, individuals led by a directive leader exhibited lower levels of anxiety after performance than they reported before. Moreover, this anxiety reducing effect was stronger for subordinates with higher anxiety levels in the beginning, thus supporting Hypotheses X.

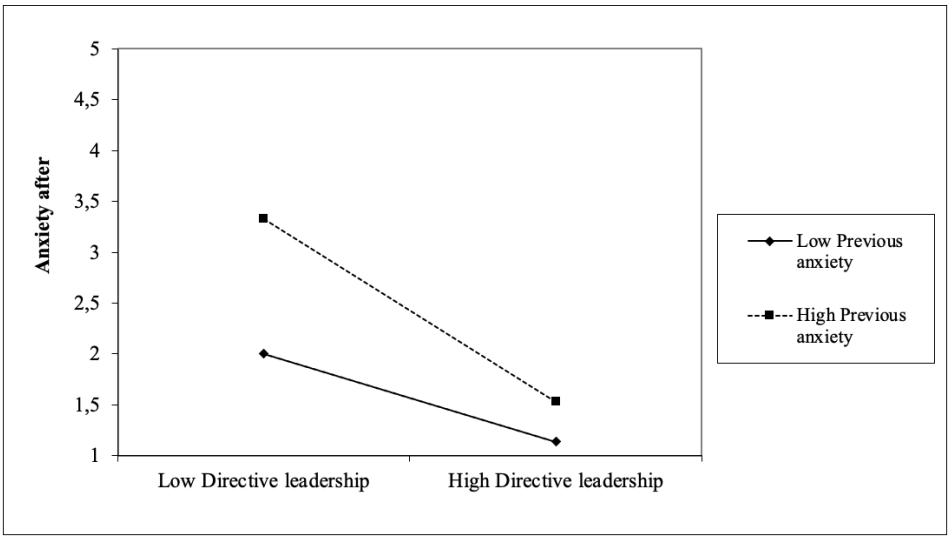

Figure 2. Interactive influence of previous anxiety and directive leadership style on anxiety after the firefighting episode.

6. Discussion

Directive leadership is associated with a leader's positional power and is characterized by behaviors aimed at actively structuring subordinates´ work by providing clear directions and expectations regarding compliance with instructions (Somech, 2006). Directive leaders help followers resolve task and role ambiguity and provide external monitoring and feedback on their performance, reducing process loss and allowing the team to execute decisions more quickly (Lorinkova et al. 2013; Sagie, 1996).

Empowering leadership, on the other hand, involves sharing power with subordinates and raising their level of autonomy and responsibility, and it manifests through behaviors like encouraging team members to express opinions and ideas, promoting collaborative decision-making and information sharing (Arnold et al., 2000; Yun et al., 2005). Although empowering leadership tends to enhance team efficacy and commitment through psychological ownership of the task and improved coordination and teamwork (Zaccaro et al., 2001) in extreme situations where lives are at risk and good decisions must be made rapidly assigning tasks and providing clear directions seems to work better to solve the problem and consequently reducing the levels of anxiety and stress triggered by an extreme situation like a fire.

Previous research has confirmed the positive influence of empowering leadership on individual performance (Zhang & Bartol, 2010) and on the development of project and action teams (Kozlowisky et al., 1999). However, other studies have demonstrated that empowering leadership comes at an initial performance cost, showing to be more effective in later developmental phases, mainly through learning about their task environment and each other's areas of expertise to develop team mental models of how to integrate their efforts, gain collective efficacy and commitment through psychological empowerment, and foster routines to coordinate their behaviors (Lorinkova et al., 2013; Kozlowski et al., 1999; Sharma & Kirkman, 2015).

Although an empowering leadership style may be more appropriate for development of shared mental models and routines for coordination and learning necessary to adapt to complex and changing environments, the consequent team development and readiness requires time (Lorinkova et al., 2013). For teams with short-term or emergent engagements and teams facing emergency situations (e.g., surgical, police, military, and firefighter teams), a directive style may be most appropriate, as teams must be able to immediately perform at a high level and cannot afford the performance delays learning errors associated with empowered teams (Sims et al., 2009; Yun et al., 2005).

Fire Protection, Smart PPE, Phase Change Materials, Normative Requirements, Care and Maintenance

Abstract

The continuous research and development regarding firefighters' personal protective equipment (PPE) has led to significant improvements in recent decades. The findings that contributed the most to the firefighters' protective clothing evolution, increasing the protection, were the use of high-performance fibers, flame-retardant polymer fibers and the changes on clothing structure namely the incorporation of a multi-layer system. Despite the evolution of firefighters PPE, every year an undesirable number of firefighters are seriously burned during firefighting operations with some of them eventually losing their life. Therefore, the need to proceed the research and development regarding thermal protective clothing arises, to increase firefighters' protection and consequently minimize firefighters' heat load and skin burn. Firefighters' protection can be further increased with the incorporation of smart textiles in the personal protective equipment, such as integrated sensors to monitor parameters such as heart rate, oxygen saturation, carbon dioxide detector and setting real-time communication with a command post. In addition to the wearable electronics, regarding smart textiles alternatives for firefighters PPE, several studies have been conducted to incorporate phase change materials (PCM) in firefighters thermal protective clothing with satisfactory results. These advanced materials will absorb the heat from the fire leading to a reduction of the amount of heat to which firefighters are exposed to and an increase of the time that firefighters can be exposed to heat. The evolution of firefighters PPE has been followed by an evolution and update of the international and national standards that specify performance requirements for firefighters' protective clothing for structural and wildland firefighting as well as technical rescue. In respect to structural firefighting, the applicable European standard is EN 469:2020: Protective clothing for firefighters – Performance requirements for protective clothing for firefighters' activities and regarding the wildland firefighting, the international standard prevailing is EN ISO 15384:2020: Protective clothing for firefighters – Laboratory test methods and performance requirements for wildland firefighting clothing. For technical rescue the applicable European standard is EN 16689: 2017: Protective clothing for firefighters – Performance requirements for protective clothing for technical rescue. Given the growing trend towards the incorporation of smart materials in firefighters PPE is important to study and develop new standards to certify these innovative protective clothing for firefighters, regardless the efforts being done within CEN / TC 248/WG 31 - Smart Textiles. To preserve the protection of firefighters protective clothing there are some actions that must be taken during the protective garments' life cycle. Therefore, recently was developed a technical report, a CEN/ TR1760:2021 that describes the guidelines for selection use, care and maintenance of smart garments protecting against heat and flame. This study will focus on the analysis of firefighters protective clothing evolution regarding the use and integration of advanced smart materials, namely phase change materials, taking in consideration the evolution and requirements of international and European standards as well as national legislation for firefighters' protective clothing.

1. Introduction

Firefighters are often exposed to high temperatures and heat-fluxes due to high radiation produced by fire during fire extinguish operations. Therefore, personal protective equipment is of extreme importance for firefighters to

ensure their protection during firefighting activities. Due to the importance of firefighters' protective clothing, over time several research and development studies were taken leading to a continuous evolution of firefighters PPE. Currently, the emergence of smart textiles opened a wide range of opportunities to increase the level of protection of firefighters' protective clothing.

1.1. Firefighters PPE evolution

The scientific developments that led to the introduction of high-performance fibers have been the first major contribution for the increase of the firefighters' personal protective equipment level of protection, however, the biggest revolution regarding firefighters' protection was the use of flame-retardant polymer fibers, namely aromatic polyamides (aramids) and polybenzimidazole (PBI). Nowadays meta-aramids and para-aramids are widely used in firefighters' PPE due to their good thermal tolerance and long-time stability at high temperatures (Hertleer et al., 2013). Alongside the research and development of innovative fibers for firefighters' PPE, the major finding that contributed to increasing firefighters' PPE level of protection, resulting from studies regarding the clothing structure, was the introduction of a multi-layer system, used currently for structural firefighting. Three layers compose this multilayer system: outer shell (flame retardant fabric), vapor barrier, and thermal barrier. The design of the multilayer system allows the wearer to be firstly protected from heat and flame but also against moisture.

1.2. Smart firefighters PPE

The research and development carried out in the field of firefighters' PPE increasingly encompasses advanced materials and/or electronic components. From the combination of these smart materials with conventional PPE appears a new typology of PPE for firefighters. Regarding the development of garments with wearable electronic technologies, many include the integration of sensors for vital function and location monitoring in textiles, communication interface and energy supply with the purpose of increase functionality and protection of firefighters clothing (Mäkinen, 2008). On the other hand, the evolution in the field of advanced materials led to the emergence of new materials which can improve firefighter' clothing functionality. Currently, the development of new materials with adaptive function, such as phase change materials (PCM) has been the subject of interest to the researchers.

1.2.1. Phase change materials

Phase change materials are substances that can absorb and release energy in form of latent heat during a phase transition (Fonseca et al., 2018). These materials are commonly used to improve thermal comfort, however, when applied in smart firefighters' PPE they can be additionally used to improve the heat protection due to its high thermal storage capacities. An extensive spectrum of PCM for textile application is available with different heat storage capacities and melting points. Since PCM becomes liquid when exposed to heat, when integrated into textiles they should be confined to a container. To avoid this problem, PCM can be encapsulated in a polymeric structure(Zhu et al., 2015). Several recent studies have shown that the addiction of PCM layer into a conventional firefighter suit can be used to mitigate severe burns, increasing the time to second burns (Zhang et al., 2021).

1.3. Standardization and Certification

Due to the nature of their job, firefighters require the use of the most suitable PPE available, to be protected from the risks inherent to their activities. Therefore, is of most importance to ensure a high quality of PPE that is assessed through compliance with standards. International and European standards specify the performance requirements for firefighters' protective clothing. Regarding wildland firefighting prevails the international standard EN ISO 15384:2020: Protective clothing for firefighters – Laboratory test methods and performance requirements for wildland firefighting clothing. On the other hand, the requirements for structural firefighting protective clothing are defined in the European standard EN 469:2020: Protective clothing for firefighters – Performance requirements for protective clothing for firefighters' activities. As for technical rescue the applicable European standard is EN 16689: 2017: Protective clothing for firefighters – Performance requirements for protective clothing for technical rescue. Although PPE sector benefits from an abundance of standards, regarding smart PPE there is still a gap in the standardization. Currently an important study is being conducted concerning the requirements and testing procedures for innovative smart protective garments within CEN / TC 248/WG 31 - Smart Textiles. In fact, a new European standard named FprEN 17673 Protective clothing - Protection against heat and flame - Requirements and test methods for garments with integrated smart

textiles and non-textile elements is now at a final stage of approval. At the same time, there have been an evolution regarding the guidelines for selection, use, care, and maintenance (SUCAM) of garments protecting against heat and flame. In this field, a new technical report (CEN/ TR1760:2021) was developed that includes guidelines regarding smart personal protective clothing.

2. Methods

The purpose of this study involves the analysis of the major differences between the structural and wildfire firefighting protective clothing as well as a comparison of the prevailing standards for both firefighting protective clothing and further examination of the alterations done to the previous standards. This study is important to define and understand the prevailing performance requirements for each type of firefighting protective clothing, being the starting point for the development of innovative smart firefighters' PPE.

In addition, the study concerning possible ways to integrate phase change materials into a firefighter protective clothing, to enhance heat protection, was approached, creating a smart PPE. The integration methods study has considered the technical report (CEN/ TR1760:2021) which presents a section dedicated to smart garments with PCM. Besides the best practices mentioned by SUCAM the integration study took in consideration also circular economy and sustainable principles using techniques as eco-design.

3. Results

The purpose of the phase change materials integration is to improve heat protection. Thus, this study will focus on protective clothing for structural and wildland firefighting and will not analyse the protective clothing for technical rescue that is only applied for protection against limited heat and flame.

According to Portuguese firefighters' legislation (dispatch 7316/2016) and accomplishing the respective standards the following figure presents the current personal protective clothing for structural and wildland firefighting.

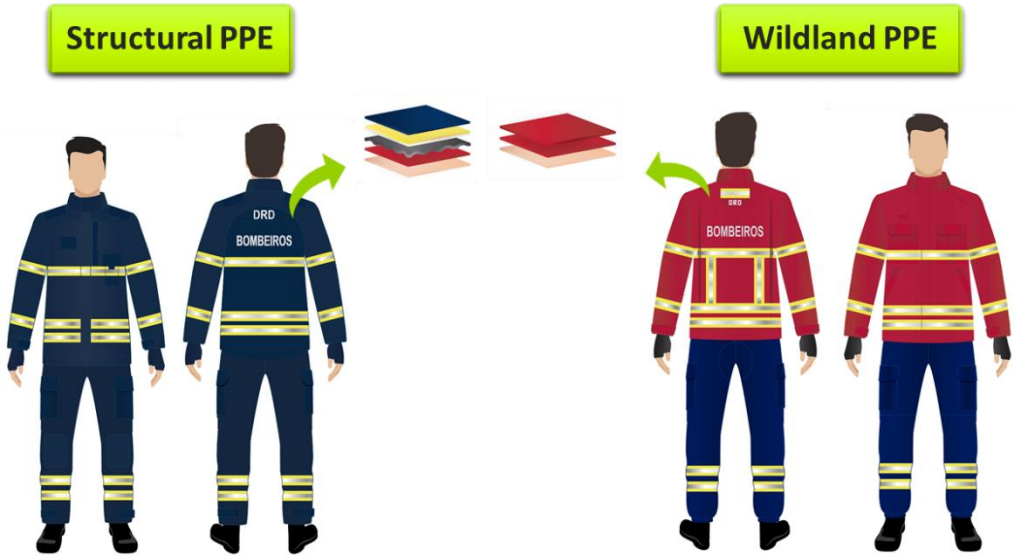

Figure 1. Structural and wildland PPE according to dispatch 7316/2016

The protective clothing suit for structural firefighting consists in a multilayer system composed by three layers with different functions as described in section 1, to be worn over the undergarment. In contrast, the wildland firefighting protective clothing suit has only one layer, outer shell, to provide protection against heat and flame, and must be worn over a long sleeve shirt.

The standards for structural and wildland firefighters' protective clothing (EN 469 and EN ISO 15384) define the performance requirements that must be accomplished. The focus of this study will be in thermal, mechanical and comfort performance requirements. The following table comprises a comparison regarding minimum

compliance values for test methods used both in structural and wildland firefighting protective clothing standards.

Table 1. Comparison between the minimum compliance values for wildland and structural firefighting protective clothing for the same test methods

Protective Clothing Standard	Standard	Description	Minimum compliance values	
EN 469:2020	EN ISO 15025	Flame spread test	A1 or A2	
EN ISO 15384:2020			A1 and A2	
EN 469:2020	ISO 6942	Heat transfer (radiation)	Level 1: $RHTI_{24}$≥10,0s $RHTI_{24}$-$RHTI_{12}$≥3,0s	Level 2: $RHTI_{24}$≥18,0s $RHTI_{24}$-$RHTI_{12}$≥4,0s
EN ISO 15384:2020			$RHTI_{24}$≥11,0s $RHTI_{24}$-$RHTI_{12}$≥4,0s	
EN 469:2020	ISO 13935-2	Main seam strength	≥ 300 N	
EN ISO 15384:2020				
EN 469:2020	ISO 13937-2	Tear strength	≥ 30 N	
EN ISO 15384::2020			≥ 25 N	
EN 469:2020	ISO 13934-1	Residual tensile strength	≥ 450 N	
EN ISO 15384:2020			≥ 600 N	
EN 469:2020	EN 31092	Water vapor resistance (Ret) / Thermal resistance (Rct)	Level 1: Ret>30 m^2Pa/W	Level 2: Ret≤30 m^2Pa/W
EN ISO 15384:2020			Ret ≤ 10 m^2Pa/W Rct ≤ 0,055 m^2K/W	
EN 469:2020	ISO 17493	Heat resistance	180°C	
EN ISO 15384:2020			260°C	
EN 469:2020	ISO 5077	Dimensional change	≤3% woven fabrics ≤5% non-woven and knitted fabrics	
EN ISO 15384:2020				

The comparison presented in table 1 allows to conclude that despite both standards use the same test methods, the minimum compliance values change for several tests. In addition to the test methods described in table 1, structural protective clothing has some specific required tests, presented in table 2.

Table 2. Specific required tests and minimum compliance values for structural firefighting protective clothing

Standard	Description	Minimum compliance values	
ISO 9151	Heat transfer (flame)	Level 1: HTI_{24}≥9,0s HTI_{24}-HTI_{12}≥3,0s	Level 2: HTI_{24}≥13,0s HTI_{24}-HTI_{12}≥4,0s
EN 20811	Water penetration	Level 1: >20kPa	Level 2: ≥20 kPa
EN 6530	Resistance to chemical penetration	No penetration to innermost surface; Index of repellence ≥80%	
EN ISO 12127-1	Contact heat test	Level 1: -	Level 2: 250 °C (10s)

Regarding test methods to evaluate performance requirements, the update of the standard for structural firefighting protective clothing in 2020, introduced the contact heat test and reduced the number of chemicals that are used in resistance to chemical penetration test. In addition, flame testing of hardware like labels (≥10 cm^2), badge and retroreflective materials as well as the moisture barrier shall be tested as part of the assembly. For the wildland firefighting, EN 15614 was superseded by EN ISO 15384 demanding now slightly higher values for the mechanical parameters and a higher temperature (260 °C) for the heat resistance of the materials.

The PCM integration in firefighters' protective clothing have considered the guidelines present in CEN/ TR1760:2021. This technical report defines guidelines regarding selection, use care and maintenance of smart garments protecting against heat and flame. The following figure presents the main topics within each step of PPE life cycle.

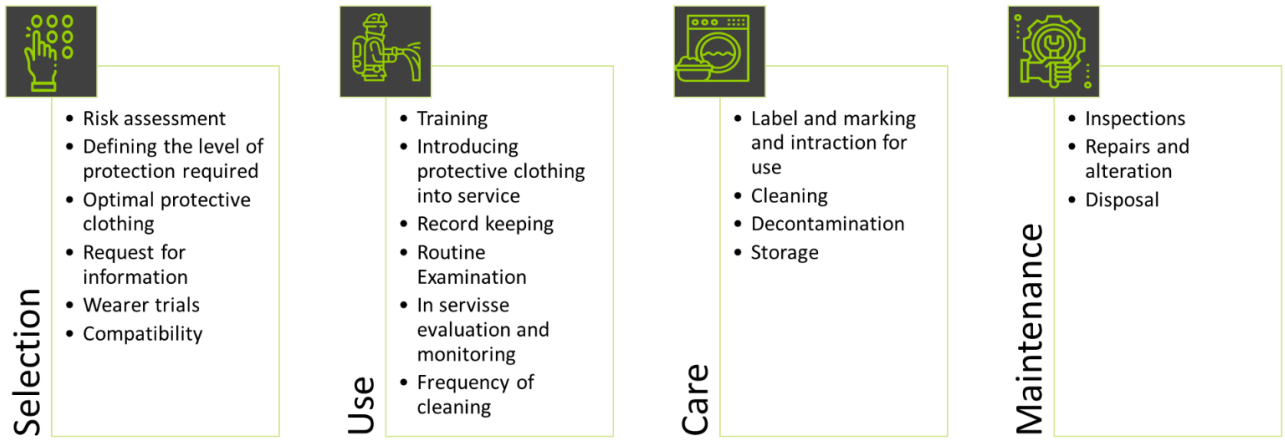

Figure 2. Main topics approached in SUCAM guideline

In addition to the generic guidelines concerning protective clothing on use, care and maintenance up to and including the disposal of the protective gear, this document provides examples of the scenarios and SUCAM procedures, being garments with PCM packages one of the given examples.

PCM packages must be selected considering the melting temperature more suitable for the exposure needs that vary with different parameters: activity level (heat produced by the body), climatic conditions, exposure length and logistical opportunities or limitations, for instance the possibility to replace the PCM packages during the mission.

Regarding cleaning and decontamination of garments with PCM, the PCM packages must be withdraw from the garment, and be cleaned according to manufacturer's instructions, and wiped with a soap solution. Garments with PCM packages must be stored horizontally during the solidification process to avoid material accumulation at the lower end of the package, and consequently, uneven cooling effect, reduced protection and potential tactile discomfort during next use. If noticing any problems during care and maintenance procedures such as PCM substance leaking or if any package has not melted even if being above the melting temperature, the situation must be reported.

Concerning the inspection of PCM packages on regular basis the user must inspect the packages according to the figure 3 and at least once a year verify if PCM will melt at their melting point. The disposal of broken packages must be according to manufacturer's instructions.

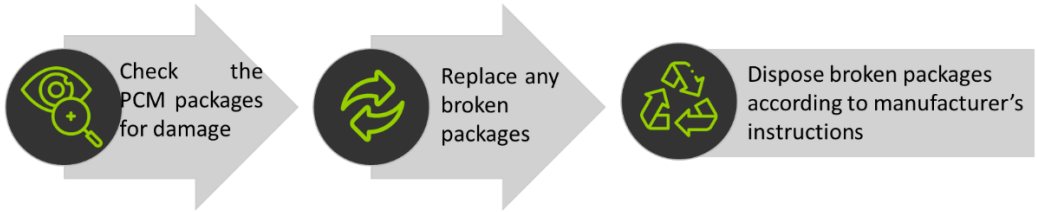

Figure 3. Inspection and disposable procedure for PCM packages

Considering that recent studies in which was found that the optimum position for the PCM layer is the closest to the external heat, PCM packages are being integrated into a vest to be worn over a conventional firefighter PPE, creating a smart protective clothing system. The design of the vest was studied to protect mainly the torso of the firefighter preserving ergonomics. However, after some firefighters feedback a second version was developed to enhance the protection of the upper limbs, Figure 4.

Figure 4. Study of PCM vest design: ergonomic (left) and enhanced protection (right)

The distribution of PCM packages in the vest took in consideration different variables namely the amount of PCM in each package, and the size and the amount of the PCM packages to achieve a commitment between heat management and breathability.

Considering SUCAM guidelines for garments with PCM packages and the different parameters concerning PCM packages distribution in the vest, the integration of PCM packages is described schematically on Figure 5.

Figure 5. Study of the integration of PCM packages in the vest

As evidenced in Figure 5, PCM packages were integrated in a matrix composed by two layers, an insulation material and a flame retardance fabric. The introduction of the PCM packages through laser cut openings makes routine inspections and cleaning procedures described in SUCAM easy and allows the replacement of broken packages. Afterwards, this matrix was inserted into the vest main structure creating a PCM vest. In addition to making SUCAM procedure easier, the design of the vest considered also circular economy principles, since this removable system allows the separation of all the components of the vest making possible to recycle them.

4. Conclusions

The use of smart textiles, and in this specific case textiles with PCM integrated, combined with conventional PPE can play an important role towards the increase of firefighter's heat protection.

Having in mind a modular approach that could fit both, wildland and structural firefighters, the analysis of the major differences between the respective protective clothing as well as a comparison of the prevailing standards and legislation was performed.

A first architecture of a PCM vest to be worn over the conventional protective clothing was designed based on the integration study done aiming at protecting mainly the torso to preserve ergonomics. Protective standards

requirements, best practices mentioned by SUCAM and also circular economy and sustainable principles using techniques as eco-design were taken into account.

The study will proceed with testing and simulation measurements in straight collaboration with ENB (Portuguese national firefighters' school), towards the solution improvement.

Abstract

In Mediterranean regions worldwide, climate and landscape change increased the occurrence and the risk of (very) large and intense fires, which override the current firefighting capacity. Fire management policies, largely focused on fighting at the expense of prevention, have proven inadequate to address this challenge. Agricultural abandonment has shaped rural mountain areas in many parts of Southern Europe since the last century, owing to diverse socio-economic and biophysical constraints such as reduced job opportunities, poor generational renewal, low accessibility and soil productivity. The cessation of traditional livestock and agricultural practices caused by rural exodus has favoured more homogeneous and flammable landscapes —with strong side-effects on fire regime, ecosystem services and biodiversity.

In fact, the challenge for managers and policy makers is no longer simply how to reduce wildfire impacts but how to reconcile socio-economic impacts of fires with their ecological benefits. Fire-smart management would clearly enable a more balanced integration of positive (reducing species competition, diseases and pests or fire intensity, and increase fire protection in wildland-urban interfaces) and negative contributions of fire to human well-being, which would inform better decision making in fire management policy and land-use planning. In practice, fire-smart landscapes can be obtained by fuel-reduction treatments and by fuel type conversion, rather than by fuel isolation. From this perspective, proactive management should therefore focus on reshaping vegetation (fuel) configuration to foster more fire-resistant and/or fire-resilient landscapes while simultaneously ensuring the long-term supply of ecosystem services and biodiversity conservation. In contrast, rewilding has been proposed as an opportunity for biodiversity conservation in abandoned landscapes. However, rewilding is challenged by the increasing fire risk associated with more flammable landscapes, and the loss of open-habitat specialist species.

Here we present three complementary studies carried out in the frame of the FirESmart project (https://firesmartproject.wordpress.com) focusing on two contrasting land-use policy scenarios (Rewilding vs High Nature Value farmlands) based on stakeholders' perception of fire-landscape dynamics, and their potential impacts on biodiversity conservation and ecosystem services. Our studies were implemented in a transboundary protected area, the Gerês-Xurés Biosphere Reserve, where we predicted the potential impacts in terms of fire regime change, species conservation and carbon sequestration.

Our studies contribute to the increasing evidence of agricultural policies as essential tools to ensure biodiversity while reducing fire hazard, an aspect that has been frequently neglected when assessing the beneficial effects of agricultural policies. Also, our findings suggest using fire to enhance rewilding as an alternative management strategy in our study area — an issue that decision makers and managers should consider when implementing rewilding initiatives in other fire-prone regions. These studies represent the needs of local communities in these mountainous areas, which are heavily

affected by rural abandonment, fire regimes, and loss of natural resources. These rural communities try to keep alive the few and scarce agricultural activities and manage the mountain landscapes. However, the reduced investment and financial support of these isolated communities has led to the decline of these traditional fuel and habitat management tools.

1. Introduction

Wildfires are a major component of disturbance regimes worldwide (Keeley et al., 2012). Despite the increasing amount of resources invested in fire suppression, the number of extreme fire events has largely increased over the last decades in southern Europe, overriding current fire-suppression systems (San-Miguel-Ayanz et al., 2013). Agricultural abandonment has shaped rural mountain areas in many parts of the Mediterranean Europe since the last century, owing to diverse socio-economic and biophysical constraints such as reduced job opportunities, poor generational renewal, low accessibility and soil productivity (Cerqueira et al., 2010; MacDonald et al., 2000).

Society has co-evolved with fire over centuries (Pausas & Keeley, 2019). In rural areas, fire was also used as a tool for land management (e.g., clearing land for pastures Chas-Amil et al., 2015; Tedim et al., 2016), which resulted in a large number of low-intensity and small-sized fires (Chas-Amil et al., 2010). At the same time, fire has been perceived by society as a damaging hazard with only negative impacts, which reinforced fire exclusion and suppression policies. In the last decades, as a result of both agricultural abandonment and fire exclusion policy, Mediterranean landscapes have become more homogeneous and flammable (Moreira et al., 2011) and therefore more susceptible and vulnerable to forest fires.

The interactions between fire and landscape dynamics in these complex socio-ecological systems hinder how to efficiently treat landscapes in terms of spatial configuration and density of treatments (Alcasena et al., 2018; Oliveira et al., 2016; Thompson et al., 2017). In protected areas, landscape management becomes more complex because legislation regulates management, which together with land ownership constraints, complicates treatment allocation (Alcasena et al., 2018). Therefore, treatment strategies must consider multiple objectives and should involve the needs and views of stakeholders in relation to fire and landscape management. In particular, fire management strategies in these areas have been directed towards promotion of agro-pastoral activities, total or partial removal of the fuel in strategic areas, and use of prescribed burning.

More recently, fire-smart management (defined as “an integrated approach primarily based on fuel treatments through which the socio-economic impacts of fire are minimized while its ecological benefits are maximized”; Hirsch et al., 2001) has been proposed as an alternative including fire as a socio-ecological process while balancing the benefits and drawbacks of fire to human well-being (Fernandes, 2013).

On the contrary, land abandonment in rural landscapes is one of the most important drivers of regional land-use change (Estoque et al., 2019), and has been suggested as an opportunity for biodiversity conservation and the reinstatement of natural ecological processes (Queiroz et al., 2014). However, rewilding holds some constraints that may limit its successful implementation. The inherent homogenization of rewilded landscapes leads to loss and fragmentation of open habitats, mainly due to shrub encroachment and forest expansion (Moreira et al., 2011). Studies also indicated that the gradual cessation of traditional farming areas, many of which known to support “High Nature Value farmlands” (hereafter HNVf), is a major cause of local biodiversity losses, accelerating population declines of species adapted to wet grasslands, pastures and other extensive agricultural areas (Franks et al., 2018; Ribeiro et al., 2014). The intricate links between land abandonment and fire regimes complexify the selection of appropriate alternative scenarios, and subsequently decision-making in fire management and planning (McLauchlan et al., 2020).

In this new era of megafires, the question is how landscape management could integrate social and ecological perspectives to solve the growing problem of forest fires. Possibly, the most effective way to integrate both dimensions of this societal challenge in fire-prone regions is mainstreaming fire-smart management as Nature-based Solution (hereafter NbS).

1.1. Aims

These studies have sought to address several important issues in landscape and fire regime management, nature conservation, and the inclusion of local stakeholders in the understanding of these complex processes.

Firstly, we analysed stakeholders' perceptions about wildfire-landscape interactions in abandoned rural landscapes of Southern Europe, and how fire and the territory should be managed to reduce wildfire hazard and ensure the long-term supply of ecosystem services. To do so, we have used a structured online questionnaire that was sent to stakeholders. We also analysed the differences in the stakeholders' perceptions among sectors and we also explore to what extent fire management strategies can be considered Nature-based Solutions using the IUCN standard.

The second study aimed to identify 'win-win' situations to reduce the impact of wildfires and maximize the provision of carbon storage and sequestration and biodiversity conservation in fire-prone regions affected by rural abandonment. We assessed the potential trade-offs between wildfire mitigation (measured through total burned and suppressed area), climate regulation ecosystem services (i.e., carbon storage and sequestration) and biodiversity conservation under fire-smart management scenarios.

Lastly, we assessed the impacts of alternative landscape trajectories and fire suppression management strategies on future fire regimes and on biodiversity conservation. We focused on changes in burned and suppressed areas and habitat availability for 211 vertebrate species. We aimed to answer the following questions: 1) How would different land-use and fire suppression management scenarios contribute to future fire mitigation (i.e. fewer areas burned associated with higher suppression efficiency)?, 2) How would those scenarios affect biodiversity?; 3) Which is the best management scenario for promoting fire mitigation and biodiversity conservation?; and 4) With agricultural policies failing to cope with rural abandonment, could a rewilding trajectory integrated with fire suppression policies contribute to enhance biodiversity conservation?

2. Methodology

2.1. Study area

These studies were conducted in the Transboundary Biosphere Reserve Gerês-Xurés (ca. 276,000 ha, of which 71% in Portugal and the remaining 29% in Spain), a representative mountain landscape of NW Iberian Peninsula. The region is located at the transition between the Mediterranean and Eurosiberian (Temperate) biogeographic zones, close to the Atlantic coast. The study area includes the entire reserve, encompassing three EU Natura 2000 sites besides two nationally designated protected areas, the Peneda-Gerês National Park in Portugal and the Baixa Limia - Serra do Xurés Natural Park in Spain. Although our study is conducted in the entire Biosphere Reserve, we intend to discern the management impacts both within and outside protected areas, given the differences between both areas in terms of socio-economic values and protection measures, which would influence how the different management strategies could be implemented.

2.2. Local stakeholders' perception and scenarios design

The questionnaire was conducted based on an online questionnaire structured in four sections related to: 1) fire; 2) landscape; 3) and potential impacts of fire management strategies on fire regime, and ecosystem services; (see details in Lecina et al. *under review*).

2.3. Modelling framework

We used a spatially explicit process-based model (REMAINS) that integrates the main factors driving fire-landscape dynamics (Pais et al., 2020). The model allows investigating how the spatiotemporal interactions between fire-vegetation dynamics, fire management and land-use changes affect fire regime at short- and medium-timescales. The REMAINS model reproduces fire-landscape dynamics according to pre-designed scenario storylines (Pais et al., 2020). In particular, the model simulates wildfires (including fire ignition, spread, burning and extinction), vegetation dynamics (natural succession), land-use changes (agriculture abandonment or intensification) and forest management.

We combined fire-landscape model simulations with species distribution models to identify the best strategies for wildfires prevention and bird conservation (between 1990 to 2050). This model was calibrated using historical fire statistics and landscape change analysis based on remote sensing information. We run fire-simulated fire-landscape dynamics under scenarios with different land-use and fire management policies, based on four storylines (Figure 1) (Pais et al., 2020).

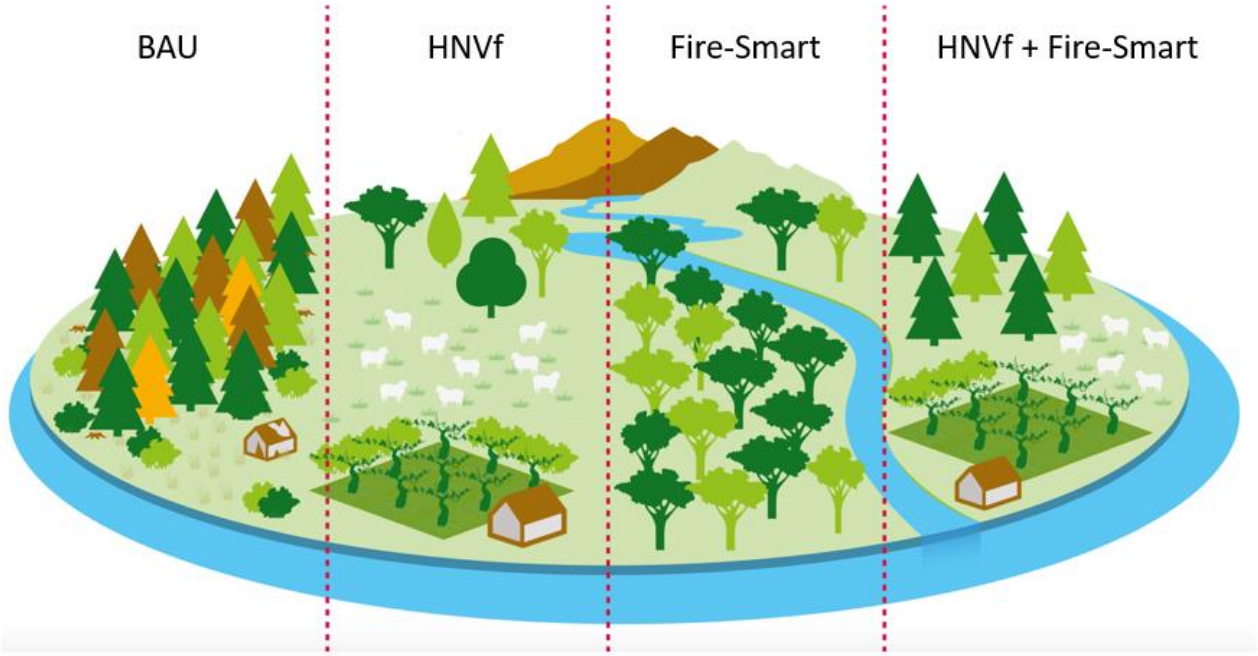

Figure 1 - Storylines: Business-as-usual scenario (BAU) describes the current trend of land abandonment; High Nature Value Farmland (HNVf) represents a policy promoting traditional agricultural activities. Fire-smart scenarios aims to create landscapes more resistant to wildfires. HNVf plus Fire-smart combines these two policies (see details in Pais et al., 2020) (extracted fr om Hernández, 2021).

To predict biodiversity distribution, we used species data from atlases and fire-landscape model simulations under the 4 most extreme scenarios. We applied an ensemble modelling approach from different modelling techniques for these species, to account for the uncertainty related to the modelling technique (see Pais et al., 2020). We conducted a biophysical assessment of the climate regulation ecosystem service (hereafter CRES) based on the carbon sequestration ecosystem function, by applying the InVEST (Integrated Valuation of Ecosystem Services and Tradeoffs) model. We evaluated the impact of fire and land-use management scenarios on this ecosystem service over a period of 63 years (1987–2050) (see Campos et al., 2021).

3. Results and conclusions

The first step showed stakeholders' perceptions about fire, its impacts on the landscape, and the fire management opportunities. Overall, there is a general agreement among stakeholders across sectors and study areas. They state that fire must be managed and support fire prevention rather than suppression policies. They also perceived that rural abandonment is the main cause of large wildfires, with more high-intensity fires impacting the study regions than in the last 30 years, a situation that they expect to continue in the future in the absence of management. Regarding fuel management, all strategies except using chemical methods were accepted by the stakeholders who perceive more positive than negative effects of fire management on forest ecosystem services. In particular, promoting agricultural and livestock uses, modifying forest species composition to increase fire resistance, and introducing large herbivores have potential to become effective Nature-based Solutions in the regions. Nevertheless, additional studies are needed to engage the stakeholders more actively in the management of these areas, as well as to evaluate the cost-effectiveness of fire management strategies. This study is a first-step analysis for the co-design and co-implementation of these fire management strategies as NbS, which will guarantee its successful application in solving the societal challenges and contributing to the sustainable development of the areas.

Our findings also found the benefits of integrating proactive land-use policies and fire-smart management strategies at the regional scale to promote sustainable solutions to the forest fires problem in abandoned mountain landscapes of Southern Europe. Overall, our results highlight that land-use policies aimed at promoting farmland areas would provide fire-suppression opportunities while simultaneously ensuring biodiversity conservation within (and around) protected areas. Our results confirm the urgent need for policies

promoting farmland areas, both in terms of future fire-suppression opportunities and biodiversity conservation. A large amount of strategically allocated cropland areas (at least 1,200 ha per year) should be gradually incorporated to the landscape along the next decades to significantly affect fire regime in the medium term. These policies would be also positive for conservation objectives since most of the species would benefit for the recovery of habitats associated with agricultural activities. In terms of long-term supply of the climate regulation ecosystem service (through carbon sequestration), our models predicted the best outcomes under large-scale fire-smart forest conversion. However, the integration of this fire-smart landscape conversion would be only acceptable for biodiversity conservation and fire prevention if embedded in landscape matrix characterized by increasing agricultural areas over the next decades.

The last study contributes to the increasing evidence of agricultural policies as essential tools to ensure biodiversity while reducing fire hazard, an aspect that has been frequently neglected when assessing the beneficial effects of agricultural policies. Also, this study suggests using fire to enhance rewilding as an alternative management strategy in our study area — an issue that decision makers and managers should consider when implementing rewilding initiatives in other fire-prone regions. Additionally, our study highlights the need for renewed political and socio-economic efforts exploring different solutions to economic incentives and/or management strategies integrating both rewilding and HNVf. In this context, our study demonstrates how an effective implementation of European agricultural policies could benefit biodiversity (through the creation of new open habitats for endangered species) while providing further fire-suppression opportunities. Our study also shows how fire suppression policies can help the implementation of rewilding initiatives in other abandoned, fire-prone mountain areas across Southern Europe (see dissemination video at https://youtu.be/x7ouTIBp__E).

Flame Length of Wildland Fires: Effect of Flame Zone Depth

Keywords

Flame length, fireline intensity, flame zone depth

Abstract

Correlations of flame length $\boldsymbol{L}$ with fireline intensity $\boldsymbol{I_B}$, based on theory and data by Thomas (1963), showed that flame zone depth $\boldsymbol{D}$ of a line fire could be neglected if $\boldsymbol{L}$ was much greater than $\boldsymbol{D}$. This has not been verified for wildland fires where $\boldsymbol{D}$ is typically a non-negligible proportion of $\boldsymbol{L}$ (*i.e.*, roughly $\boldsymbol{L/D} < \sim 2$). Here we report on experiments with line-source fires from a gas burner where $\boldsymbol{I_B}$ and $\boldsymbol{D}$ were controlled independently ($0.15 \leq \boldsymbol{L/D} \leq 13.6$). The resulting correlation showed $\boldsymbol{D}$ significantly reduced $\boldsymbol{L}$ for a given $\boldsymbol{I_B}$ over the entire range of observations and was in accord with independent data from spreading fires. Flame length is reduced because the horizontal extent of deep flame zones entrains more air for combustion than assumed by theory involving only the vertical flame profile. Fire behavior modeling that relies on correlations of $\boldsymbol{L}$ with $\boldsymbol{I_B}$ for scaling of heat transfer processes would likely benefit by including the effects of $\boldsymbol{D}$.

1. Introduction

Flame length $\boldsymbol{L}$ (m) of wildland fires is used for modelling heat transfer by radiation (for determining view factor and emissivity) and convection (for determining flame velocity and temperature profiles). It also has practical utility for wildland firefighters as a visual proxy for intensity.

Many empirical studies have shown that $\boldsymbol{L}$ is a power function of Byram's (1959) fireline intensity $\boldsymbol{I_B}$ (kW/m) from linear fire sources such that $\boldsymbol{L \propto c I_B^{\,n}}$. The coefficient $\boldsymbol{c}$ and exponent $\boldsymbol{n}$ in the line fire correlations vary considerably for wildland fires, leading some to suspect the $\boldsymbol{L}$-$\boldsymbol{I_B}$ relationships cannot be compared among fuel types, for example grass vs. shrubland (Alexander 1982; Alexander and Cruz 2012). Importantly, some of the variation in $\boldsymbol{I_B}$ derives from how it is estimated based on Byram's (1959) formula ($\boldsymbol{I_B = H m'' R}$) for spreading fires because of uncertainty in heat yield of the fuel ($\boldsymbol{H}$, kJ/kg), overestimation of fuel mass consumed in flaming per unit area ($\boldsymbol{m''}$, kg/m^2), and sometimes unsteady spread rate $\boldsymbol{R}$ (m/s). Differences have also been attributed to variations in the geometry of the fuel source, fuel material (Steward 1964, Quintiere and Grove 1998) (natural biomass, different hydrocarbon gas, or liquid fuels for example), and the difficulty with obtaining consistent measurements of fluctuating flame length (Zukoski et al. 1986; Newman and Wieczorek 2004).

Data and theory by Thomas (1960, 1963) supported the reasoning that effects of flame zone depth $\boldsymbol{D}$ (m) would become negligible as $\boldsymbol{L}$ greatly exceeded $\boldsymbol{D}$. This paper describes an experiment to test that assumption. We employed a laboratory sand-burner apparatus that allows precise independent control of the gas flow rate and magnitude of flame zone depth $\boldsymbol{D}$.

2. Methods

A propane-fuelled sand burner was constructed at the US Forest Service, Missoula Fire Sciences Laboratory for the purpose of studying flame structure and heat transfer from stationary flame zones (Figure 1). This sand burner is similar to the one described by Finney et al. (2020) but double the size, having rectangular dimensions of the burner box of 1.22 m × 3.66 m. The sand box is 0.15 m deep with 8 perforated tubes running the long axis (3.66 m) along the inside bottom surface under the sand. The burner box is mounted on a tilting platform 3.66 × 7.3 m in size with 4.8 m uphill decking made of flame-resistant Super Fire Temp board 2.54 cm thick.

The downhill decking is 1.2 m (Figure 1) in length. Each tube is controlled separately for gas flowing from a common manifold so that any combination of tubes can be fired with a controlled rate of propane. Gas flow is regulated by an Alicat ® mass flow controller capable of flowing up to 1500 standard liters per minute (SLPM).

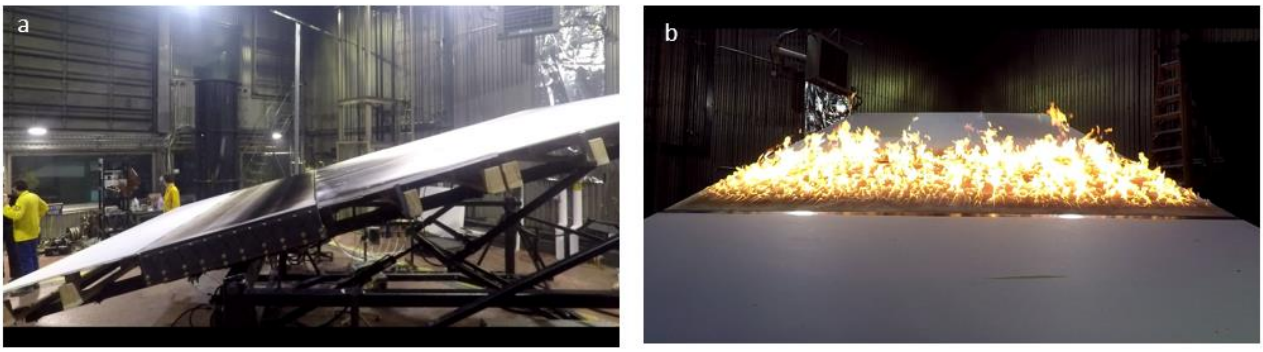

Figure 1- Pictures of propane-fuelled sand burner on a) tilting platform and b) with flames issuing from sandbox.

These experiments were conducted with the platform oriented horizontally so that length of diffusion flames could be measured in the pure vertical dimension. This flame source can be considered buoyancy dominated because the vertical velocity of the propane is so low. Two vertical graduated poles were placed at the foreground edge of the long dimension of the burner in full view of a high-speed camera (Figure 2). The long dimension was chosen because it could more directly incorporate the spatially variable peak and trough structure of line-source flames (Finney et al. 2015) and the non-steady and pulsatile dynamics happening at any given location along a linear flame front (Cetegen et al. 1998). The camera was adjusted to the approximate height of the flames at each setting of propane mass flow rate – 300, 600, 900, 1200, and 1500 SLPM with field of view extending the full 3.66 m width of the burner. For all flow rates, 1-8 burner tubes were opened for 10 seconds of filming.

Video was recorded at 240 frames per second (fps) to minimize smearing from flame movement in each frame. Video was processed to discriminate flaming from non-flaming in each frame using a cut-off brightness value of 90%. Individual binary images were then added to form a probability field for each intensity-flame depth combination and overlayed with a rasterized height gradient determined by the graduated reference poles (Figure 2b). A visual comparison of the video with the probability image suggested that impressions of flame height coincided with the 20% probability contour. For each pixel between the height poles in the image, we obtained the raster height value intersected by the 20% flame presence contour, the mean value of which was an estimate of $\boldsymbol{L}$ (Figure 2c).

Flame length correlations from the gas burner were compared with data from 100 laboratory fires spreading through laser-cut cardboard fuel beds in wind and on a sloping surface (Finney et al. 2013, 2015). Fire spread rate was obtained using thermocouple arrays, flame depth was measured from digital video cameras, and flame length was estimated ocularly. Fireline intensity was calculated from the fuel loading and measured spread rate.

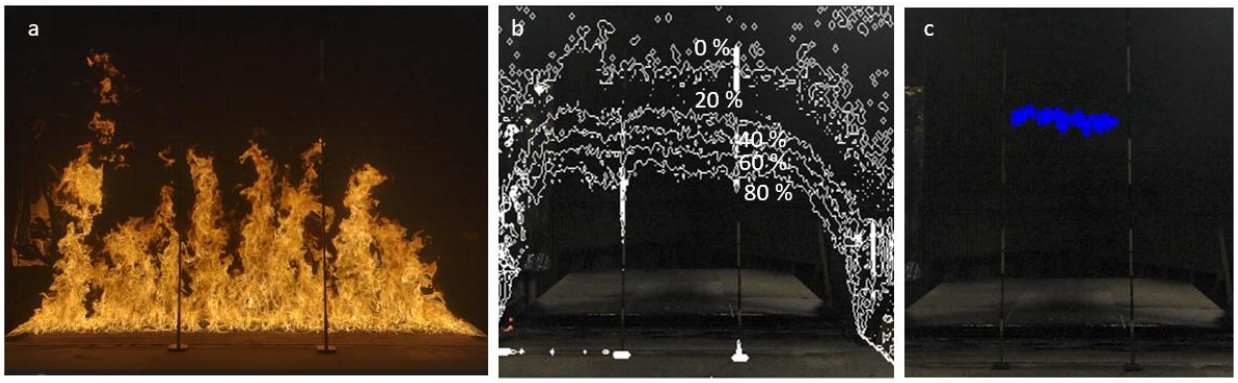

Figure 2 - Image processing of flames is illustrated for a 1200 SLPM gas flow rate with 0.3m flame zone depth D for a) single image of flames from video taken at 240 frames per second showing graduated height poles in the foreground, b) contours of flame presence from 10 seconds of video, and c) points along 20% contour corresponding to an average of $L = 1.55$ m tall (L/D=5.40).

3. Results

The gas burner experiment produced flame length data from a total of 40 combinations of total gas flow rates to the burner (i.e., fireline intensity $\boldsymbol{I_B}$) and number of burner tubes (i.e., flame zone depth $\boldsymbol{D}$) (Table 1). Ratios of $\boldsymbol{L/D}$ ranged from 0.15 to 13.6.

Table 1. Ratios of L/D resulting from experimental combinations of fireline intensity and flame zone depth.

Flame Length/Flame Depth (L/D)								
I_B	**Flame Zone Depth *D* (m)**							
(kW/m)	**0.15**	**0.30**	**0.46**	**0.61**	**0.76**	**0.91**	**1.07**	**1.22**
123	3.20	1.50	0.87	0.60	0.36	0.27	0.20	0.15
246	5.60	2.70	1.73	1.25	0.84	0.67	0.54	0.43
369	9.00	4.30	2.73	1.95	1.40	1.13	0.91	0.78
492	11.20	5.40	3.33	2.40	1.84	1.50	1.23	1.05
615	13.60	6.60	4.27	3.00	2.32	1.80	1.51	1.28

Trends of $\boldsymbol{L}$ as a function of $\boldsymbol{I_B}$ for the gas burner data (thin black curves in Figure 3a) had slopes more like Thomas' (1963) correlation than Byram's (1959). Most importantly, the data showed a strong negative effect of $\boldsymbol{D}$ on the relation of $\boldsymbol{L}$ and $\boldsymbol{I_B}$ for the entire range of variables tested. This is explained using the dimensionless expression of Thomas (1963, eq. 4*ii*):

$$L/D = f(Q'^2/gD^3)^n \quad [1]$$

where $\boldsymbol{Q'}$ is the volumetric flow rate of gas (m^3/s per meter of flame front). Because $\boldsymbol{Q' = I_B/(\rho H)}$, eq. [1] can be rewritten in terms of $\boldsymbol{I_B}$ and absorb the constants into a single coefficient. Using the sand burner data, the empirical coefficient and exponent for the reformulated equation were found by applying nonlinear regression to the experimental data (Figure 3b):

$$L/D = 0.01051\left(I_B^2/D^3\right)^{0.3867} \quad [2]$$

which simplifies to illustrate the significant effect of $\boldsymbol{D}$ on $\boldsymbol{L}$ for the gas burner data:

$$L = 0.01051\left(I_B^{0.774}/D^{0.161}\right) \quad [3]$$

A plot of the burner data shows $\boldsymbol{L}$ was closely predicted by eq. [3] (Figure 3c). Independent data from spreading laboratory fires (Finney et al. 2013, 2015) in Figure 4a showed that when only a function of $\boldsymbol{I_B}$, $\boldsymbol{L}$ was generally overpredicted by Thomas' (1963) correlation and underpredicted by Byram's (1959) at higher intensities. The data trend was well approximated by the correlation from Eq. [3], where $\boldsymbol{L}$ is a function of both $\boldsymbol{I_B}$ and $\boldsymbol{D}$ (Figure 4b).

4. Discussion and Conclusions

The gas burner apparatus allowed precise control over intensity independent of flame source dimensions and revealed the important role of $\boldsymbol{D}$ in determining $\boldsymbol{L}$ in these line-source fires. This result contrasts with Thomas' (1963) data for a similar range ($\boldsymbol{L/D}$ <7) where the exponent for the fitted correlation in eq. [2] (Figure 3b) was found to be 1/3 for $\boldsymbol{L/D}$ > 3 and thus, cancelled the influence of $\boldsymbol{D}$. Steward (1964) also established the theoretical exponent of 1/3 for line fires but experimentally obtained a larger exponent of 0.363 by analysis of a variety of fuel sources for which $\boldsymbol{2 < L/D < 11}$. The flame length data assembled by Quintiere and Grove (1998) largely conform to the 1/3 exponent, but only for $\boldsymbol{L/D > \sim 10}$. Such tall flames with narrow bases are unrealistic for spreading fires in the field and laboratory, suggesting the 1/3 exponent in eq. [2] is not applicable to flames for which $\boldsymbol{L/D < \sim 10}$. Indeed, the following shows that the underlying theory leads one to *expect* an exponent greater than 1/3 for such fires.

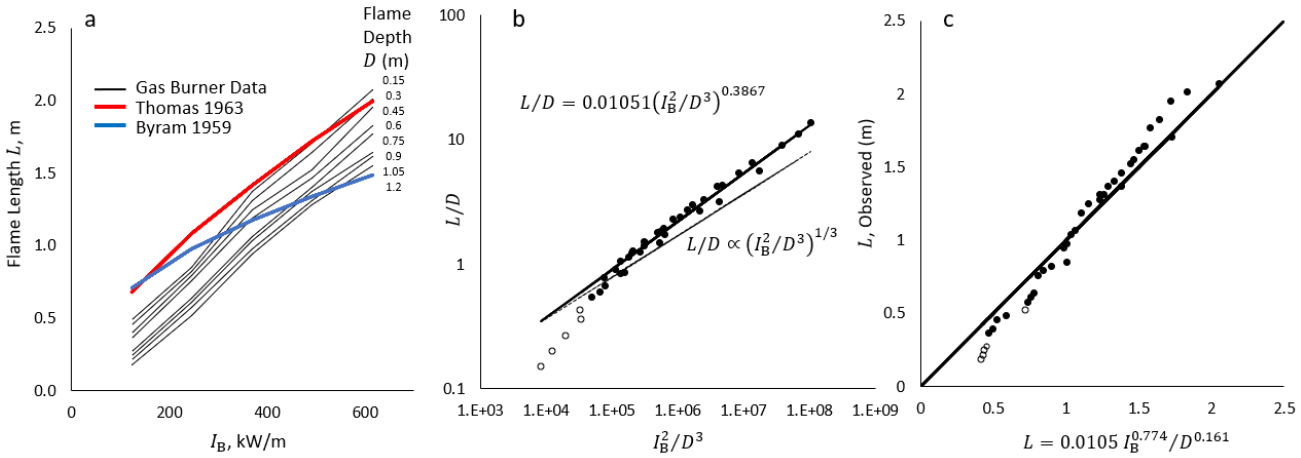

Figure 3. Results of gas burner data a) for flame length L in relation to fireline intensity I_B compared with correlations by Byram (1959) (eq. [1]) and Thomas (1963) (eq. [5]), b) the statistical fit of L/D data compared with Thomas' correlation and c) L observed vs. predicted by eq. [3]. Open circles are observations where L/D<0.52 and flames would likely not form a single plume (Heskestad 1991).

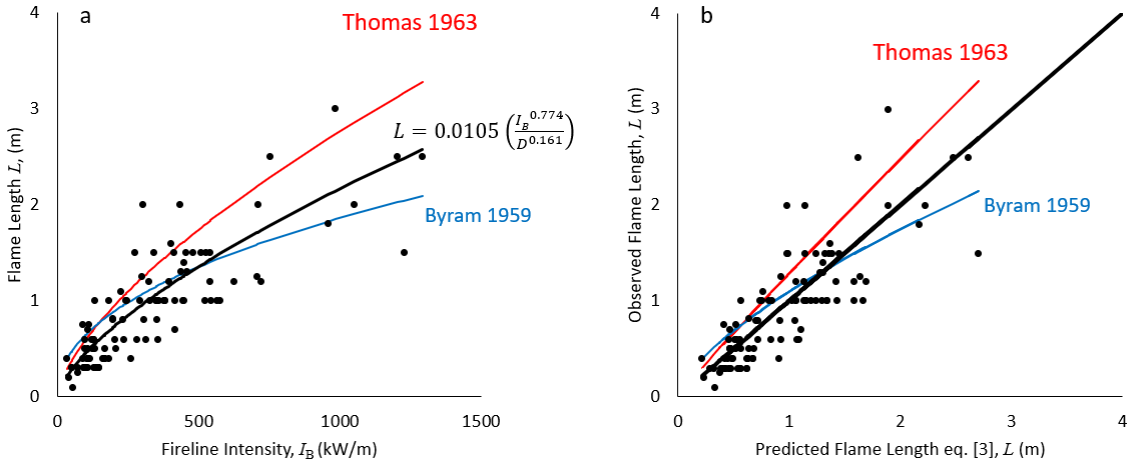

Figure 4. Data from 100 laboratory fires spreading with wind or slope show a) L as a power-function of I_B is generrally overpredicted by the relations of Thomas (1963) (RMSE=0.469) and underpredicted by Byram (1959) at higher intensities (RMSE=0.349), but b) stronger agreement with flame length predicted by eq.[3] (RMSE=0.337).

The roles of $\boldsymbol{I_B}$ and $\boldsymbol{D}$ on $\boldsymbol{L}$ are dependent upon how air is entrained into a turbulent flame. Turbulent entrainment supplies air required for combustion of fuel gases emitted near the ground. Taller flames result from higher fuel flow rates because gases must travel further before adequate mixing allows combustion. Flame length theories have relied upon two principal assumptions. First, air entrainment takes place entirely along the vertical profile of the flame (Thomas 1960, 1963, Steward 1964, Grove and Quintiere 2002, and Nelson et al. 2012). Second, the exterior surface area of the flame profile subjected to air entrainment has been assumed to be linearly proportional to the flame depth and length as would be found if the flames were triangular, rectangular, or trapezoidal. With these assumptions, Thomas (1963) showed that the exponent in equation [1] has the expected value of 1/3, cancelling the effect of $\boldsymbol{D}$ as shown in Figure 3b. This assumption has been assumed to hold where $\boldsymbol{L}$ is much greater than $\boldsymbol{D}$ (Thomas 1963, 1967).

The data in our study clearly contravened the above assumptions because $\boldsymbol{D}$ significantly reduced $\boldsymbol{L}$ in the range $\boldsymbol{0.15 \leq L/D \leq 13.6}$ which is entirely common for spreading wildfires. Published data sets showed median $\boldsymbol{L/D}$ ratios for heading fires of 1.6 (Finney et al. 2013, 2015); 1.4 (Nelson and Adkins 1986, 1988); 0.55 (Catchpole et al. 1998); 1.67 (Sneeuwjagt and Frandsen 1977); and 1.7 (Nelson et al. 2012). However, backing and no-wind fires had greater $\boldsymbol{L/D}$ ratios of 1.81 (Catchpole et al. 1998) and 2.48 (Wilson 1990). All such fires produce inwardly curved flame profiles (Figure 5) that increase entrainment and combustion along much of the horizontal surface in proportion to $\boldsymbol{D}$. Thus, deeper flame zones experience greater combustion of flame gases

traveling along the horizontal fuel bed than allowed by traditional entrainment theory (Thomas 1960, 1963, Steward 1964, Grove and Quintiere 2002, and Nelson et al. 2012) and consequently produce shorter flames for a given intensity. Thomas' (1963) original scaling in equation [1] reflects the increased entrainment with an exponent greater than 1/3, meaning that $\boldsymbol{L}$ depends both on $\boldsymbol{I_B}$ and $\boldsymbol{D}$.

The effect of $\boldsymbol{D}$ on $\boldsymbol{L}$ suggests an important but undescribed negative feedback mechanism that would serve in limiting the spread rate of wildfires. Negative feedbacks are clearly involved in limiting fire spread rate because immediate acceleration of spread and intensity after ignition ultimately gives way to reasonably steady spread. We had earlier reported on the role of $\boldsymbol{D}$ in reducing convective heating through its reduction in the gas temperature profile adjacent to the flaming edge (Finney et al. 2020). A similar effect of $\boldsymbol{D}$ on $\boldsymbol{L}$ would decrease radiation view factor and reduce scaling of convective processes dependent upon flame size, including flame velocity. Both effects of $\boldsymbol{D}$ would work together to dynamically limit fire spread rate as the flame zone depth expands in a spreading fire.

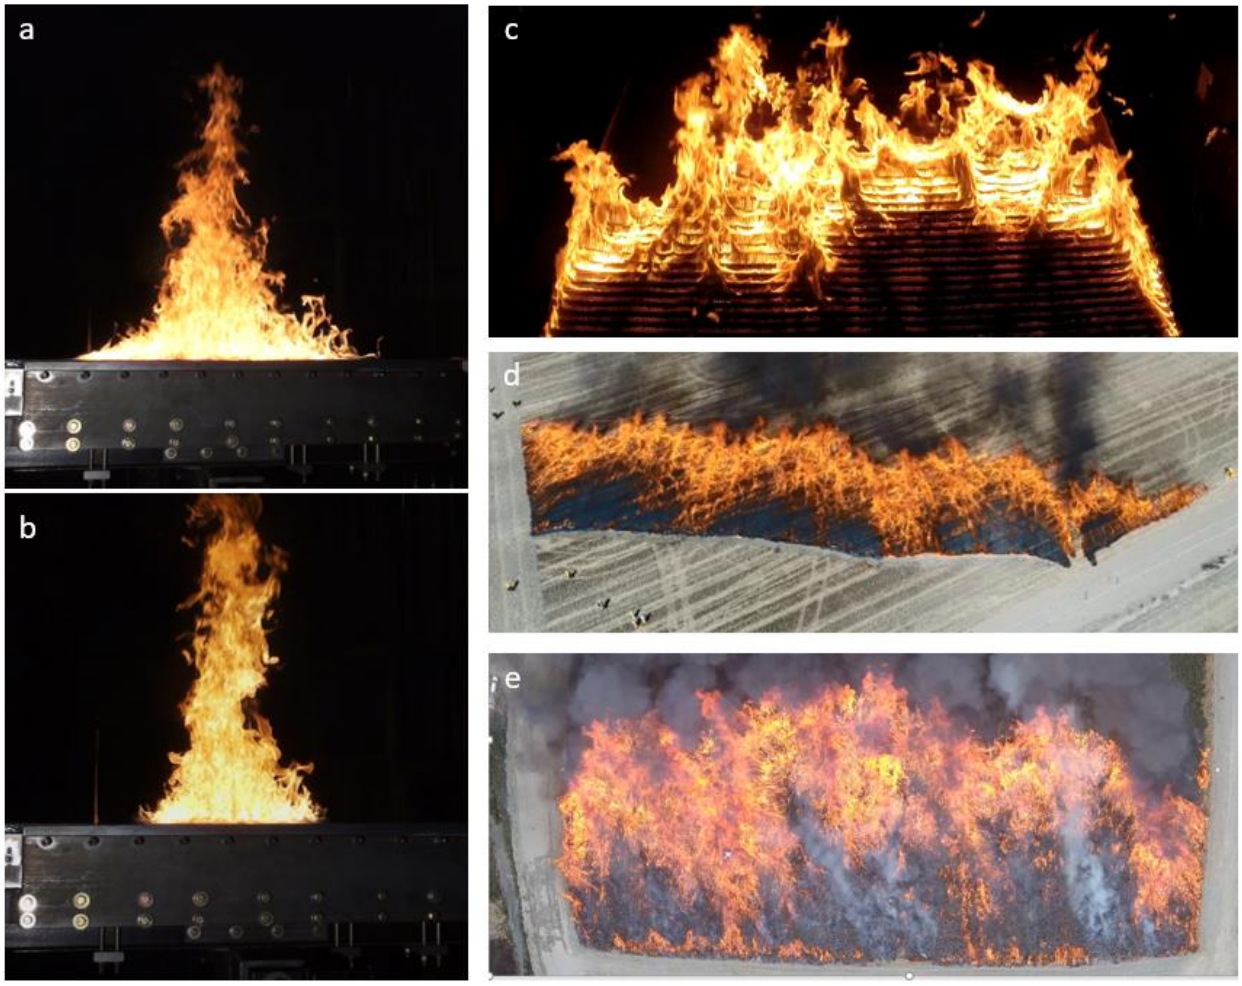

Figure 5. Images of curved flame profiles from gas burner flames a) I_B=205 kW/m; D=0.91m, b) I_B=205 kW/m; D=0.46m. Ground water, well drilling, logistics, water flow, effectiveness

Abstract

Almost without exceptions, in case of long time wildfires, the continuous water supply is always a logistic problem. One of the several reasons is obviously that most of the wildfires occur during droughts, when there is no rainfall and the natural water sources have low flows. Another problem with the water supply is that the frontline of fire and the water source are usually quite far apart from each other. In this case, firefighters are facing a logistical problem, where not only the limited number of fire trucks, but also the slow movement of these vehicles or even blocks have to be taken into account. The Hungarian example presented in the paper shows the use of local opportunities, just as the imaginative use of groundwater can provide a suitable water source at the fire site. With regard to the effective water transport, the question arises as to whether the average water flow that can be provided during a conventional long-distance water transport can also be provided by the water flow of wells drilled on the fire site. The research shows that, under certain conditions, the groundwater provided by drilled wells can be an alternative solution to the logistical difficulties of long-distance water transport.

1. Introduction

The generation of wildfires can be traced back to human negligence (Chas-Amilm 2010, Teknős and Debreceni 2022). In order to save human life and property, firefighters use several tactics to fight against wildfires (Restás 2003). They can use so-called hand tools for firefighting purposes, ground power machines, aircrafts for aerial firefighting or counter fire, but the most common solution is to extinguish the frontline of fire with water. One of the characteristics of wildfires is that forests ignite when the availability of water sources in wildland is already limited, i.e. during droughts (Bodnár et. al. 2019). In this case, the water required for firefighting can be replaced with artificial water sources. For this purpose, based on plans, we create artificial reservoirs, which we maintain and provide the right amount of water in them. The disadvantage of artificial water sources is that their construction and maintenance costs are high and their efficiency will only prevail if there is a wildfire nearby and they need to be used. Until they are used, the costs so far may seem unnecessary. Another characteristic of wildfires is that the frontlines are often far from the forest roads that can be used by heavy fire trucks, therefore the so-called long-distance water transport is also difficult (Bodnár 2016). On the one hand, traffic on dirt roads is rather slow, and on the other hand, the soil in the observation plot in the paper is rather sandy. As a result of this, heavy, water-filled fire trucks simply sank in the sand. The above mentioned problems can be justified by a number of examples, so it is clear that effective firefighting requires either a different firefighting method or a new solution to the water supply problem. Based on the above, the authors aimed how to provide the amount of water needed for firefighting in the most flammable area of Hungary (Bacs-Kiskun County) at the same time.

2. Methods

Authors have examined and analysed the relevant literatures focusing on the logistic problems of the firefighting and water supply. In addition, authors conducted discussions with the local firefighting experts on the subject. Case studies, made after the latest fires in the Bacs-Kiskun County, have also analysed focusing on the problem

of water supply. Moreover, authors made a real experience in well drilling at a random place at the county and measured the water capacity of the well (flow rate) with using a simple water pump.

3. Results

The authors were able to prove that the area is high vulnerable with the help of previous case studies on large wildfires in Bács-Kiskun County (Gyapjas 2007). During firefighting, natural water sources are only available to a limited extent (Farkasinszky 2007a and 2007b) the so-called long-distance water transport is difficult and slow on dirt roads (Árpás 2007) and the risk of blocks are high. Study area is highly threatened by the climate change so suppressing fires in this area seems to be more and more difficult in the future (Teknős 2019, Kovács and Jakab 2021).

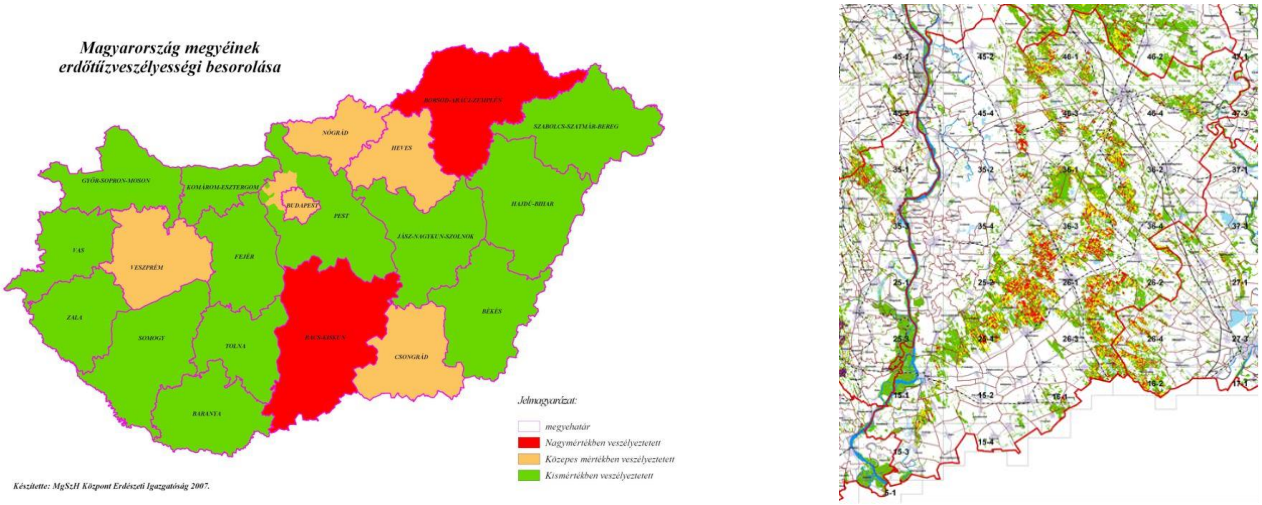

Figure 1. Fire danger classification of counties in Hungary (left) and the fire danger classification of forests at Bacs-Kiskun County (right) (Gyapjas 2007)

Figure 2. Water transport vehicles trapped in sandy dirt road (Gyapjas 2007).

Based on the geographical analysis, it can be stated that Bacs-Kiskun County is basically a flat area (plain), without significant prominence, but the surface is covered with sand in many places. During the search for water sources, local firefighters suggested that wells used for irrigation of agricultural land should also be considered as potential water sources. Based on experience, these simple wells can be created in a short time, and their water flow appears to be relatively stable even at the order of a few hundred litres per minute (Higuera 2015). Based on the above, the authors first reviewed the area of the observation plot and then the whole country in terms of groundwater availability. For this purpose, the official groundwater map of Hungary (MBFSz maps 2022) and other relevant literatures were analysed (Grundwaters in Hungary 2006; Kovács and Jakab 2021). According to it, there is a water layer a few meters below the wildland area of Bács-Kiskun County, which can

be easily reached with the help of a well drilled, due to the sandy soil (Fig. 3). Based on it, the authors conducted an experiment to drill a well at a random selected spot in the county.

The experiment had several purposes.

- First, the authors wanted to prove that the well could be drilled easily and quickly on the soil that characterized the county.
- Another objective of the experiment was for the authors to be able to demonstrate that the water flow provided by the well is stable, so it can provide the same amount of water for at least 24 hours.
- Third objective of the study was to create graphics on which we can find the tipping points where drilled well able to supply as much water as tradition solution.

Figure 3. Ground water level in Hungary below the surface (left) (MBFSZ maps) and measuring the water flow after drilling (archive of authors).

The authors involved in the experiment the Municipality Fire Brigade of Szabadszállás and a well drill master. The well drilling master did the professional part of the work (well drilling), the firefighters helped with the preparation and setup of the pump after drilling. During the experiment, the water layer was available in less than 2 hours, slightly deeper than expected, at approximately 5 metres deep. The preparation of the well with 60 mm diameter of well tube, the setting of the pump and the further preparatory works took an additional 1 hour. The water flow, which was then measured for 1 hour, reached 400 $lmin^{-1}$, which appeared to be completely stable. Drilling master stated also that drilled wells can produce stable water amounts after about 1 hour usage. It is proved on the selected place drilling wells can supply firefighters with stable water flow. Based on the results of the experiment, authors calculated the assumption that in case of drilling 2 wells after professional preparation, firefighters can be able to provide a water flow of 800 $lmin^{-1}$ after 3 hours of the arrival of the fire forces. The authors went on to find out whether this amount of water (from the well) competes with the amount that can be provided by long-distance water transport.

In case of long-distance water transport, the following can be expected: the average speed of the water transporter is considered to be 30 kmh^{-1}. Based on it, the vehicle travels a distance of 5 km in 10 minutes and returns in another 10 minutes, thus making a total of 10 km in 20 minutes in both directions. As a result of it, the average flow rate of a 10,000 litre tank is 250 $lmin^{-1}$ (Fig. 4 left). The maximum value of the water flow is obtained when the vehicle is not moving, so it is filled and then emptied locally. In this case, the water flow is maximum (500 $lmin^{-1}$). The water flow increases in a straight line with increasing the average speed, while it is inversely proportional to the distance (Fig. 4 right).

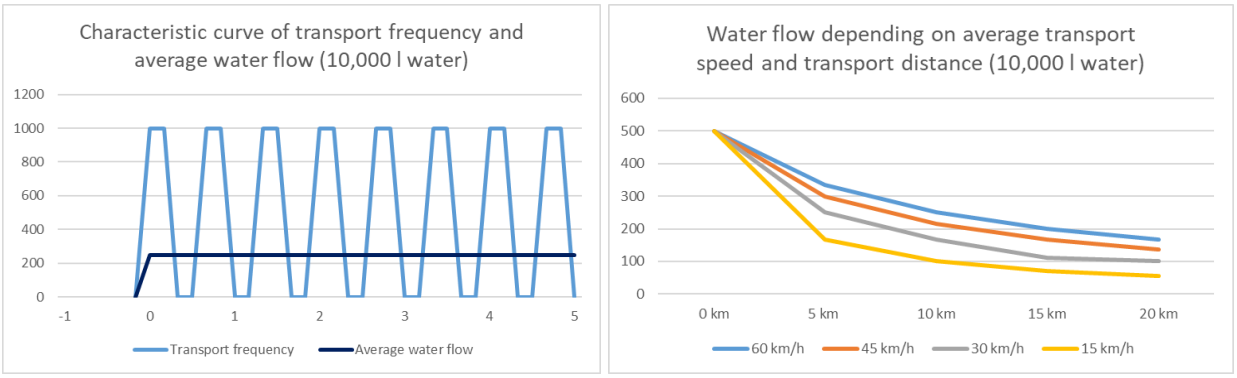

Figure 4. Characteristic curve depending on transport frequency and average water flow in case of 30 kmh^{-1} average transport speed and 5 km transport distance (left) and water flow rate depending on average transport speed and transport distance in case of 10,000 l water capacity (right).

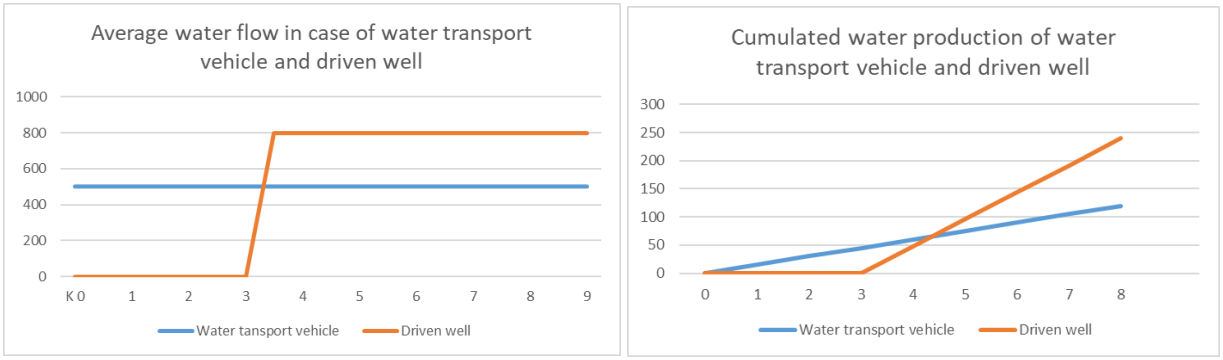

Figure 5. Average water flow in case of water transport vehicle and driven well (left) and cumulated water production of water transport vehicle and driven well in optimal cases (0 km) (right).

4. Conclusion

The results show that water transporters can be replaced by drilled wells after about 3 hours. The results also show that the farther the water has to be transported, the more difficult it is to transport the water, and the more difficult (slower) is the fire site to approach. The diagrams also show when the cumulative amount of water in drilled wells with higher water flows reaches or exceeds the amount of water provided by water transporters. According to the above, authors considering that during a long firefighting, water transporters can also be replaced or their capability can complete by drilled wells, depending on the given conditions. The authors suggest further research into the international applicability of this method. Example, based on the ground water map of Europe (GWM of Europe 2022) the fire departments could measure their responsible area where ground water can be acceptable by reasonable efforts especially focusing on the forest fire threatened areas, like Mediterranean region. Even if the study area has a good capacity using ground water for supporting firefighters, as a new method it can be an option in other places too. In order to compare the efficiency of the two methods from an economic point of view further research is also required.

Wildfire; Mapping; ALS; First Nations; Forestry

Abstract

Climate change and institutional forest management practices have lead to more frequent and severe wildfire events around the world, a trend that is projected to increase in coming years. Wildfire plays an important role in maintaining ecological systems, but wildfires also pose threats to health, safety, infrastructure, and ecosystem services. Reactionary response to these threats has predominantly informed management decisions in recent decades and greater focus on mitigation and adaptation is needed. Through a community-directed consultation process, the goal of this work has been to provide direct, operational information to aid in local management decision making for a First Nations community in British Columbia, Canada. Using a combination of field sampling and high-resolution Airborne Laser Scanning (ALS) data, we assessed vertical and horizontal fuel loading at fine resolution. Our analysis found a high degree of fuel loading heterogeneity in areas characterized as homogeneous using coarser fuel layers and provided a means of identifying high fire risk areas that may be targeted for ecosystem rehabilitation aimed at reducing current and future fire risk. We discuss how this spatially explicit data can be used to evaluate feedback between forest dynamics and fuel loading, information critical for managing forests for multiple objectives into the future. Following our analysis, we compiled our results into an interactive decision support web mapping platform designed with the goal of providing a user friendly, accessible land management planning tool for the community.

1. Introduction

Wildfire is an integral part of natural forest dynamics across a range of different forest types globally (Moritz et al., 2014). In many areas, fire serves an important role in maintaining forest ecosystem functioning by rejuvenating plant health, creating animal habitat and forage, and mitigating the risk of large scale destructive stand-replacing wildfire events (Driscoll et al., 2010). In addition, wildfires also account for significant contributions to the global carbon budget (Driscoll et al., 2010; Ager et al., 2010). Although wildfire plays an important role in maintaining ecological systems, management objectives relating to wildfire are most often directed at mitigating the near term and immediate threats it poses to society (Duff et al., 2017). The negative impacts of wildfires on human health and safety, values and infrastructure, and ecosystem services cannot be ignored. However there is room for more attention to be paid towards managing wildfires to promote the positive impacts they can have in forest ecosystem dynamics. Understanding how wildfire will interact with a given landscape and forest ecosystem requires information about the three most influential factors for fire behavior: weather, topography, and fuels. Of these three elements, the only one manageable on an attainable scale is fuels. Having the ability to meausre fuel load and structure at scale across forest ecosystems is critical to understanding how to better manage wildfires overall. In addition, the ability to include and prioritize local community knowlegde and input in forest management planning can greatly enhance the positive impact of managment actions.

2. Project Overview

This project is part of a multi-year collaboration between a First Nations community in southwestern British Columbia and University of Northern British Columbia researchers Patrick Robinson, Dr. Scott Green, and Dr. Che Elkin, with support from the Pacific Institute of Climate Solutions. This project is a community-directed initiative, with the aim of assessing how high resolution aerial laser scanning (ALS) data can best be used to

evaluate and quantify forest fuels, and directly aid in fire risk mitigation, forest ecosystem restoration, and climate adaptation planning efforts at local and regional scales. The project is guided by the shared goal of promoting the re-establishment of traditional management principles and practices, which pre-date modern intitutional mangement and have been around since time immemorial. In collaboration with the community, the goal is to provide information relating to wildfire fuel load distributions with local context that is directly applicable and immediately useful to the community's unique forest management planning and ecosystem restoration objectives. Additionally, the results of the analysis are intended to contribute to and support general wildfire fuel mapping efforts around the province and amongst the broader scientific community.

Previous work and existing data have established that the community is facing significant risk of catastrophic stand replacing wildfire. To address this risk effectively, the spatial distribution and connectivity of hazard fuels types is required in greater detail than previously existed. High resolution data provided by ALS has the potential to describe fuel structure and distribution with the detail required to enable tangible and prioritized management throughout the study area. This work probes beyond fuel mapping alone, taking into consideration community objectives and First Nations Traditional Ecological Knowledge in the process of determining how wildfire and fuels distribution, both past and present, play a role in the restoration and responsible future management of forests for multiple values. In addition, there is interest in the identification of areas potentially suitable for the integration of prescribed burning practices in support of landscape-level wildfire resilience and risk mitigation, as well as the cultural revitalization of traditional burning practices.

3. Study Area

The study area is located in southwestern British Columbia, Canada, east of Lillooet in the Pavilion Ranges Ecosection (Figure 1). In the past, the area has experienced a relatively frequent fire return interval (6.6 to 11.6 years over the last 500 years), of regular low-intensity surface fire within fire resilient, open forest areas of Douglas Fir and Ponderosa Pine stands, and less frequent fire occurrence in higher elevation stands comprised of Montane Spruce and Lodgepole Pine (Gray et al., 2002). Over the past 100 years, largely as a result of aggressive fire suppression, the forests throughout the area have become less fire resilient with increased hazardous fuel load build-up, resulting in an altered fire regime of less frequent and more severe fires. In response to the increased fire risk, several areas throughout the territory have undergone fuel treatments, fire-smarting, and ecosystem restoration initiatives, including thinning and pruning, with a particular focus placed around community areas and recreation sites (Diver, 2016).

Figure 1- Map of Southwestern British Columbia, indicating the general location of the study area in red.

4. ALS Data

Airbourne laser scanning (ALS) data was collected for the entire study area at approximately 15 points per square meter. ALS can be used to model forest biophysical structure and inventory variables at a fine grain (plot level) over a large landscape extent (Hayashiet al., 2016; Hummel et al., 2011; Treitz et al., 2012; White et al., 2016). Forest structural characteristics are critical for develping forest fuel load maps, which classify fuel attributes relevant for the evaluation of fuel treatments, risk mitigation and other related planning activities (Chen et al., 2016; Hayashi et al., 2016; Peterson et al., 2015; Pimont et al., 2016). ALS data has the capacity to significantly enhance the current spatial understanding of forest fuels by providing detailed three-dimensional forest structural characteristics (fuel metrics) for entire landscapes (Ahmed et al., 2015; Coops et al., 2016; Filotas et al., 2014; Gao et al., 2014). Improving the spatial resolution of the fuel mapping enables more confidence in fire and forest management planning and promotes more informed decision-making for ecosystem restoration and general management objectives.

Forest fuels can be considered as a physical complex composed of surface fuels, understory fuels, ladder fuels and canopy fuels. Some of the key metrics used to describe these structural attributes include total tree/canopy biomass, canopy bulk density, canopy base height, canopy fuel loading, stems per hectare, ladder fuel load, understory fuel load, and basic surface classification (fuel/non-fuel) (Jakubowksi et al., 2013; Zhao et al., 2011; Reinhardt, 2006). We acknowledge the importance of understanding ground fuels as a fundamental component of fire risk mapping, however this study focuses on above-ground forest fuel structure. Considering that these above ground metrics all relate to structural components of the forest, ALS data is well suited to provide this type of data.

5. Empirical Data

Empirical forest and fuel data were collected in the form of field plots throughout the study area and used to calculate various forest fuel load metrics. To develop the models responsible for deriving the fuel metrics from the ALS point cloud, empirical field data is required to train and calibrate the models (Andersen et al., 2005; Zellweger et al., 2014). The empirical field data in this application was collected in the form of forest plots designed to capture relevant structural characteristics of the various forest types in the study area, pertinent to fuel load calculation (Andersen et al., 2005; Price & Gordon, 2016). The forest sample plot characteristics have been informed by reference to the literature and reliance on the best practices described by White et al., (2013). A random stratified sampling framework was used to ensure a representative sample set across the complete range of forest type diversity.

6. Modelling and Analysis

We used a machine learning framework to develop predictive models for several important forest fuel characteristics in common forest types of interior southwestern BC with the goal to determine how forest structure differs across the landscape and how those differences are reflected in ALS derived fuel metrics. The following objectives guided this work:

- Being able to accurately evaluate the distribution of metrics for describing fuel load throughout the study area (i.e., Canopy Bulk Density, Canopy Base Height, Ladder Fuel Density, Understory Fuel Density) across multiple forest strata in a way that enables the community to easily target focal areas for restoration and treatment;
- Assess the variation in fuel loading components within the standard Canadian Forest Fire Danger Rating System Fire Behaviour Prediction system fuel types categories, and to test if emergent clusters of fuel loading classes can be used to better classify fire risk across the landscape; and
- Analyze how historic management practices and recent forest ecosystem restoration activities have altered fuel loading.

Random Forest (RF) was used to model the fuel metrics by identifying statistical relationships between the ALS data and the empirical data.

7. Results

The landscape level fuel load distribution map products produced from the process described above have proven effective in their ability to accuratley describe fuel struture throughout the study area, and have produced relatively high R^2 values (Table 1). As expected with ALS derived data, the model confidence is lower in the fuel metrics that describe fuel attributes for lower elements of the vertical forest/vegetation profile (i.e., Ladder Fuel Density and Understory Density). This is largely due to the effect of the upper canopy components shading out the lower components during the ALS data collection, however preliminary field validation excercises have helped to validate the accuracy of these lower level metrics as seen in the ladder fuel density image displayed in Figure 2.

Fuel Metric/Response Variable	R^2 Value
Tree Height	0.90
Canopy Bulk Density	0.86
Canopy Fuel Load	0.84
Canopy Base Height	0.89
Ladder Fuel Density	0.33
Understory Density	0.38
Total Biomass	0.95

Table 1- R^2 values for the model results, produced for the k-fold cross validation.

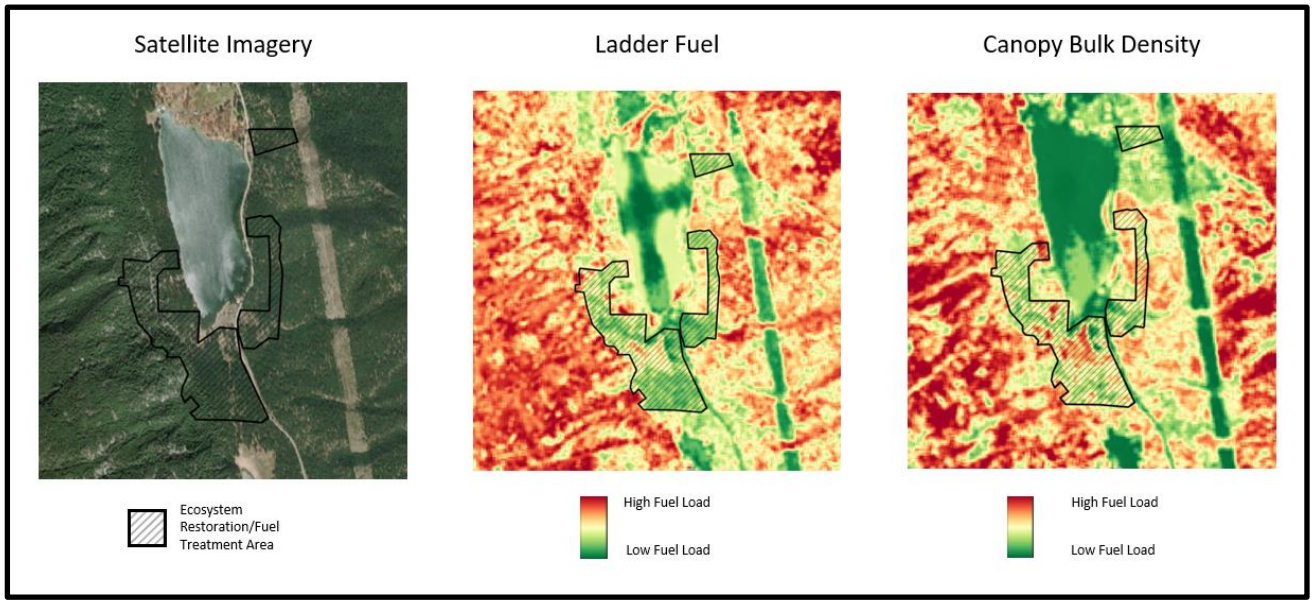

Figure 2- Comparison of modelled fuel metric products for a known fuel treatment site in the study area. All three maps display the same area with the black hashed boundary indicating an area that has been thinned and pruned for fire risk reduction. The map on the left indicates the inability to differentiate the treated area from the untreated areas in the satellite imagery, whereas the Ladder Fuel and Canopy Bulk Density maps indicate the subsequent ability to distinguish the areas of increased and decreased fuel load (i.e., treated vs. untreated) with the ALS derived products.

8. Web Mapping Platform

One of the main priorities of this work has been to promote community capacity building by providing information accessibility, research methods transparency, and direct collaboration. With that in mind, a suite of web mapping tools have been developed to provide a comprehensive GIS decision support platform to the community. The platform provides user-friendly access to important spatial data visualizations, enables community-directed management planning, and facilitates co-development of management solutions.It

encourages discourse regarding management objectives by providing a means for translating technical data directly to the solution seeker in a way that is accessible and useful. The web map tool is essentially a multi-part story map, made in Arc GIS online that functions as both as a data sharing outlet/communication network and a decision support platform for fire risk mitigation and general forest management planning.

9. Conclusion

Ongoing work continues with the community to utilize the results of the ALS fuel modelling and integrate them into current and future management planning. In addition, further development and design refinement of the web mapping platform continues in collaboration with the community to continually improve the ability to leverage the results of this study towards tangible managment objectives, as well as build the internal capacity of the community.

Abstract

The bulk density as definition represents the ratio between the packing ratio and the density of the vegetation. Therefore, it is directly related to the fuel load, the height and to the porosity of the vegetation. In fact, the bulk density plays an important role in fire propagation and behavior. Due to its dependence on the fuel porosity, the bulk density influences heat transfers inside the fuel bed, so, it can affect directly the rate of spread. Or, the bulk density influences also the fire intensity and flame characteristics (residence time, height and depth) due to its dependence of the fuel load and fuel bed height. However, despite the important influence of the bulk density on fire propagation, the literature does not clarify its impact on fire behavior, different points of view can be exanimated.

So, the aim of this study is to investigate the role played by the bulk density upon both propagation parameters and heat transfer of a surface fire through a homogeneous vegetation layer. Investigations were conducted numerically using "FireStar2D", a complete physical model based on multiphase formulation. Also, experimentally, tests were constructed at the university of Corsica at laboratory scale under no wind and no slope condition. In order to study the elementary effect of the bulk density on fire behavior, three different cases were evaluated: (a) variable fuel load with a constant bulk density, (b) variable fuel load and variable bulk density, (c) variable bulk density with a constant fuel load.

Case (a) was only studied numerically, the obtained results are in agreement with the literature: the rate of spread increases with the fuel load until a specific value where the ROS becomes independent of it. Case (b) was evaluated numerically and experimentally using a fix fuel bed height. The numerical and the experimental results showed that the ROS is barely affected by both fuel load and bulk density. Finally, the results of the last case, with a constant fuel load, showed numerically the same tendency proposed by Rothermel: the rate of spread reaches a maximum value at an optimal packing ratio that depends of the surface-volume ratio of the vegetation. Or, experimentally the ROS decreases with the increase of the bulk density. Different variables such as the optical thickness, the fire intensity, the residence time, the radiation and convection heat fluxes have been analyzed.

1. Introduction

Surface fire spread behavior is always related to the vegetation complex structure (Rothermel and Anderson 1966; Balbi et al. 2010; Rossa 2017), described by the properties of the fuel particles (fuel moisture content, density, surface to volume ratio, fuel load, bulk density, fuel bed depth, and packing ratio). Each one of these properties has its own effect on fire propagation. For instance, several studies have showed that the rate of spread decreases with the increase of fuel moisture content (Morvan 2013; Awad et al. 2021). Others showed that the rate of spread increases with the fuel bed height, and the fuel load (Morvan and Dupuy 2004; Rossa and Fernandes 2018; Awad et al. 2020). However, the effect of the vegetation bulk density and packing ratio on fire behavior has always been an examination subject due to the different point of views of its impact listed in the literature (Morvan and Dupuy 2004; Rossa and Fernandes 2018; Awad et al. 2020). In fact, as mentioned, the bulk density is directly dependent on the vegetation fuel load, height and porosity which can have opposite effects on fire behavior. Several studies noted a decrease of the rate of spread with the bulk density or the packing ratio (Rothermel and Anderson 1966; Catchpole et al. 1998). Several explanations of this tendency

were proposed: a large bulk density, therefore a large packing ratio and a low porosity leads to less diffusion of oxygen inside the fuel bed. Also, the radiation from burning fuel particles, heated by the flame base, impinges on the unburnt fuel on a distance equal to the extinction depth δ (Balbi et al. 2007) (equation 1) that is inversely proportional to the bulk density.

$$\delta = 4/\beta s \quad (1)$$

Where, β is the packing ratio and s is the surface to volume ratio.

However, other studies showed another tendency. Rothermel (Rothermel and Anderson 1966) performed several experiments using fuel beds of excelsior and sticks, showed that the ROS reaches a peak under an optimal packing ratio. For $\beta \leq \beta_{opt}$, the heat loss between fuel particles was important, it was explained by the increase of the air cooling effect inside the fuel bed with higher porosity. Or, for $\beta \geq \beta_{opt}$, the porosity decreases and the ratio of air fuel decreases. Qianqian He et al 2022 (He et al. 2022) showed that the surface heat transfer increases under lower packing ratios which increases the rate of spread (ROS). Or, under higher packing ratios, the surface heat transfer does not vary significantly, and, the ROS reduction in this case is attributed mainly to the internal heat transfer dominated by radiation.

The main purpose of this is to determine the elementary effect of the bulk density of fire behavior. Therefore, three different cases were evaluated: (a) variable fuel load with a constant bulk density, (b) variable fuel load and variable bulk density, and finally (c) variable bulk density with a constant fuel load. Several numerical simulations and experimental tests were conducted. Fire propagation parameters have been analyzed as the rate of spread, the fire intensity, the radiative and the convective heat transfer, and the residence time.

2. Study case (a): Variable fuel load with a constant bulk density

Previous studies showed that the fuel load has impact on fire behaviour, especially on the rate of spread and on fire intensity (Rothermel 1972; Morvan and Dupuy 2001; Weise David R., Zhou Xiangyang, Sun Lulu 2005; Zhou et al. 2005). Morvan and Dupuy (Morvan and Dupuy 2004) have demonstrated that the fuel load with a constant bulk density is a factor that determines the mode (thin or thick) of the porous medium where the fire front propagates. They found out that the rate of spread increases with fuel load until a specific value where it becomes independent. This behaviour can be explained by introducing a critical optical thickness τ_{opt} related to the fuel extinction length δ and to fuel height that determines if the vegetation medium is considered to be thick or thin.

$$\tau_{opt} = \frac{s\beta}{4}.e \quad (2)$$

In fact, if $\tau_{opt} < 1$ the porous medium is considered as a thin and all the vegetation depth participates to the fire front propagation. And, if $\tau_{opt} > 1$ only a depth equal to the extinction length δ that participates to the fire front propagation.

In order to study the influence of the fuel load on fire behavior with a constant bulk density, simulations were performed using fireStar2D, in a 2D domain, 170 m long and 35 m height. A homogenous layer of Australian grassland, whose physical properties are described in Table 1, lied between x = 20 m and x = 170 m. Different fuel loads are considered in this study by changing the fuel height between 0.3 and 1 m and maintaining the same fuel density and packing ratio.

Figure 1 shows that ROS increases with the fuel load (up to 0.5 kg/m^2) until reaching a value beyond which the dependence of the fuel load becomes relatively weak. This tendency can be related to the fire propagation mode in the porous medium.

Table 1- Vegetation characteristics

Fuel density (Kg/m^3)	500
Surface to volume ratio S/V (m^{-1})	4000
Packing ratio	0.002
Fuel load (Kg/m^2)	0.3-1
Height (m)	0.3-1

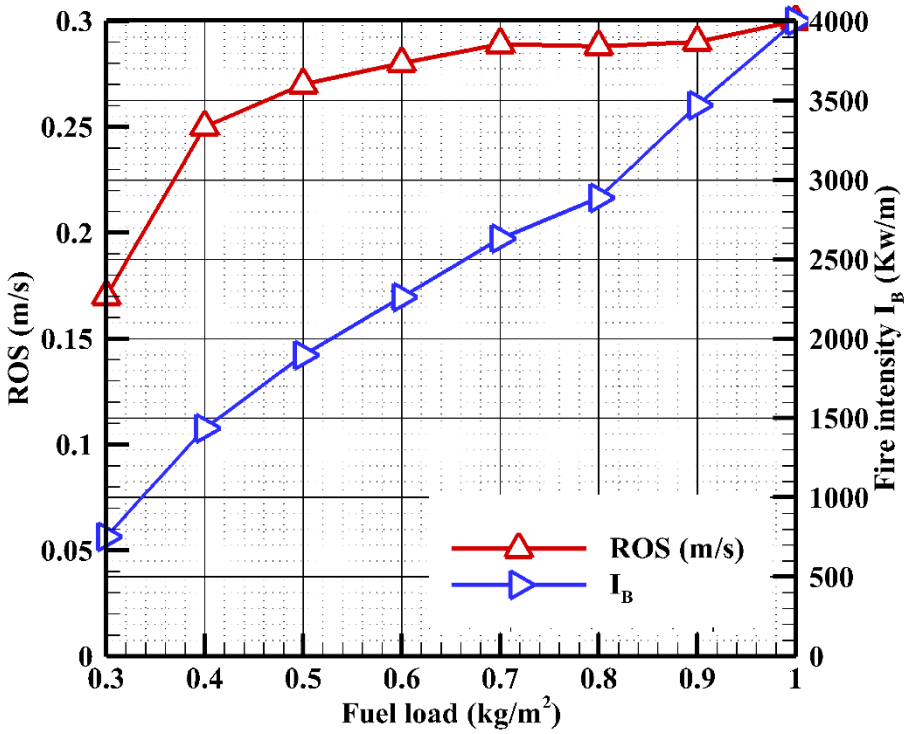

Figure 1- The rate of spread and Fire intensity evaluated for the grass for different fuel load with a constant bulk density under no slope no wind condition using FireStar2D

For a relatively thin vegetation medium ($\tau_{opt} < 1$) obtained for e < 0.5 m all the fuel-bed depth participates to the fire propagation. Therefore, the ROS increases with the fuel load. But, for a thicker vegetation medium, δ > e, radiative heat transfer does not penetrate the entire depth of the fuel bed. The lower fuel bed layers are not heated enough to participate to fire front propagation.

In another hand the fire intensity continues to increases with fuel load, as shown in figure 1. In fact, fire intensity depends directly of mass degradation rate and of the heat of combustion of the vegetation:

$$I = \dot{m} \, . \, \Delta H_c \qquad (3)$$

Where $\dot{m}$ (kg m^{-1}s^{-1}) is the vegetation degradation rate evaluated by the summation of mass losses due to pyrolysis and charcoal combustion producing CO and CO_2 gases.

3. Study case (b): variable fuel load and variable bulk density

3.1. Numerical tests

In this paragraph the fuel bed height remains constant or the fuel load and the bulk density (packing ratio) are variables. Simulation were conducted using the grassland (table 1) under no wind and no slope conditions. The different configurations are represented in table 2.

Table 2- Different configurations of grassland evaluated with Firestar2D

Packing ratio	0.0014-0.0032
Fuel load (Kg/m^2)	0.49-1.12
Height (m)	0.7

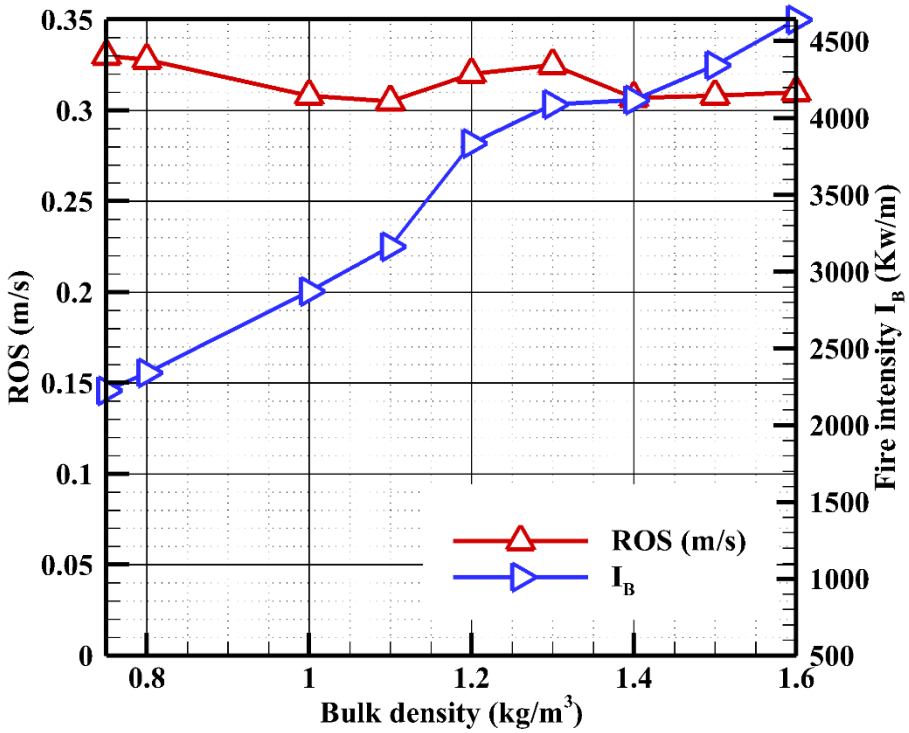

Figure 2- ROS and the Fire intensity variation in function of the bulk density for a constant fuel bed height 0.7 m evaluated using FireStar2D

Figure 2 shows that for a constant fuel bed height, with variable packing ratio and fuel load, the variation of the ROS is barely dependent on either bulk density or fuel load. In fact for the different configurations, the optical thickness τ is higher than 1 ; so the fire propagates in a thick medium where the extinction length δ is always less than the fuel bed height. Or, δ is inversely proportional to the packing ratio, therefore the depth of the vegetation that really participates to the fire propagation decreases with the increase of the packing ratio. This tendency is in agreement with the experimental results showed by Campell Lochrie (Campbell-Lochrie et al. 2021).

3.2. Experimental tests

Twelve tests were conducted at the laboratory of the university of Corsica with the excelsior in order to evaluate the influence of the bulk density and the fuel load when the fuel bed height remains constant.

Four different bulk densities were evaluated. The properties of the fuel are listed in the table 3.

Table 3- Excelsior characteristics

Fuel density (Kg/m^3)	780
Packing ratio	0.0023-0.0035-0.0046-0.0058
Fuel load (Kg/m^2)	0.2-0.3-0.4-0.5
Height (m)	0.11

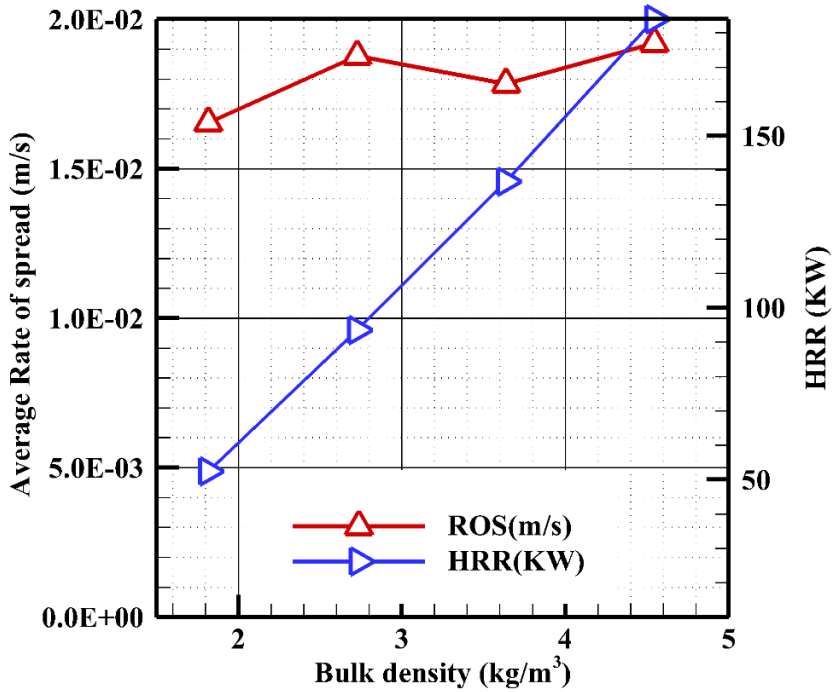

Figure 3- ROS and HRR variation in function of the bulk density for a constant fuel bed height 11 cm evaluated experimentally

The results of experimental tests are in agreement with the numerical results (Figure 3): the rate of spread barely depends of the bulk density or the fuel load when the fuel bed height remains constant. However, the fire intensity and the residence time increases with the bulk density (Figure 4).

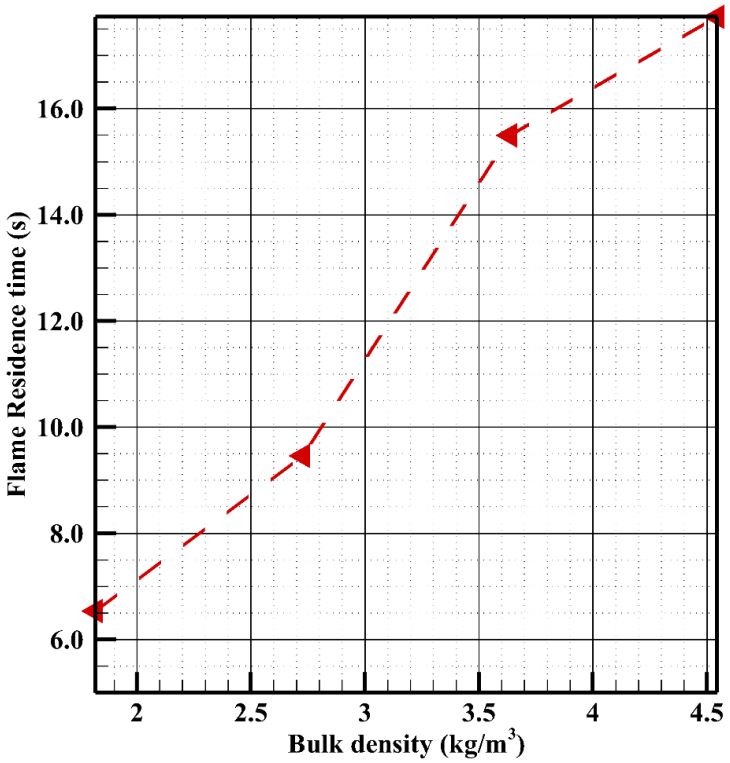

Figure 4- Flame residence time variation evaluated experimentally in function of the bulk density for a constant fuel bed height 11 cm

4. Study case (c): variable bulk density with a constant fuel load

4.1. Numerical tests

In this paragraph the fuel load remains constant or the bed height and the bulk density (packing ratio) are variables. Simulations were conducted using the grassland (table 1) under no wind no slope condition. The different configurations are represented in table 4.

Table 4 - Different configuration of grassland evaluated with Firestar2D

Packing ratio	**0.0014-0.0035**
Fuel load (Kg/m^2)	0.7
Height (m)	0.3-1

Numerical results shown is figure 4 are in agreement with the tendency proposed by Rothermel [2]: the ROS reaches a maximum for an optimal bulk density (Figure 5).

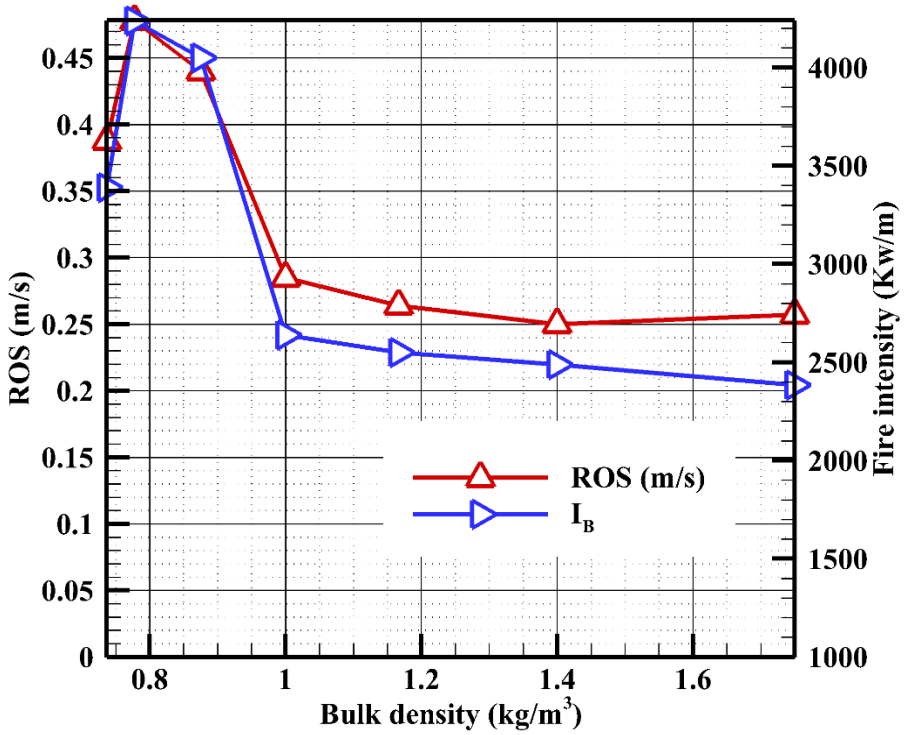

Figure 5- ROS and fire intensity variation in function of the bulk density for a constant fuel load evaluated numerically for the grass

4.2. Experimental tests

3 tests were conducted experimentally at the laboratory of the university of Corsica using the excelsior with a constant fuel load. The different configurations are represented in table 4.

Table 4- Different configuration of excelsior evaluated experimentally

Packing ratio	0.0039-0.0064-0.0017
Fuel load (Kg/m^2)	0.4
Height (m)	0.13-0.08-0.03

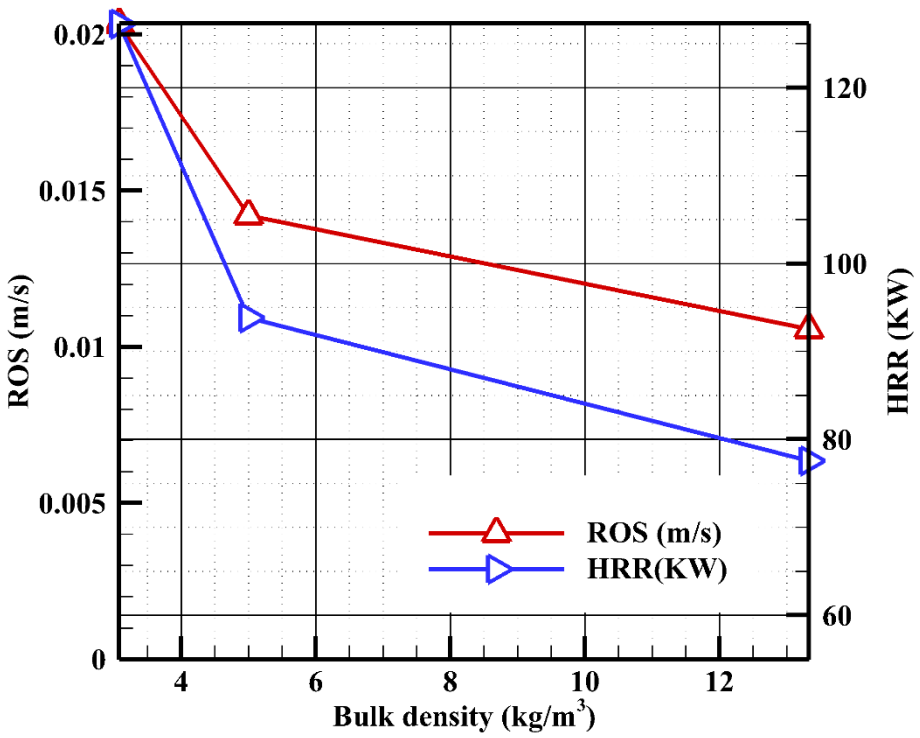

Figure 6- ROS and HRR variation in function of the bulk density for a constant fuel load evaluated experimentally for the excelsior

Figure 6 shows that the ROS and the HRR decreases with the increase of the packing ratio. In fact, this result can be explained by the fact that the packing ratio increased, the porosity of the fuel bed decreases therefore the inlet of the oxygen inside of the fuel bed also decreases. In another hand the increase of the packing ratio decreases the extinction length and therefore the total depth of the vegetation participating to the fire front propagation which explains the decrease of the HRR.

5. Conclusion

The effect of the bulk density on fire behavior is related directly to the fuel bed height and to the fuel load. For this reason, three different cases were evaluated numerically and experimentally:

(a) variable fuel load with a constant bulk density: the rate of spread increases with the fuel load or height until a specific value where it becomes independent of it; or the fire intensity increases with the increase of the fuel load.

(b) variable fuel load and variable bulk density: with a constant fuel bed height, the rate of spread is barely dependent of the fuel load or the bulk density, However the fire intensity increases with fuel load.

(c) variable bulk density with a constant fuel load: the rate of spread reaches a maximum value for an optimal packing ratio depending on the surface to volume ratio of the vegetation; the same tendency was found for the fire intensity.

Abstract

Wildfires are a growing threat, especially in Mediterranean climate areas during periods of drought. Wildfire research community continues to investigate propagation mechanisms on a large scale considering the thermal and fluid mechanics effects, or the main fire emissions (CO, CO2, H2O, H2, CH4). However, research on the effect of abiotic stresses on the plant emission during wildfires remains lacking, despite the fact that Mediterranean are considered important volatile essence emitting and storing species. This article addresses the effect of combined hydric and thermal stresses on physiology and emissions of two important Mediterranean shrub species; Rosmarinus officinalis and Cistus albidus that are largely consumed in wildfires. Different levels of hydric stress were applied on plants of the two species in a greenhouse. Thermal stress was executed by placing the water stressed plants inside a hermetic enclosure equipped with a radiant panel of maximal radiant heat flux of 84kW.m-2 and a fire-resistant glazed window for visualisation. The gaseous emissions of the plants under thermal stresses were collected and analysed by two complementary devices: an instantaneous gas analyser for CO, CO2, H2 and CH4, and adsorbent tubes by using the techniques of adsorption and desorption (by pyrolysis) for emission collection and analyses, respectively. Simultaneous pyrolyses experiments were realised on a foliar scale of the water stressed plants. Gases of pyrolyses separated with gas chromatography and identified using mass spectrometry. The heating tests showed a good reproducibility for pyrolyses of leaf samples and interesting variations between the monoterpene emissions of stressed and unstressed plants. At plant scale, number of tests for each plant species at a given hydric stress level were insufficient to give trends and strong results because of some imposed technical problems and the constraints of public health crisis. However, these tests allowed us to adapt experimental protocols and devices for further testing such as: plant location and fixation, heat flux ramp, sampling location, use of adsorbent tubes, hydric stress duration and normalisation of measured concentrations according to the plant size.

1. Context and objectives

1.1. Context

Wildfires are a growing issue, especially in Mediterranean climate areas during periods of drought where more and more uncontrollable fires are observed such as: megafires, too large and strong to be confined, and eruptive fires, too fast and unpredictable to be able to fight. These last years have been particularly disastrous with worldwide mediatised megafires (Fernando et al. 2022). As to eruptive fires, these are sudden and impressive wildfire accelerations occurring without wind, or moderate one, which have already caused more than 150 fatalities so far [2-8], mainly among firefighters involved in the extinguishing operations.

According to Schneider et al. (2021) "there is a strong need to increase the basic understanding of the propagation mechanisms of wildfires to improve the scientific tools needed for firefighting and fire prevention". Classical propagation of a wildfire is mainly due to two correlated mechanisms: important heat transfers

(energy) and formation of flammable mixtures ahead of the fire front (gases). Heat is transmitted principally by thermal radiation and convection. Flammable mixtures are formed from the only available fuel (vegetation) while it is heated, pyrolysed, and burnt. Wildfire research community continues investigating propagation mechanisms of the fire front such as thermal radiation (Frangieh et al. 2020) or buoyant flame dynamics (Finney et al. 2015). Research on eruptive fires issue are also focusing on airflow considerations (Viegas et al. 2009, Chatelon et al. 2014) such as induced wind, flame attachment, inclination angle, etc. Mentioned studies on wildfire propagation take into account large scale mechanisms such as thermal and fluid mechanics ones, or take into account the main chemical compounds resulting from degradation and combustion (CO, CO_2, H_2O, H_2, CH_4). However, there is a lack of investigation on the role of plants (Fernando et al. 2022) and the large range of molecules released during wildfires at the fire front knowing that Mediterranean plants are particularly rich in volatile essences (Owen et al. 2001). Hydric and thermal stresses have been studied independently showing influence on plant emissions (Barboni 2006, Chetehouna et al. 2014, Ormeño et al. 2007, Lavoir 2010, Ciccioli et al. 2014, Courty et al. 2014, Lemoine et al. 2013) but to our knowledge there is no study on combination of these wildfire stresses. This project intends to better understand the biological and thermochemical aspects of wildfire propagation taking into account a wider range of molecules involved in it and the role of two combined wildfire stresses.

1.2. Objectives

Experiments consisted of submitting two plant species (*Rosmarinus officinalis* and *Cistus albidus*) to different levels of hydric stress first, and then to a thermal stress similar than the one of the arrival of a wildfire. During these tests, we studied plant behaviour by analysing their physiology and their emissions (composition and concentration) at leaf and plant scale.

1.3. Team and funding

This study was conducted in the mark of Rawaa Jamaladdeen's thesis from P' Institute and in collaboration with Associate Professor Fabienne Dédaldéchamp from the laboratory EBI (Ecology and Biology of Interactions, SEVE team) and Engineer Researcher Laurent Lemée from IC2MP (Institute of Chemistry of Environments and Materials of Poitiers), as part of two Master internship grants from Labex Interactifs (Ms. Kenza Ait Ali Yahia) and EUR-InTREE which is a new training about Interfaces from a physico-chemical aspect in Poitiers (M. Axel Rigoulet), and a grant from P' Institute.

Associate Professor Fabienne Dédaldéchamp brought her expertise in biology [17] during plant conditioning to hydric stress and plant physiology analyses and issues. We co-supervised with her and Rawaa Jamaladdeen Ms. Kenza Ait Ali Yahia, a second year Master student in Green Chemistry, Catalysis and Environment (CVCE, University of Poitiers). She helped us during hydric stress conditioning, physiology analyses at EBI laboratory and thermal stress tests at P' Institute. Engineer Researcher Laurent Lemée brought his chemistry expertise for accurate chemical analyses by thermodesorption of adsorbent tubes. We co-supervised Mrs. Axel Rigoulet a first year Master student (EUR-CVCE). He helped us on leaf pyrolyses and adsorbent tubes analyses at IC2MP.

2. Material and methods

2.1. Plant conditioning to hydric stress

For this part, we benefitted from the greenhouse equipment of EBI laboratory. *Rosmarinus officinalis* and *Cistus albidus* were chosen to be Mediterranean plants typically concerned by documented eruptive fires (Courty et al. 2014) but also to be physiologically different (Ormeño et al 2007). 20 plants of each species were correctly watered, 20 others were submitted to hydric stress. The end of the hydric stress was decided according to physiology analyses made in EBI laboratory to keep plants alive for heating tests: plant soil moisture, leaf water amount and chlorophyll concentration. Hydric stress conditioning required about two to three weeks depending on the weather (sunny/cloudy, humid/dry). Other microscopic and macroscopic analyses were done to get more data on the influence of hydric stress. Analysed parameters included stomatal conductance, osmotic pressure and water status of leaves which are directly related to the plant emissions (Ormeño et al 2007, Lavoir 2010). Pictures of the plants were done and analysed with image based software in order to normalise emission quantification according to plant sizes during thermal tests. For each of the two species, we got physiological

observations during hydric stress and a normalisation method for emission quantification according to plant size.

Watered and non-watered plants were then submitted to thermal stress (cf. below).

2.2. Heating tests at plant scale

2.2.1. Material

For this part, we benefitted from a compartment of 1 m^3 equipped with a radiant panel lent by PRISME laboratory (Fig. 1). The latter can provide a maximum of 84 $kW.m^{-2}$ of radiative flux and is made with a fire resistant glazed window for plant surveillance. It was instrumented with thermocouples, fluxmeters and a cooled scale (Fig. 1 left).

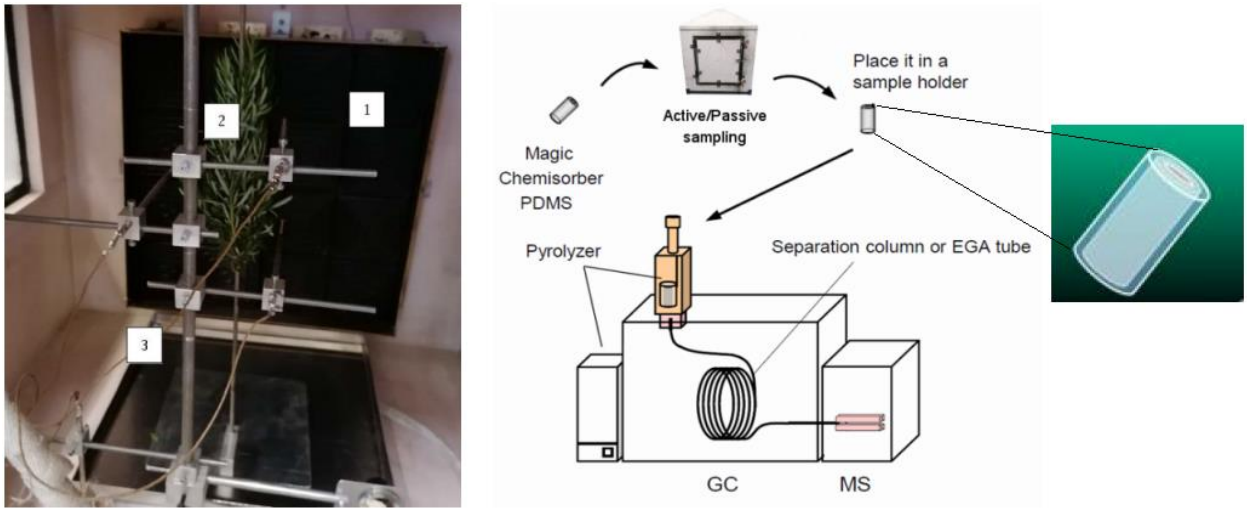

Fig. 1. On the left: photograph of Rosmarinus plant (2) submitted to thermal stress inside a 1m³ compartment equipped with radiant panel (1) and lent by PRISME laboratory (Bourges). On the right: method of analysis with adsorbent tubes

Two complementary gas analysis devices were used during tests: a mobile analyser introduced from the top of the compartment to quantify continuously O_2, CO, CO_2, H_2 and CH_4; and adsorbent tubes to identify VOCs (Volatile Organic Compounds) by trapping them *in-situ*. Trapped compounds were identified by TD-GC-MS (Fig. 1 right), i.e. they were thermally desorbed (TD), separated with gas chromatography (GC) and identified using mass spectrometry (MS). The pyrolysis products were identified by comparison of their mass spectra with NIST (National Institute of Standards and Technology) mass spectral library and thanks to their retention times. The adsorbent tubes, also known as SPEE (solid phase extraction elements), are titanium tubes coated with polydimethylsiloxane (PDMS). For each test, an adsorbent tube was placed into the heating compartment at the ground level and another one was placed inside an active sampling composed from a pump and a flexible connecting the pump to the compartment. It allowed us to compare the gas composition at different heights knowing that density is very variable between e.g. isoprene and sesquiterpenes.

2.2.2. Protocol

At the end of hydric stress conditioning, plants were retrieved from the greenhouse and introduced one by one inside the compartment. Plants were cut at their basis and depending on their size, one, or two superimposed plants, were attached to a stand close to the radiant panel (see Fig. 1 left). Consequently to preliminary tests, we chose to impose a temperature/heat flux ramp of 30 minutes not to exceed 200°C at the plant level in order to avoid hemicellulose degradation and study only vegetation emissions. After each heating test, we retrieved data of temperature, heat flux, light gases concentration over time (continuous analyser), and the two adsorbent tubes for analyses by TD-GC-MS desorb, separate, identify and quantify the VOC emission. Thermodesorption of of adsorbed compounds was performed from 150°C to 280°C with a heating rate of 500°C/min and 1 min at final temperature.

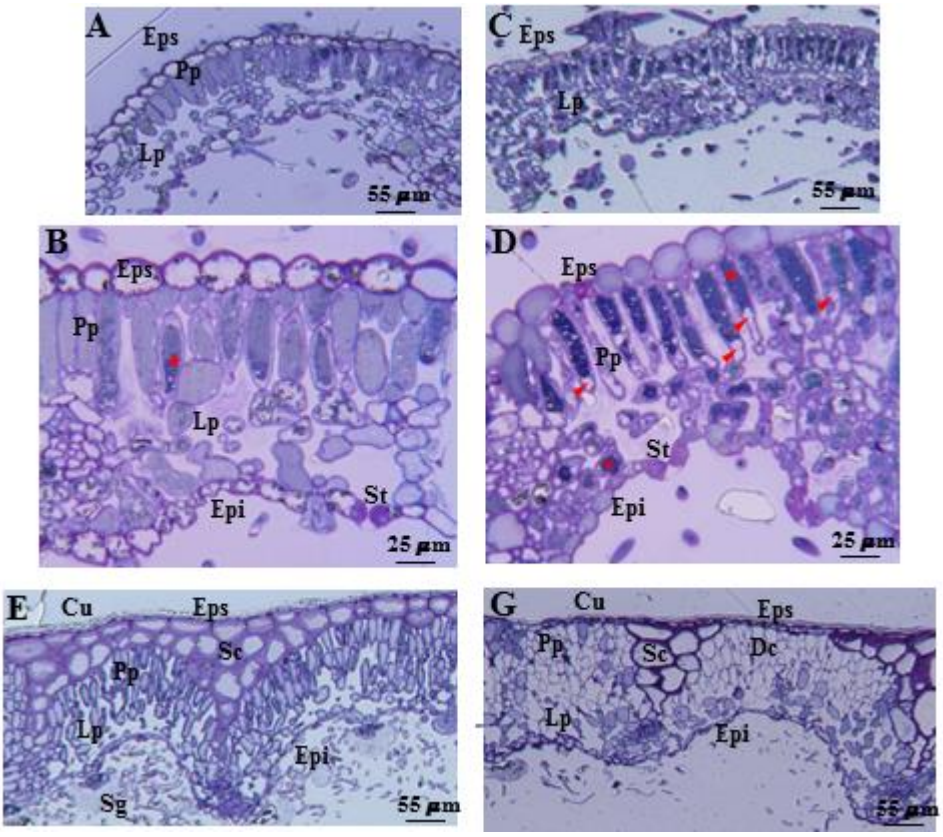
2.3. Heating tests at leaf scale

Leaf samples were cut from plants during the hydric stress conditioning and pyrolysed at IC2MP. The pyrolyser was a Multi-shot Pyrolyzer EGA/PY-3030-D which was coupled with a GCMS-QP2010 Ultra Gas Chromatograph-Mass spectrometer. The pyrolysis products were carried by a helium gas flow to the GC column and separated on a TR5-MS capillary column (dimensions: 30.0 m, 0.25 mm i.D, 0.25 µm phase thickness). The injector was a split/splitless. The MS device was a quadrupole analyser, the ionization mode was electron impact (70 eV).

Around 15 mg of not lyophilized leaves (equivalent to one rosemary leaf or a piece of cistus leaf) were placed into an inox cup and the pyrolysis was carried out in the isothermal mode at 180°C (temperature of maximal emissions of plants (Barboni 2006, Chetehouna et al. 2014, Courty et al. 2014) for 1 minute. When cut leaves needed to be stored for later experiments, they were conserved inside glass tubes covered with aluminium foil in a freezer at a temperature of -21±1°C.

3. Results

The physiological analyses show clearly the influence of the hydric stress at microscopic scale (Fig. 2) with a decrease in vacuole volume and an increase in secondary metabolite synthesis for stressed plants. For *Rosmarinus officinalis*, we also observed dead cells (Dc) (Fig. 2.d) indicating that hydric stress was worse than for *Cistus albidus*. The heating tests showed a good reproducibility for pyrolyses of leaf samples and interesting variations between stressed and unstressed plants regarding monoterpenes and fatty acids (Fig. 3). At plant scale, number of tests for each plant species at a given hydric stress level were insufficient to give trends and strong results because of technical problems, sanitary restrictions and specificity of each plant. However these tests allowed us to adapt experimental protocols and devices for further testing such as: plant location and fixation, heat flux ramp, sampling location, use of adsorbent tubes, hydric stress duration and normalisation of measured concentrations according to the plant size.



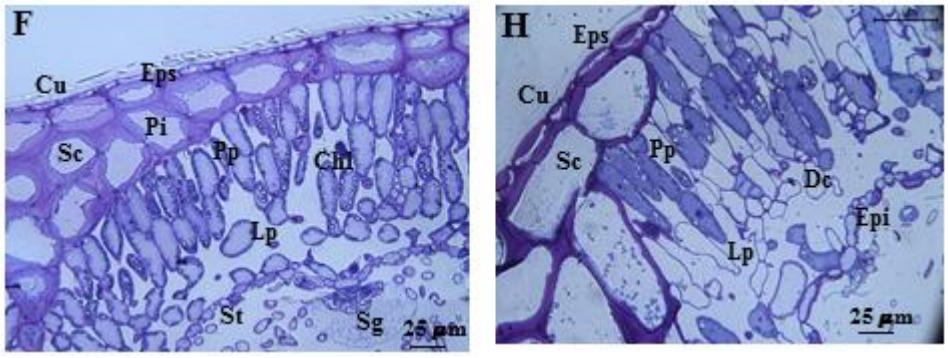


Figure 2: Cross section of Cistus albidus (A,B,C,D) and Rosmarinus officinalis (E,F,G,H) leaves, Plants growing condition: well-watered (A,B,E,F) and without water supply for 16 days (C,D,G,H). Abstract

The fuel flammability, combustibility, and fire spread properties depend on several parameters, such as the heat flux, moisture content, wind, and the fuel load. Flammable ignition occurs when the emitted organic volatile components flow mixed with air reaches a minimum rate corresponding to the lower flammability limit. The gas flow of these components depends on the fuel quantity (load) and its temperature. Therefore, ignition time depends on the fuel load.

In this work, the effect of the load on ignition time of live *Pinus Halepensis* needles is investigated using a cone calorimeter (providing three incident heat flux intensities). The average fuel moisture content is around 50% on a wet basis. Ignition time exhibits an exponential trend for all the incident heat flux intensities considered with a correlation coefficient $R^2 > 0.96$. The exponent corresponds to a characteristic load $\bar{m}_0$ around 1 kg/m^2 slightly dependent on the incident flux within statistical errors. For very small loads compared to $\bar{m}_0$ ignition time is nearly independent of the load because the time required for water evaporation is neglected compared to that required for a volatile mixture with air to reach the lower flammability limit. For larger loads (in the range of 0.38 kg/m^2 to 1.27 kg/m^2), the time required for water evaporation introduces a shift in ignition time which increases linearly with the load. Finally, for large loads compared to $\bar{m}_0$, the fuel bed thickness becomes larger than the optical length, and only its top layer is heated, transmitting thus heat to the internal layers by conduction. Therefore, the internal layers evaporate water and cool the upper one, leading to the exponential ignition time with the load. For dry fuels, ignition time appears independent of the load.

1. Introduction

Fires are considered in ecology as one of the most important and traumatic disturbances. Mediterranean ecosystems are particularly sensitive to conditions favoring fires: repeated climatic droughts, strong and frequent winds, accumulation of combustible biomass resulting from forest plantations, the abundance of rural areas, and the low exploitation of the forest (Di Castri, 1981). During the period from 1985 to 2006, a total burned area of 779,872.11 ha was recorded for 32,354 fires. *Pinus Halepensis* and *Cork Oak* forests fuels paid the heaviest price. Based on these statistics, we choose to study *Pinus Halepensis* needles. Ignition conditions depend on several parameters such as the heat flux, water content, wind, load, etc. Regarding the first parameter, there is a critical heat flux for flammability (Terrah et al, 2018; Sabi et al, 2018; Mindykowski et al, 2008). Concerning the second parameter, it has recently been shown that there is no critical water content for flammability, but for each moisture, there is a sufficient heat flow to allow ignition (Terrah et al, 2018). During the exposition of the fuel to a heat source, its temperature rises, and flammable volatiles is emitted and mixed with air. The composition of gas in the air increases with temperature and reaches a critical concentration allowing ignition under a critical temperature. The time for gas flow to reach the critical composition (lower flammability limit depends also on the load). Ignition time dependence on the load is investigated here for different incident flux intensities.

2. Heat transfer and experimental setup

The *Pinus Halpensis* needles with an average moisture content of 50% (on a wet basis) are harvested the same day to ensure their live character. The sample is placed in a cylindrical holder with a diameter of $0.1\ m$, and exposed to thermal radiation flows ranging from 10 to 21 kW/m^2 provided by a cone calorimeter (Fig.1a) equipped with an electrical resistance of 3000W. The calibration of the heat flux is realized by using a heat flux sensor Hukseflux SBG01 working in the range from 0 to 200 kW/m^2. The desired heat flux intensities are obtained by varying the distance between the sample and the cone calorimeter (Fig.1b). Vegetation ignition is controlled by a pilot flame located 1cm above the sample. Ignition is considered successful if the flame persists for a time longer than 4s, and ignition time is recorded.

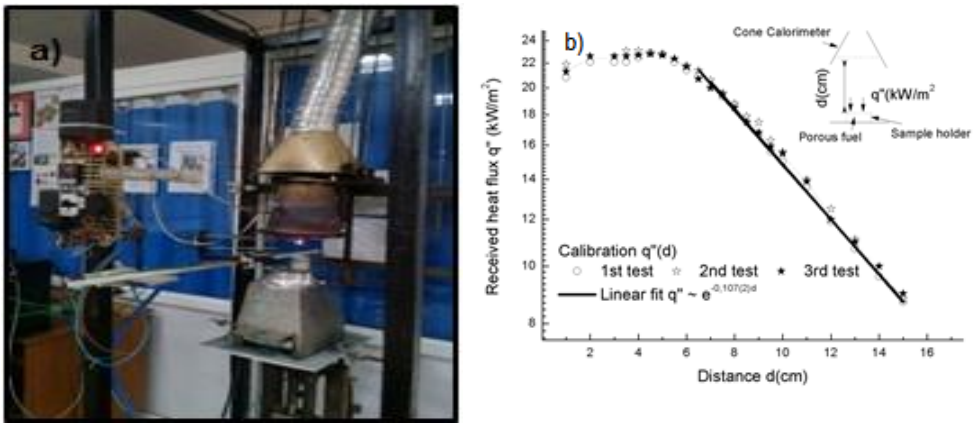

Figure1: a) the experimental setup, b) a schematic representation of the heat flux calibration

The net absorbed heat flux by the fuel $q"_{net}$ is related to the absorbed incident heat flux and that lost by the fuel bed. Neglecting conduction heat transfer, the net heat flux reads:

$$q"_{net} = aq"_{inc} - h(T - T_0) + \sigma\varepsilon\left(T^4 - {T_0}^4\right) \quad (1)$$

Here h is the convection coefficient, σ is the Stefan Boltzmann constant, ε is the emissivity of the fuel, and T_0 the ambient temperature. The samples were prepared with caution to keep similar arrangements of the species as far as possible. As the fuel bed is porous, the heat transfer mechanism involves the packing ratio φ which measures the average volume proportion of fuel in the sample:

$$\varphi = \frac{4\,m}{S \times e \times \rho} \quad (2)$$

Where m is the sample mass, S its surface, e its thickness, and $\boldsymbol{\rho}$ the particle density. The porosity (proportion of air in the bed) is directly related to the packing ratio $(1 - \varphi)$. The surface-to-volume ratio SVR was also found to influence the ignition and combustion properties of the fuel bed (Schemel et al, 2008; Santoni et al, 2014). Flammability properties might be influenced by the optical length δ of radiation that corresponds to the extinction coefficient defined as CFR (1981):

$$\frac{1}{\delta} = \frac{\varphi \times SVR}{4} \quad (3)$$

This quantity is an important optical parameter of porous material, and allows the determination of the absorption probability a, which is related to the thickness e as Callister & Rethwisch (2914):

$$a\ \alpha\left(1 - e^{-e/\delta}\right) \quad (4)$$

The replacing (2) in (3), this quantity is related to the fuel load ($\bar{m} = m/S$) as:

$$\frac{e}{\delta} = \bar{m}\frac{SVR}{\rho} \quad (5)$$

Since the fuel considered is the same (same $\boldsymbol{SVR}$ and density), ignition time (t_{ign}) is related to the load $\bar{\boldsymbol{m}}$.

3. Results and discussion

Fig.2 shows the variations of ignition time with the load $\bar{m}$ for three heat flux intensities ($17\ kW/m^2$, $13.83\ kW/m^2$, and $10.93\ kW/m^2$). The load is changed by varying the mass of the fuel bed, the area S of the sample holder being constant. Note here that the depth of the fuel bed may change from one sample to another depending on the packing ratio from equation (2). From (5) the fuel bed thickness (e) varies linearly with the optical length (δ) for the same load. From this figure (presented on the semi-logarithmic scale) ignition time seems to increase exponentially with the load for all the heat flux intensities considered with a correlation coefficient larger than 0.96 as:

$$\left(t_{ign} \propto e^{\bar{m}/\bar{m}_0}\right) \tag{6}$$

The growth exponents determined from the fitting slopes in Fig.2, correspond to characteristic loads $\bar{m}_0$. The exponential trend appearing in Fig.2 involves a characteristic quantity as in other fields (like the relaxation time in charge or discharge of a condenser). The characteristic load seems to depend only slightly on the incident heat flux: $\bar{m}_0 \approx 1.05 \pm 0.05\ kg/m^2$ for an incident heat flux of $17\ kW/m^2$, $0.99 \pm 0.03\ kg/m^2$ for $13.83\ kW/m^2$ and $1.14 \pm 0.02\ kg/m^2$ for $10.93\ kW/m^2$). For small loads ($\bar{m} \ll \bar{m}_0$) ignition time is nearly constant. Indeed, as the load is sufficiently small, the whole surface of the sample will be heated at the same time, and the time for water to be evaporated is neglected compared to that of volatiles and their mixture with air to reach the lower flammability limit. For loads in the range $0.38 < \bar{m} < 1.27\ kg/m^2$ (i.e close to $\bar{m}_0$) ignition time increases linearly with the load (the time of water evaporation induces a delay before ignition).

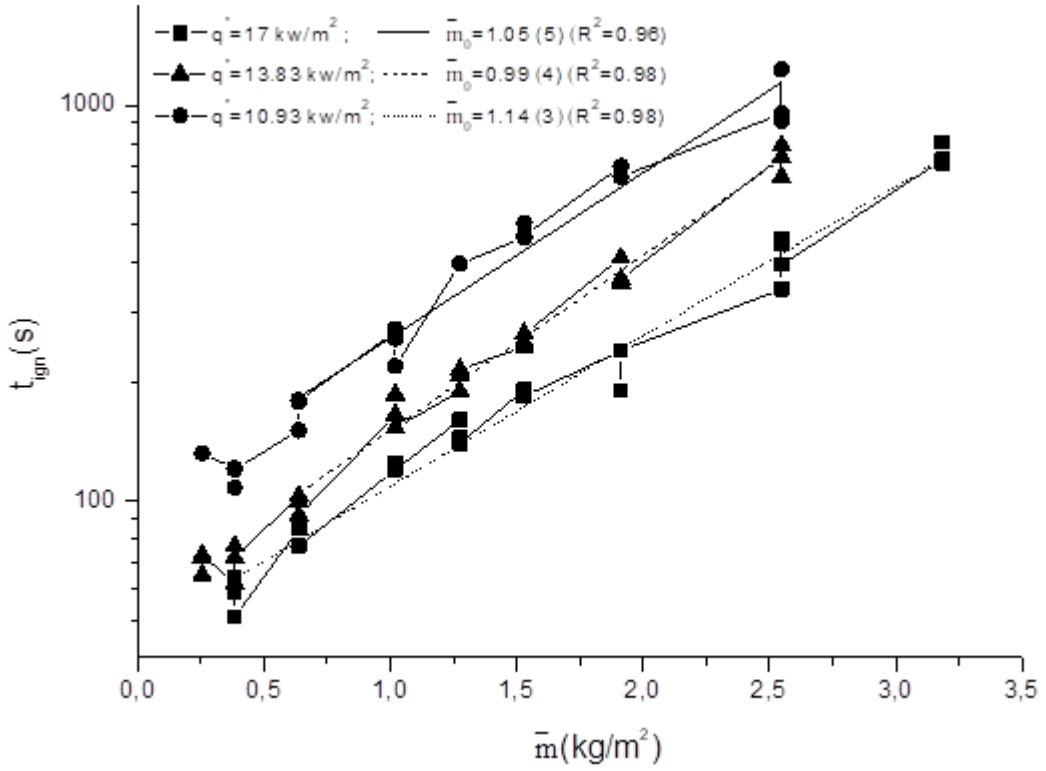

Figure2: Variation of ignition times vs. the load ($\bar{m}$) for the three different heat flux intensities: 17 kW/m², 13.83 kW/m² and 10,93 kW/m². The lines represent the exponential fits, and the characteristic loads are estimated from the fit slopes.

For larger loads ($\bar{m} > 1.27\ kg/m^2$) the trend of ignition time becomes exponential. The exponential trend is explained by the fact that the fuel bed thickness becomes much larger than the optical length, and the heat flow heats only the top layer of the fuel bed, which heats the internal layers by thermal conduction. The water evaporated from these inner layers cools the top layer which delays their ignition (Drysdale, 2011). This transition from a constant ignition time to an exponential increase with the fuel bed load can be explained by the transition from thermally thin to thermally thick fuel beds If the fuel bed itself is thermally thin, there is no temperature gradient, and all the water will be evaporated before ignition. If the fuel bed is thermally

thick, there is a temperature gradient so the deeper layers of fuel could still be cool enough to be evaporating water (and diluting the pyrolyzed). Hence, the characteristic load ($\overline{m}_0$) corresponds to a crossover fuel bed thickness separating the thermally thin and thermally thick regions.

4. Conclusion

In this work, we studied experimentally the effect of the fuel load on ignition time using a cone calorimeter delivering three different heat flux intensities. An exponential trend of ignition time is observed for all heat fluxes, with the corresponding characteristic load of around 1 kg/m^2 slightly dependent on the heat flux. The exponential trend is explained for large loads ($\overline{m} > 1.27\ kg/m^2$) by a complex heat transfer process due to the large fuel bed, thickness compared to the optical length. Only a top layer of the sample is heated and heats the internal layers. Water evaporation of the inner layers cools the top layer and therefore delays ignition.

Innovative Fire Fighting Strategy

Joseph Perry

Private R&D Consultant. 15 Habanim st., Ramat-Hasharon, Israel, {josephperry@bezeqint.net}

Keywords

Fire Fighting "Tank", Fire Fighting Bombs, Firefighting robot, Advanced Firefighting Technology gun

Abstract

Recent developments in heavy weapon design can be applied to fighting forest fires since both situations involve hazardous environments that present a high risk of damage to physical assets and extreme danger to human participants.

In military applications, heavy armored or robotic systems are designed to match the task at hand. For example, tanks are used to break out a fortified area, robots are used to clear mines and obstacles, and aerial or artillery bombing precedes every ground attack. Similarly, the proposed Fire Fighting Tank & Robots (FFTR) and Fire Fighting Bombs (FFB) would be designed to meet the rough duty of forest fire suppression. The FFTR crew (4) will carry out their firefighting activity without leaving the vehicle, exactly like the crew of a main battle tank during a military operation.

The advantages of using a FFTR include: the ability of operating within the fire itself (FF robots), the ability to clear its own path or to create firebreaks, and continuous operation in cooperation with chemical airdrops or other firefighting techniques, without the need to withdraw or protect human firefighters.

Furthermore, the proposed FFTR concept includes a unique liquid fire-suppressant delivery system, a “gun” that applies liquid and gas mixing technology developed for use in rocket technology thus having a firefighting capability of almost 10 times that of conventional fireman's hose. The same technology of liquid and gas mixing is used with the FFB to intensify the aerial firefight eight folds as compared to present methods. This means that a medium category, low cost, firefighting aircraft (Air-Crane helicopter) will be practically converted into a super heavy category aircraft (747-400 Supertanker), which is very expensive and difficult to operate.

To shorten the R&D stage, existing components and technologies will be used.

1. Introduction

Recent developments in heavy weapon design can be applied to fighting forest fires since both situations involve hazardous environments that present a high risk of damage to physical assets and extreme danger to human participants. In military applications, heavy armored or robotic systems are designed to match the task at hand (Sapaty, 2015). For example, robots are used to clear mines and obstacles, and aerial or artillery bombing precedes every ground attack. Similarly, the proposed Fire Fighting "Tank" & Robots (FFTR) and Fire Fighting Bombs (FFB) would be designed to meet the rough duty of forest fire suppression. Furthermore, the proposed FFTR concept includes an Advanced Firefighting technology (AFT) gun (AFT, 2022) that applies liquid and gas mixing technology developed for use in rocket technology thus having a firefighting capability of almost 10 times that of conventional monitors.

The FFTR will be operated by a crew of 4 firefighters: the commanding officer, the driver and two FF robots operators. The advantages of using a FFTR include: the ability of operating within the fire itself (FF robots), the ability to clear its own path or to create firebreaks, and continuous operation in cooperation with chemical airdrops or other firefighting techniques, without the need to withdraw or protect human firefighters.

To retard wildland fires, fire-retarding material is typically dropped into, or in front of the advancing fire from aircraft such as helicopters or airplanes. To be effective, the conventional Aerial Firefighting dropping must be performed from an altitude no higher than 60 m above the treetops (Lovellette, 2000). But such low flights are extremely difficult and dangerous, particularly at night. The FFB will be dropped from any appropriate altitude and be activated at the most effective distance above the fire.

The basic Fire Fighting Bomb structure will be similar to the conventional aerial bomb. The explosive fill will be replaced by a solid propellant (Sodium-azide) and a bulk of water. The heavy high fragmentation steel body

will be replaced by biodegradable material or aluminum shell. Once the requisite threshold has been reached or exceeded, the FFB fuse ignites the solid propellant resulting in a gas bursts into the water tank that forces the bomb shell to open. The opened FFB will release a huge fire-retarding aerosol cone precisely at an optimal level above the fire, resulting in effective rapid extinguishing as compared to conventional methods. This means that a medium category, low cost, firefighting aircraft will be virtually converted into a super heavy category aircraft, which is very expensive and difficult to operate.

To shorten the R&D stage, existing components and technologies will be used.

2. Fire Fighting Tank & Robots (FFTR)

2.1. The FFTR system

The FFTR system (see Fig. 1) will include the following components:

- Firefighting vehicle
- AFT main gun
- Two firefighting robots
- Camera drone

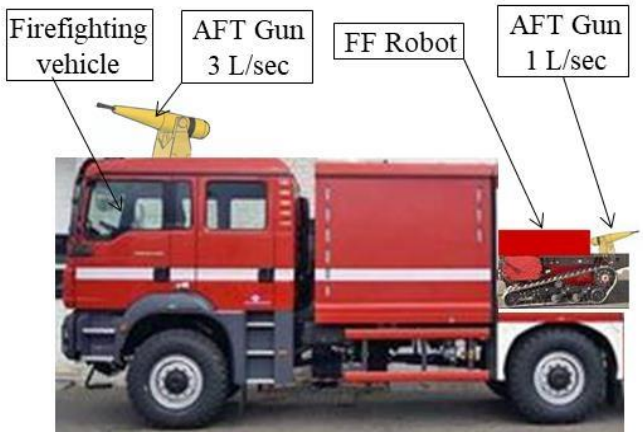

Fig. 1 Fire Fighting Tank & Robots (FFTR)

The FFTR will be operated by a crew of 4 firefighters: the commanding officer, the driver and two FF robots operators. The commanding officer will operate the main AFT gun and the camera drone.

2.2. Firefighting vehicle

The FFTR can be based on MAN TGM 4x4 fire truck, a Volvo FMX, a Mercedes Benz Actros and many other vehicles.

The chassis and the outer shape of the cabin will remain the original one, but all the other parts will be modified to fit the FFTR tasks.

The cabin interior will be fitted for the 4 crew members (instead of the original 6) and the rest of the space will be used for computers and control panels.

The cabin will be sealed against the chemical and biological contaminations and will have a Temperature and Humidity Control (THC) that maintains environmental conditions so that the firefighters can comfortably work in.

The estimated total FFTR weight will be 15000 kg (33070 lb.). Special design efforts will be made to develop a Rapid Deployment (RD) FFTR, weighting only 10,000 kg (22,050 lb.) that will be air transportable by helicopter.

2.3. The main AFT gun

The major innovation of the FFTR firefighting system is based on the Advanced Firefighting technology (AFT) gun (see Fig. 2), which is based on rocket technology and its application to liquid and gas mixtures (AFT, 2022).

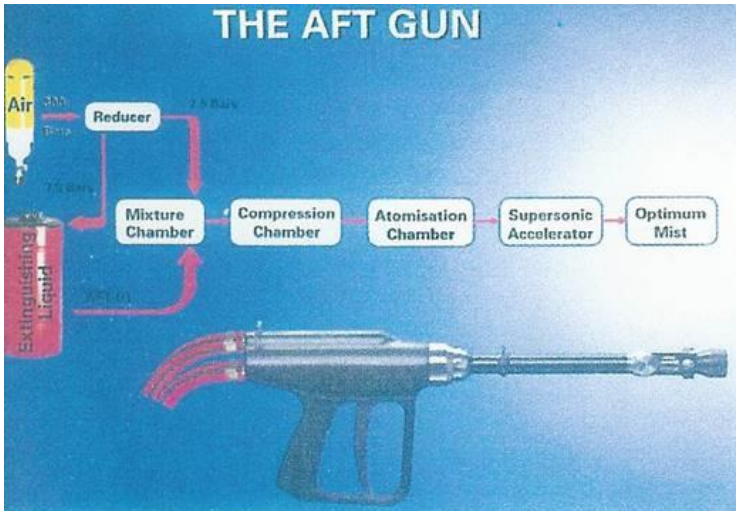

Fig. 2 The advanced firefighting gun

The AFT Gun technology creates a narrow distribution of an ultra-fine water mist (100-150 μm) that covers much larger surface area as compared to the conventional water monitor (almost 50 times). This results in rapid cooling of the burning area, due to extensive heat absorption by water evaporation. The combined effect of cooling and blanketing, results in effective rapid extinguishing of the fire. The AFT gun uses significantly less water (almost 10 times) as compared to conventional systems, hence reducing the total FFTR weight and extending time between resupplies.

The AFT gun generates a lot of steam that endangers the fire-fighters in their direct fire extinguishing actions. Operating from the protected FFTR and using the FF robots, solves this problem in a very effective way.

The roof mounted main AFT gun will be developed similar to the existing one, but with larger flow rate and lancing distance.

The main AFT gun will be mounted on a special, remotely controlled weapon station, similar to the medium caliber weapons installed on any type of military vehicles.

2.4. Firefighting robot

To shorten the R&D stage, an existing robotic platform can be used such as the TC800 FF Colossus, among others (see Fig. 3).

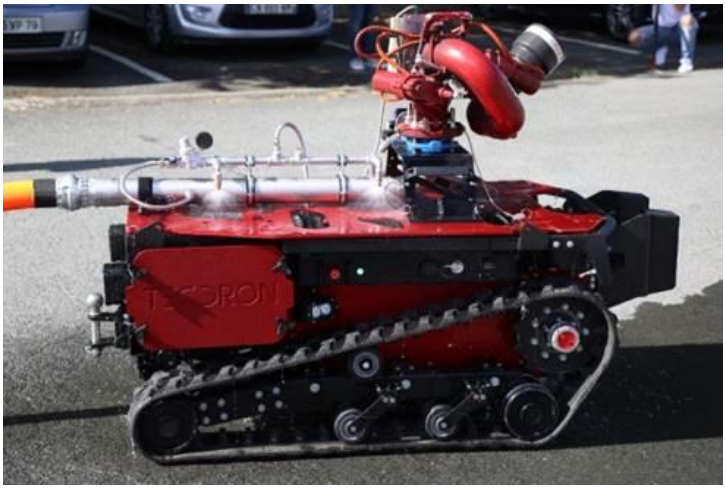

Fig. 3 Firefighting robot TC800 FF Colossus

TC800 FF is a remotely operated robot with autonomous navigation capabilities designed to assist fire-fighters during operations.

The FF robot's upper deck will be used for the installation of the existing AFT gun, a water tank and pump.

Most of the firefighting robots in development or being used today are tethered by a fire hose which supplies water, allowing continuous operation with a running time of 2-4 hours (see Fig. 4).

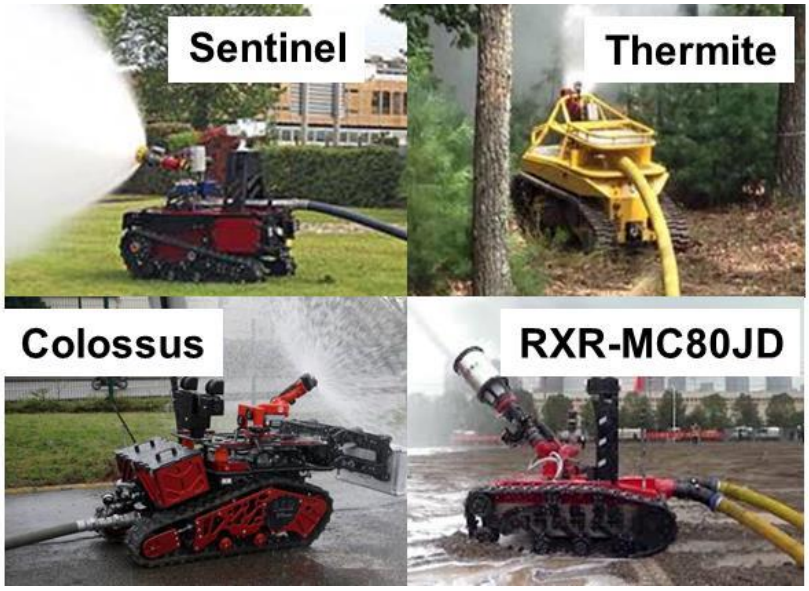

Fig. 4 Firefighting robots tethered by a fire hose

This heavy and relatively rigid hose disrupts the robot's maneuvering to overcome obstacles, especially in forested area.

One of the few water-autonomous firefighting robots is the MVF-5 U3 Multifunctional Remote Controlled Robotic System. It is equipped with 2500 l water tank but weights as much as 16000 kg and is very robust and slow.

The proposed firefighting robot will be equipped with AFT gun which uses significantly less water (almost 10 times) as compared to conventional systems. For example, the proposed robot equipped with 250 l will have the same firefighting capability as the MVF-5 U3 Robotic System but weighting only 1300 kg.

This unique quality enables the robot to be air-transportable taking its place immediately with the first attack, which is the most important to prevent fire expansion.

The FF robot will be equipped with special tools to cut trees and bushes for fire lane formation and FFTR's pass-way clearance similar to these installed on Russian Uran-6 (see Fig. 5).

Fig. 5 Uran-6 unmanned multifunctional demining system (Army 2021)

At the front of the Uran-6, there is one bulldozer blade and standard Flail tool, the heavy metal parts (chains and balls) of which will be replaced by a flexible part of the fire bat.

3. The Fire Fighting Bomb (FFB)

3.1. Hybrid Fire Extinguishing Systems (HFES)

Hybrid media is a combination of inert gas, typically nitrogen, and atomized water that creates an atmosphere that does not support combustion (Raia 2014). The inert gas is used to atomize the water into small, 250 µm (10 µinch) droplets. The atomized water droplets provide a large available surface area for heat absorption, and are easily converted to steam to provide cooling and oxygen dilution.

Fig. 6 Hybrid fire extinguishing nozzle discharging

The hybrid media discharge is regulated by nozzles operating at a controlled nitrogen pressure that controls the discharge rate. Water is delivered to each nozzle at a controlled flow rate, mixed with the nitrogen, and atomized into small droplets (see Fig. 6). The longer suspension time, and the nitrogen, makes Hybrid Fire Extinguishing Systems effective on concealed or shielded fires. In many instances, these fires would not be reached by larger droplets that tend to fall directly to the ground. The cooling effect of water mist takes place when the water mist droplets absorb the heat radiation from the fire. Nozzles discharge fine water mist at high velocity wetting the fuel and the area around the fire. The pressure employed in the water mist fire protection system is a key aspect in the fire extinguishing quality of water mist. Oxygen displacement happens at the heart of the fire when the water mist droplets turn into vapor and take oxygen from the fire.

The nitrogen is stored in high pressure canisters but can be also generated by Sodium-azide reaction. Sodium-azide is the gas-forming (nitrogen) component in many car airbag systems. Once the requisite threshold has been reached or exceeded, the airbag control unit will trigger the ignition of a gas generator propellant to rapidly inflate a fabric bag.

These beneficial water mist attributions were used for Fire-Fighting Bomb (FFB) development.

3.2. Fire Fighting Bombs (FFB)

The combination of climate changes and the expanding human development in the wildland-urban interface create devastating fires that are burning and spreading more quickly than they did 20 years ago. To retard those fires, fire-retarding material is typically dropped into, or in front of the advancing fire from aircraft such as helicopters or airplanes.

The basic Air Fire Fighting Bomb (AFFB) structure is depicted on figure 7.

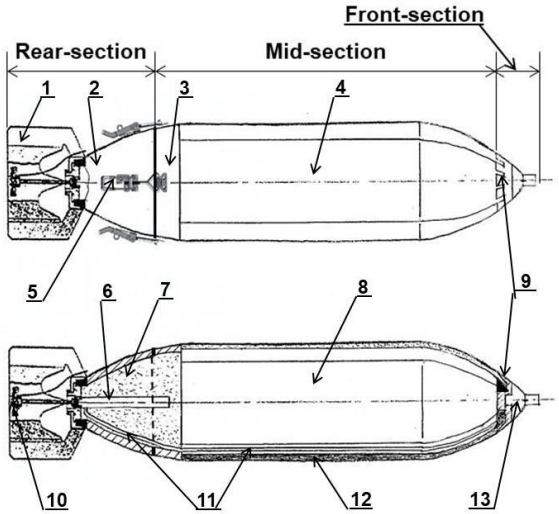

Fig. 7 The Fire Fighting Bomb basic structure

The explosive fill will be replaced by the Sodium-azide propellant and a bulk of water. The heavy high fragmentation steel body will be replaced by biodegradable or aluminum parts.

Once the required gas pressure is exceeded, the FFB case disintegrates, creating an ultra-fine water mist similar to the HFES nozzle (see Fig. 6). Exactly as the AFT technology this water mist will cover an enlarged surface area as compared to the conventional aerial firefighting resulting in effective rapid extinguishing using significantly less water as compared to conventional methods.

To be effective, the conventional Aerial Firefighting dropping must be performed from an altitude no higher than 60 m (200 ft.) above the treetops. But such low flights are extremely difficult and dangerous, particularly at night. Most of the aviation-related wild-land firefighting fatalities results from failure to maintain clearance from terrain, water, or objects. The FFB can be dropped from any appropriate altitude and be activated at the most effective distance above the fire (see Fig. 8). This will eliminate completely the aerosol losses and will increase the fire extinguishing efficiency. In case of unexploded FF bomb, there will be no human casualties due to the fact that FF robots will operate on the ground.

Fig. 8 FFBs opens on an optimal level above the fire

To demonstrate the FFB fire extinguishing efficiency we compare it to Erickson S-64 Air-Crane fire-fighting helicopter. The Air-crane can be fitted with a 2,650-gallon (~10,000 liter) retardant material tank to assist in the control of bush and forest fires.

Let's take as an example a 200 L (66 gallon) FF bomb. The estimated weight of the external body and the propellant will be approximately 50 kg (110 lb.), so the total weight will be 250 kg (551 lb.). The Erickson S-64 Air-Crane helicopter can carry 40 of such bombs at 10,000 kg (22,050 lb.) total weight.

The FFB efficiency will be similar to that of the AFT gun (10 times higher) but to be on a safe side, let us assume a lower value of 8. The outcome of this assumption is that the fire-fighting capability of 200 L FF bomb will be equal to 1600 L of the conventional water dropping. If we multiply this water volume by the FFB number (40) we get 64000 L, which is similar to water carrying capacity of 747-400 Supertanker.

This means that a medium category, low cost, firefighting aircraft has been virtually converted into a super heavy category aircraft, which is very expensive and difficult to operate.

Large-scale fires; fuel management; wildfire resilience; climate change adaptation; settlement protection.

Abstract

The 2021fire season in Greece was disastrous in terms of area burned (140,000 ha), from six large-scale events (>10,000 ha) and one mega-fire in Evia Island (46,000 ha). These fires burned under extreme drought conditions and paradoxically, with moderate to low wind speeds, mostly inside low elevation conifer forests (*Pinus halepensis*) and shrublands. The concurrent burst and propagation of several large-scale events lead, once again, to the collapse of the firefighting mechanism, like what happened during the 2007 fire season when more than 260,000 ha burned. As a result, wildfires of 2021 were extinguished only when they reached the sea (Evia) or previously burned areas (western Attica), with firefighting forces completely unable to successfully contain them for weeks. The large number of reinforcements from other countries helped the government officials to understand and clarify (after debriefing) that with the current firefighting operational philosophy of the Greek Fire Service, it is impossible to contain large-scale wildfires. They detected several issues, including the total dependence on airborne firefighting means (Greece had during 2021 one of the largest aerial fleets in Europe), the inability of firefighters to operate inside forested areas, the prohibition of backfires, the slow creation rates, or complete lack, of vegetation clearings for creating new fuel breaks during firefighting, and the lack of appropriately previously treated areas. This sparked a debate among political parties and the society of what can Greece do from now on to prevent future mega-fires that can have devastating economic effects not only to the local population (e.g., northern Evia, an island that has based its local economy to forest products and recreational tourism), but also to the country's economy (>4 billion euros in 2021). Another important issue is the environmental impact caused by the loss of forest carbon pools, soil loss and erosion, increased water runoff and degradation of the aesthetic quality, all having a long-lasting effect on the affected areas. The above lead the Greek Government to take a series of measures that were proposed, including legislation changes, administrative organization reforms and adaptation of firefighting operational tactics. A breakthrough is considered the re-creation of six special forest fire operation crews (a total of 500 people) following the standards of the US smokejumpers or hotshots' crews. These crews are foreseen to be allowed to use backfires, after a necessary planned legislation reform. Another important legislation change was the simplification of bureaucracy that will enable landowners outside city limits to easily perform mild fuel reduction operations inside their property, currently illegal without permission. Despite these changes, an important component of improved fire risk governance is still missing. Fuel reduction is applied at the wrong scale, with inappropriate treatment methods, without proper planning and measurable outcomes and to landscape parts that can hardly influence fire propagation and intensity. In this work, we provide the context and a set of proposals and measures for fuel management that we believe are missing and if applied, can enhance prevention, and improve the firefighting effectiveness, considering ecological, economic, and operational issues.

1. Introduction

The importance of forest management in mitigating large forest fires risk for the protection of human lives and the wildland-urban interface (WUI) is increasingly emphasized. It is a fact that Mediterranean climate regions experience an ever-increasing trend for creating new and/or expand existing human settlements inside or close to natural areas which, in turn, cause pressures on the environment with the introduction of alien to native vegetation species, deforestation and human activities in wildlife areas that increase the fire risk (Moreira et al. 2011). As a result, the mixing of natural and human systems has created densely populated landscapes with large amounts of fuel that will certainly be affected by difficult to suppress near-future large-scale wildfires. The combination of forest cover increase, reduction of the annual recoverable timber and the consequent

accumulation of dead and live biomass (Figure 1) indicates the need to increase the annually managed area to reduce the rate of spread and fire intensity in locations where wildfires can damage residential areas, cultural monuments, ecological sites and values, and ecosystem services.

Figure 1: Typical conditions of unmanaged low-elevation coniferous forests in Greece, having large quantity and continuity of dead and live fuels

The recent extreme wildfire season of 2021 has prompted forest management authorities and policy makers of Greece to reconsider the existing policies regarding fire risk governance. Of all the measures proposed and implemented so far by the Greek Government and other public agencies, the least emphasis has been given to the fuel reduction efforts and especially, how they should be applied to achieve a change in future fire behavior that can be utilized to improve the efficiency of firefighting. Recently, the Greek Government announced a 50-million-euro program that will fund fuel reduction and fire protection projects, but it is still unclear how these projects will be allocated on the landscape, what will be their size and arrangement, what forested ecosystems are eligible to receive these projects, what is their expected and measurable impact on the behavior of future wildfires, who will apply them and with what management methods.

With this work, we attempt to advice and guide the Greek Government's effort to plan and fund these projects and avoid pitfalls that will result in reduced effectiveness, rare or no encounter with future fires, and failure to protect settlements and other values-at-risk. In addition, we will start by describing the main lessons learned during and after the 2021 fire season and describe how they guided so far, and how they will, government efforts to improve fire risk governance and implement changes to established outdated forest (and fire) management policies of 50 years ago.

2. Lessons learned from forest fires of 2021

The most valuable lesson learned, especially for the cases when large-scale wildfires were approaching or burning inside the WUI, was that the existing firefighting tactics of waiting along the roadside, avoid getting into forested areas away from the road network, and spraying parts of the fire front or flanks with water, is a failed strategy. Not only it cannot contain or stop a typical raging large-scale wildfire with flame lengths of up to 50 m and spread rates of up to 10 km/h, but it keeps an important number of firefighting forces occupied to a lost cause. In addition, by giving emphasis to a passive and narrow scale strategy to protect homes and properties instead of an active that involves operational planning at a landscape level and inside forested areas, it gives space and time to the wildfire to escape or surpass the still suppression units. When this happens, firefighting forces start chasing the fire or desperately call for aerial support. The large dependence of ground

forces on aerial support to achieve alteration in fire behavior leads to requests that not only do not ensure airborne means are necessary but also are not in clear alignment with a wildfire's incident strategy and with agency and interagency general fire management goals and objectives (Stonesifer et al. 2021), increasing aircraft and personnel fatigue. As a result, the Greek Government decided to create a special firefighting unit with 500 persons divided into six crews, with training in the US to learn modern firefighting tactics, including the backfire technique (currently prohibited, but soon to be legalized).

Before the 2021 fire season, when homeowners and landowners wanted to protect their property from wildfires with preventive fuel treatments, they were required to either request a permission from the Urban Planning Agency, if their property was within urban area limits, or from the Greek Forest Service (GFS) if it was outside. For both cases, the owners were obliged to file a technical study with the trees that needed to be cut and then, after a time-consuming process (bureaucracy and corruption were the two reasons for multi-year delays in granting those permissions), get the permission; otherwise, they could have serious legal issues. Owners were reluctant to go through that process since it required both time and money and as a result, they let their property without any fuel treatment. The simplification of bureaucracy that enables landowners outside city limits to easily perform mild fuel reduction operations is an important legislation reform.

Finally, evacuation of settlements has become the mainstream policy of the Greek Civil Protection agencies. To avoid fatalities from wildfires approaching the WUI or urban boundaries, as was the case of the 2018 small scale event (1,300 ha) of Mati at the outskirts of Athens that killed more than 100 people, large-scale evacuations happen even in cases where there is low or no probability of the fire to enter the settlement.

3. How fuel treatments should be applied in Greece to improve their efficiency?

The three pillars for the suppression of large-scale wildfires are (Figure 2): 1) the combined suppression from ground forces and airborne means, 2) in areas with previously implemented fuel management, and 3) by applying passive fire suppression and indirect firefighting, such as the backfire technique. Prerequisite for the above is the existence of strategically allocated fuel treatment units, with adequate extent and treatment intensity. As the international experience shows, areas receiving fuel management must be able to drastically reduce the fire rate of spread even without fire suppression. To achieve this, a series of conditions must be met.

First, local government agencies have neither the planning expertise nor the technical skills to perform fuel treatments. We propose the entire fuel treatment funding to be transferred to the GFS, an agency with the necessary skills to accomplish this task, after a substantial increase from 25 million euros per year to at least 50 million euros. The GFS should oversee the application of the planned fuel treatments on all lands, even without the consent of the landowners. To allow this, a legislation reform is required. This is necessary because the fragmented landscape among multiple owners does not leave much space for consensus and collaboration; and as a result, the planned projects can be cancelled. The planning of project allocation should be done by considering (Palaiologou et al. 2021): a) the dominant weather patterns of each area, b) the vegetation and fuel conditions, c) the possibility of encountering a future wildfire, and d) their estimated impact on fire spread and intensity. This can be accomplished only if stochastic fire behavior modelling is applied. By simulating thousands of wildfires, we can account for different ignition locations and weather scenarios, and reveal hidden trends and patterns on the landscape from fires that have not happened yet but are highly possible to occur in the near future.

After the best candidate sites are found, it is necessary to consider the scale and arrangement of the applied projects and also, the fuel treatment methods applied to maximize their efficiency. Small scale or isolated projects should be avoided, and the treated area should be large enough to counter the scale of a large wildfire. Projects should form a network or create a protective "umbrella" around values-at-risk or settlements if this is the fuel treatment priority (Ager et al. 2013). One of the most important challenges for forest managers is to consider and decide between competing landscape management priorities, and such a challenge creates a complex spatial trade-off problem (Ager et al. 2017). Developing a broader set of forest management priorities tailored to specific areas should be based on fire regimes, human values, and land uses. Different arrangement and scale of fuel treatments and management methods are required when the priority is settlement protection vs. strategic containment vs. ecological restoration of forested ecosystems vs. timber production (Ager et al. 2013).

Regarding the fuel treatment methods, the combination of mechanical treatments, mostly thinning, pile burning, and grazing is a promising choice that does not require legislative reforms. Ideally, prescribed fire can further reduce implementation costs, but it is currently illegal. To avoid hazardous fuel accumulation, logging residuals should be either lopped and scattered or piled to be burned when conditions allow it. Also, pruning of trees that are left after thinning is suggested to break the continuity of the ladder fuels. Finally, the forests most in need to receive fuel treatments are the low elevation conifer forests (*Pinus halepensis* and *P. brutia*), especially those mixed with shrubs in the understory. In addition, cold tolerant species such as fir (*Abies* spp.) on higher elevations present an aggressive expansion against other forested ecosystems. Combined with climate alterations and severe droughts, these young coniferous forests present an ever-increasing fire risk. Fuel management is required there as well to restore the ecological balance (these ecosystems were intensively treated up to the 1980s with traditional agroforestry practices, including the use of fire to clean the forest understory).

Figure 2: Combined suppression from ground forces and airborne means near roads and fuel breaks

4. Conclusion

The main problem is that Greece perceives wildfires as a suppression problem rather than a forest management one. Instead of covering fire suppression with a "veil" of heroism that expects from the "heroes" to enter the fire like ancient warriors in battles, we propose the use of improved firefighting tactics and combine them with preventive forest management. Claims that the problem of mega-fires and their transmission into settlements will be solved by hiring more firefighters or by purchasing additional aerial firefighting equipment, unfortunately, do not recognize the nature and ecology of wildfires, nor are they aware of the latest scientific data. Wildfires are a complex problem and require the synergy of many actors, methodologies and practices to mitigate their dire effects, and only partially. It is considered *a priori* knowledge that there is no way to eliminate fires from the fire-adapted ecosystems of Greece, and they will continue to manifest no matter how many measures are taken. It is impossible to deal with each ignition, or with simultaneous high-intensity wildfires, regardless of how many firefighters and aircraft the country possesses. Therefore, fuel management with proper application is crucial to improve the chances of successful containment of large-scale wildfires.

North Euboea fire, property safety, self-protection

Abstract

The fire in North Euboea in August 2021 was burning continuously for two weeks and destroyed an area greater than fifty thousand hectares, Greece's biggest ever from a single fire. The response planning of the Greek Civil Protection and the public fire management mechanism urged for preventive evacuation even in cases the fire front was tens of kilometers away from the villages requested to be evacuated. This was dictated by the loss of hundred two people in the fire of Mati three years ago (2018). The locals criticize that the government's decision left firefighters without permission to fight the flames even in the case where lives weren't threatened. The ad-hoc reaction of the local rural population, who self-organized themselves and substituted the absence of the public fire services, saved several houses and properties that would be condemned to be burned due to the diehard evacuation planning. Analysis of the information gathered from local authorities and citizens who participated in these ad-hoc response teams proves the potential of involving the local population as first responders in large wildfires and fire emergencies in the wildland-urban interface and rural areas.

1. Introduction

Wildfires severely affect the communities and the properties developed in the wildland-urban interface (WUI). Thus, these communities, whose living is directly linked with the natural landscape and the surrounding forest, must become more resilient and proactive about fires. A sound way to achieve this is to develop a Fire-Adapted Community, meaning a community that can deal with a wildfire with little or no assistance from firefighters (Ingram, 2015).

Local communities can be adapted to wildfires in different ways. On many occasions, the response of the firefighting mechanism focuses strictly on protecting structures and houses, which allows a significant growth of the firefront, developing heat loads beyond any control and causing substantial human lives and property losses. On other occasions, social power, environmental resilience, and fire management can be combined to improve the situation (Marey-Perez et al., 2021; Moritz, M.A et al., 2014; Twidwell et al., 2019).

Fire spread by a combination of a moving firefront and airborne burning and glowing embers. Building losses during wildfires occur because of structure ignition and exposure due to embers (called firebrands), radiant heat, and direct flame contact. Embers are light enough to be blown through the air and can result in the rapid spread of wildfire by spotting (Quarles L.C. et al., 2010, CALFIRE,n.d.), in which case the embers are blown ahead of the active firefront, starting new fires). In the case of villages and settlements where the peripheral buildings create a wall to the rapid fire propagation, the structures in the perimeter are exposed to radiant heat and flame contact. There it is usually concentrated, the firefighting effort. However, spotting embers may travel, land, ignite vegetation or accumulated debris inside the village or settlement, or even enter the home or attic through openings or vents, igniting furnishing or combustible debris in those locations. The roof is considered the most vulnerable design element, and the construction material is a critical factor in the structure's resilience. Houses with wood or shingle roofs are at high risk of being destroyed during a wildfire. Vents create openings for flying embers, while windows often break even before the home is on fire due to the flames' heat. The presence of homeowners can prevent the ignition or extinguish spot fires that cross over the fire defense line at the initial

stage. This opportunity is lost in case a flat evacuation order is issued. The above is empirical knowledge broadly available in the communities thriving in mountainous areas and near the forest.

In Australia, the "Prepare, Stay and Defend or Leave Early" policy emphasizes that in the case of bushfires, it is often the safest option for people to remain in their homes in case they are caught in the path of a bushfire. They are thus protected from the radiant heat of the oncoming fire and can take measures to protect their homes from being destroyed by the fire. (Loh, 2007)

Recent major wildfire disasters in Europe reveal that government authorities and civil society, notably rural communities, are not sufficiently prepared and coordinated to prevent and reduce the risk of wildfires. Such coordination is necessary to defend local communities and rural assets at stake against the adverse direct and indirect impacts and consequences of wildfires.

A degree of self-government is a characteristic of many such communities, expressed in the form of rejection of interference from outside, represented by externally generated rules and regulations. This stems from the fact that the population in rural and working landscape areas has developed the ability to be sufficient in self-protecting their villages due to their lifestyle. These communities conceptualize trust differently as well. In some cases, they may have minimal political confidence in government agencies but relatively high social confidence in local authorities, volunteer groups, or their neighbors. (Billings,2021)

1.1. The North Euboea fire event

Fires are not uncommon in the pine forests of Euboea Island, but they swelled to massive proportions in the summer of 2021. Forests cover 23% of Evia, with 33% of this land burned (8% of the island's 'area) and approximately 10% of this area being agricultural land. The fire weather conditions were characterized by an extreme heatwave affecting Greece, Turkey, and the southern Balkan peninsula, lasting from the last days of July until the first ten days of August 2021. The heatwave was the worst recorded in the past 30 years.

The fire started in the afternoon of 03/08/202 and raged for two weeks, burning tens of thousands of hectares before it was contained and secured on the 17th of August. Despite low winds, due to the accumulated forest fuel loads developed because of the inadequate management in most of the forests in the area, flames wound their way up and down mountains and around villages, devouring one-third of the island's ' pine forests and olive groves. As a result, Evia's’ wildfire is the country's most significant ever single fire. The total burned area was 51245 ha, and the affected area comprised two municipalities: Istiaia-Aidipsos & Mantoudi-Limni-AgiaAnna.

The fire extensively consumed the area's primary production, including timber, honey, resin, olives, and figs, and destroyed several assets, infrastructures, and touristic investments. However, the fire's extent, the size of the burned area, the number of the burned houses (150), and the burning of their surroundings were limited.

The result is quite attractive since it was achieved despite the policy adopted in 2021 by the General Secretariat of Civil Protection and the Hellenic Fire Service to evacuate several villages consistently in the vicinity of an active fire. The purpose of this policy is to avoid fatalities at any expense. The emphasis on evacuation resulted from heated political clashes in the aftermath of the East Attica fire of July 23, 2018, in the settlements of Neos Voutzas and Mati, which had caused 102 fatalities (Xanthopoulos G., Athanasiou M., and K.Kaoukis, 2022).

Due to the previous fatal fire in Mati (2018), with a hundred two lives lost, the government prioritized evacuations over the preservation of land. This was partly successful since only two fire-related deaths were reported in Euboea. However, multiple reports show that this diehard decision of the government left firefighters without permission to fight the flames even in case human lives weren't explicitly in danger. The General Secretariat of Civil Protection gave frequent orders to evacuate villages via 112 service messages during the fire. However, many residents ignored the alerts and stayed in their villages to defend their homes and properties. Their decision limited the damages to the houses and structures and contributed to the effectiveness of response at the local scale during the fire.

Several people from the villages challenged by the flames of the Euboea fire and stayed to defend their town, when interviewed by the media, claimed that if they had evacuated their villages, as the civil protection recommended, everything would have been burnt down to ashes perhaps even two days sooner. (Frost-Euronews, 2021).

During the fire and after its suppression, many residents and local citizens criticized the government's ineffective and passive reaction, which they consider to be the main reason for the unprecedented disaster. They experienced a situation where instead of the public firefighting service, volunteer fire corps and locals who defied evacuation orders and remained behind, fighting the fires with tree branches, garden hoses, and any means they had to ferry water have saved hundreds of houses and thousands of hectares from being burned. (Schmitz- DW, 2021; Frost-Euronews, 2021)

2. Methodology

The methodology used for gathering information and processing data to extract relevant knowledge comprised of the following techniques:

- Desk-based research from public sources, news press, and electronic media, including websites, online videos, and social media.
- Earth Observation data during and after the fire, including satellite imagery and information from relative data services.
- Collection and analysis of UAV recordings from villages within the fire perimeter, having more than one house burned, and representing various types of landscape and vegetation forms and
- Extended field visits focused on collecting testimonial information and recital of events from more than 45 residents who experienced the fire crisis in their villages. Open-ended questions were used in an interview format also linked with contextual discussions. The information regarding the exposure of the burned houses, the features (vulnerabilities) of the surrounding environment, and the fire proneness of the landscape on the broader area was recorded on-site, post-processed, and analyzed.

In addition, information on fire behavior and propagation characteristics were collected based on the observations of the personnel from local authorities and volunteer firefighters who substituted the firefighting mechanism inside the villages during the fire.

The analysis aimed to gain, as extensively as possible, an understanding of the fire conditions to which the properties and their owners were exposed, the safety challenges they faced, and their assessment of the situation. Organizational prerequisites, societal and solidarity aspects, good practices for self-protection, and interaction with the local authorities were elaborated with the residents of the villages in the context of locally organized open discussions.

3. Results

The local population of the North Euboea's villages is familiar with living in a forest and agricultural region and forest fires. Due to their professional activity and relation with the forest and rural environment, they have local knowledge of the forest. They have the skills required for addressing an active fire situation. They own and can use agricultural machinery, pumps, small tanks, etc., which help protect properties and infrastructure without public services. The protection of the houses was facilitated by the fact that most of the dwellings and structures in the area were made of concrete, although they may also have some wooden elements. The information analysis showed that several isolated properties (mainly villas or farms) exist in the vicinity or inside the forest in this type of rural landscape. The mainland areas fall in the classic Mediterranean villages, with dense construction elements developed around a central "village square." The outer area of these villages is surrounded by pine forests (Pinus brutia) and patches of olive trees. In the coastal areas of the North Euboea, like in most of the touristic regions in Greece, the WUI is similar but has a linear than circular development with the forest surrounding the built part from one side.

Based on the information gathered, the damage caused by the fire around many settlements and other points of economic activity (e.g., orchards with houses or other buildings, farms, etc.) was limited compared to the fire consequences to their surroundings (Figure 1). This mainly concerns settlements and places reached by the fire after the second day. In this case, the residents had the time to organize themselves and respond to the fire almost exclusively on their own.

In most cases, especially after the second day, the residents did not follow the warnings and prompts for evacuating their places and were self-organized, deciding to remain in their villages. This spontaneous reaction, supported by the capabilities of the rural population, led to saving many houses and properties. Self-organization in ad-hoc groups of volunteers and solidarity with neighbors' property was proven the critical success factor for protecting homes and properties.

Several houses were protected this way by these self-organized ad-hoc citizen groups. As a result, they experienced no damage, even if placed in the middle of burning dense and high vegetation. On the contrary, uninhabited or evacuated houses within the boundaries of the settlements or located in remote forest areas suffered significant damage (Figure 2).

For safety reasons, camps and touristic resorts inside the forest were evacuated immediately following the official warning for an urgent evacuation order. All assets falling in this category were utterly burned down to ashes.

Figure 1. Houses with minor damages due to the construction material and existence of defensible space

Figure 2. Houses with significant damage due to pure or aged construction materials

4. Discussion

The involvement of local communities in forest fire management, the use of their skills, and capabilities, such as the contribution of their resources to protect properties and infrastructures in the absence of public civil protection services, need to be considered within the wildfire management organization. However, this can be

an efficient strategy, particularly in the case of villages and settlements whose populations thrive and work in the forest.

Homeowners and the local populations are the first responders and the critical stakeholders for addressing the lack or the inefficiency of the public firefighting and civil protection organization. In light of the ongoing climate change and global warming, it is imperative to invest in the knowledge, skills, and capabilities of the local communities, as a complementary resource, in managing large-scale wildfire events. Civil protection organizations must integrate the local society into the fire management cycle by exploiting all existing capabilities and human resources in holistic fire protection and resilience plan.

Moreover, wildfire management regarding the security and protection of local communities needs to be addressed mainly at the local level. The community needs to be prepared and ready before the fire occurrence to manage the fire threat efficiently and effectively. Adequate maps per community/settlement need to be developed, prioritizing the protection need of the municipalities in the broader region. Assets at risk, location of vulnerable populations, and in-place sheltering possibilities need to be identified and communicated to the community and local authorities. Self-protection of villages entails the preparation of simple plans depicting who will stay on-site in case an evacuation is issued due to the fire and what they must do. Similarly, the plan needs to foresee who will evacuate and how. Such plans need to be updated, discussed, and shared within the community and with all stakeholders involved in fire management every year.

Keywords

Logistic, forest roads, fire trucks, tipping point, fire frontline, tools

Abstract

In order to protect human life, property and the environment from wildfires, professional and voluntary fire departments are the first interveners in Hungary. One of the major challenges of firefighting against wildfires is the logistics. Such a logistic challenge is the migration to the fire site with different fire vehicles. The logistic challenges of wildfires usually developed in rural areas, on dirt roads of the forest, away from the residential areas. These areas are difficult to approach with some fire trucks that are not specifically designed for these purposes. These difficulties affect the efficiency of firefighting. In the paper, the Author draw conclusions from the logistical difficulties of firefighting against wildfires that are suitable for proving the time loss of migration and to determine how the time loss affects the spread of a fire and the effectiveness of firefighting. The Author shows how the frontline ($T_{frontline}$) of a fire can change due to time loss (Δt) at 1 m/min, 5 m/min and 9 m/min fire propagation ($V_{fire\ propagation}$). By using a formula, the Author also calculate the size of frontline fire. As a result of the paper he determines the amount of time loss with a new method, which is related to the increase of fire frontline.

1. Introduction

According to The Global Risks Report 2022 created by the World Economic Forum, for the next five years, respondents again signal societal and environmental risks as the most concerning. However, over a 10-year horizon, the health of he planet dominates concerns: environmental risks are perceived to be the five most critical long-term threats to the world as well as the most potentially damaging to people and planet, with "climate action failure", "extreme weather", and "biodiversity loss" ranking as the top three most severe. (WEF 2022). Climate change is a challenge in many areas of science, society and life, so it also has an impact on the disaster management. The above mentioned climate change factors provide a greater opportunity to ignite the combustible fuel, which increases the risk of wildfires. The wildland as a natural area carries many social values in itself, so we protect it from fires (Almeida 2021).

Firefighting is often a long and complex process (Figueras 2015), the main stages of it is to stop the fire spread, to eliminate the flames and to supress the fire. In the process, firefighters face a huge number of logistical challenges (Jain 2020). Several researchers have investigated the logistic difficulties of firefighting. (Rácz, 2016), (Bodnár, 2016). The first deep investigation in the topic was carried out by (Restás 2003) in Hungary, who examined the effectiveness of increasing the number of firefighting interventions with a value - time function, but he also analysed the time elapsed during the steps of firefighting, the network of logistics bases and their distance. Other research focuses on threat of forest and vegetation fires and the possibilities of intervention (Bodnár 2019), and the forest fire detection (Bodnár 2018).

2. Methods

In order to achieve the research objectives, I studied the most important national and international literatures focusing on the topic of the logistics of firefighting. In addition, I have had personal consultations with various experts and participated in international scientific conferences and study tours. I presented my logical conclusions and results using histograms and diagrams. In illustrating the logistics problems, I made schematic diagrams and explanatory drawings, the analysis of it helped me to understand the mathematical foundations of

my efficiency analysis. During the logistic challenges of firefighting, I examined the effects of time loss caused by migration on poor quality roads. I also took pictures of poor quality roads on my observation plot (Figure 1).

Figure 1- Poor quality dirt roads in the forest, nearby a water source in Hungary.

In addition, I examined the extent and impact of time loss, caused by migration to the fire site on poor quality dirt roads. For my research, I edited a conceptual Figure (Figure 2) which shows how far a fire truck can travel on different types of roads in a given amount of time. I did not simply characterize the problem of time loss during marching, but I first related it to the increase in length of the burnt fire frontline.

To investigate the approach of fire site, I established my assumptions based on the experiences of drivers of fire trucks. According to drivers and relevant national legislations, a fire truck has an average speed of 60 km /h on driveway and an average speed of 20 km/h on dirt roads (Decree, 2011). The average speed of 20 km / h on dirt road is a third of the speed on a driveway, so there is a logical proportionality between the two values. Consequently, I consider the two values to be acceptable and authoritative during the research. After determining the speed of the fire trucks, I also have to assume a migration time. The average time to approach a fire site with fire trucks is 15 minutes in the European Union is (Müller, 2020). Based on my own analysis, the Hungarian fire brigades cannot yet fulfilling this in all cases, so during my research (schematic figure) I expect an intervention time of 20 minutes. Areas in literatures refer to so-called white spots as areas that are not approachable from a professional fire brigade during the specified 25-minute migration period (Berczi and Papp 2017). This time is an upper limit, so I consider the 20-minute long marching time I have chosen to be logically acceptable.

For my research, I edited a schematic figure (Figure 2), which shows how far a fire truck can travel on different types of roads. In the figure, the vertical axis indicates each route possibilities and how many km the fire truck can travel on a driveway. The horizontal axis shows the travel on dirt roads for the remaining time. The green line indicates the distances reached within 20 minutes (reality). The red line indicates the distance of 20 km (goal). The area between the green and red lines gives the difference in efficiency (Time loss).

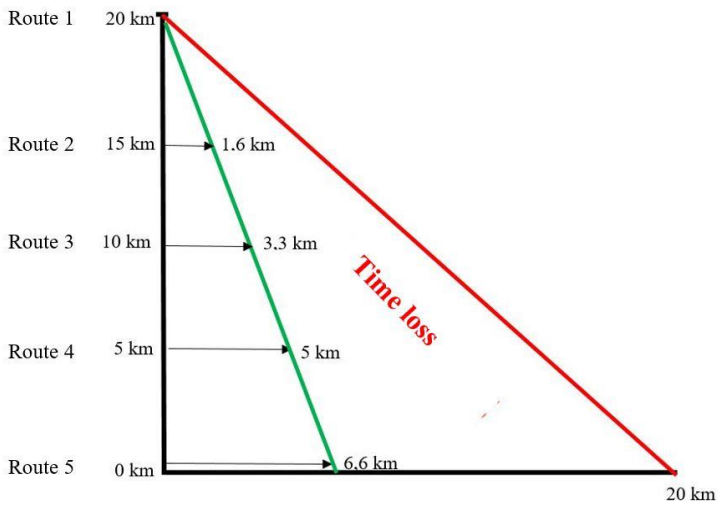

Figure 2- Schematic figure of different migration route combinations.

On *Route 1*, the approach of fire site is entirely on driveway with a speed of 60 km / h (in 20 minutes), so the maximum distance that a fire truck can be covered is 20 km. I consider it to be the most favorable condition. On *Route 5*, fire truck travels along the dirt road (with a speed of 20 km / h), so it cannot cover the distance of 20 km, only a fraction of it, which is 6.6 km. I consider it to be the most unfavorable condition. Of course this case is only a logical assumption, as all fire stations are located so as to be approach on driveways. The Figure also proves the logical conclusion that the more a fire truck travels on a dirt road, the less distance it takes in 20 minutes. I have plotted five different hypothetical route options.

I have already analyzed the best and the worst route options (Route 1 and 5), for the other routes traveled the distances change as follows. In Route 2, site approach will take place on a 15 km driveway and then on a 1.6 km dirt road (which would be 5 km on a driveway). This ratio is already 10 km - 3.3 km in Route 3 and 5 km - 5 km in Route 4. Figure 2 demonstrate my logical assumption that the site approach on a dirt road results in a significant time loss, which affects the effectiveness of firefighting. Table 1 illustrates the traveled distance in km (in 20 minutes) in six routes options. In addition, I also calculated the average speed of the fire truck on the different route options.

Table 1 - Approach to the fire site on different types of routes. Created by the author.

Approach to the fire site on different types of routes			
Routes	**Traveled distance (km)**	**Average speed**	**Elapsed time**
1.	20	60 km/h	20 min
2.	16,6	50 km/h	20 min
3.	13,3	40 km/h	20 min
4.	10	30 km/h	20 min
5.	6,6	20 km/h	20 min

In case of wildfires, fire trucks sometimes travel long distances on narrow dirt roads in order to approach a fire site, which is a significant time loss in terms of firefighting. This happened in Hungary in case of large fires in the Southern Great Plain (Kaskantyú, Törtel). Case studies have also been prepared on this topic (Bodnar, 2017). In the next chapter I will examine how much the length of the frontline fire increases as a result of the time loss.

3. Results

After the analysis of the site approach, I calculated (Table 2) how the frontline ($T_{frontline}$) of a fire can change due to time loss (Δt) at 1 m/min, 5 m/min and 9 m/min fire propagation ($V_{fire\ propagation}$). By using the bottom formula, I also calculate the size of frontline fire (conditions: homogeneous wildland fuel, calm wind, flat terrain).

$$T_{frontline} = 2x\Delta t x\, v_{fire\ propagation}\, x\, \pi \quad (1)$$

Table 2 - Changes in the frontline of fire during different fire propagations.

Changes in the frontline of fire during different fire propagations					
Time loss (min)	0	10	20	30	40
1 m/min	0	63	126	188	251
5 m/min	0	314	628	942	1 256
9 m/min	0	556	1 130	1 696	2 261

I would like to note that, from the modelling point of view of, fire propagation can only be characterized by a circular shape on flat terrain in case of homogeneous fuel and calm winds, in all other cases the ellipse shape should be considered as dominant (Rothermel, 1972). However, at ellipse, the increase in circumference is not linear but larger than in case of circle, so this proves my conclusion. In Table 2 I rounded my results for a more comprehensible illustration. As a result of Table 2, I conclude that, on the one hand, the longer the travelled distance decreases in 20 minutes, the more time loss will be (it makes sense). On the other hand, the more is time loss, the longer the length of the fire frontline will be. To illustrate my conclusion, I created Figure 3, where I illustrate the relationship between time loss and the increase in fire frontline at the fire propagation speeds (1 m/min, 5 m/min, 9 m/min) examined above. It is clear from the graph that as the lower velocity section increases, the length of the unnecessarily increasing frontline changes linearly.

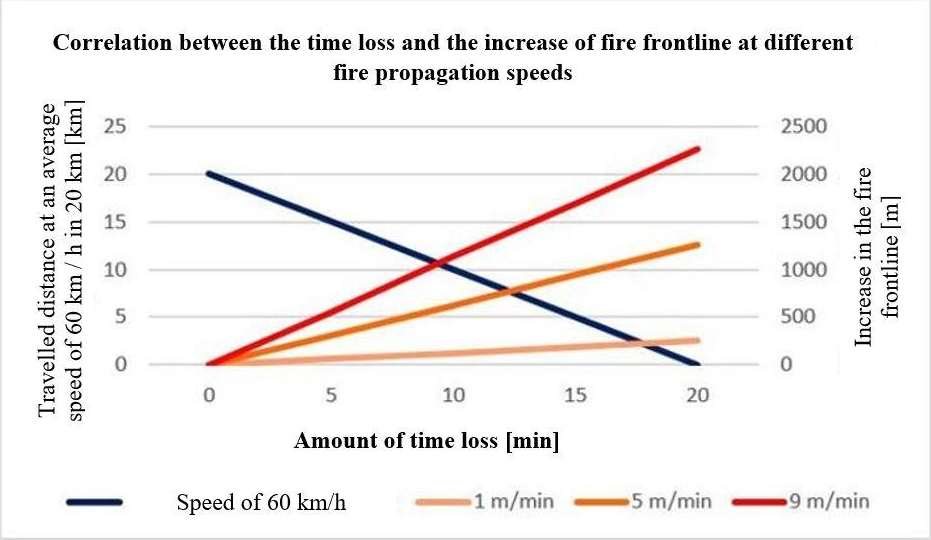

Figure 3 - Correlation between the time loss and the increase of fire frontline at different fire propagation speeds. Created by the Author.

Poor terrain conditions reduce the effectiveness of firefighting not only during site approach but also later during the constant water supply. However, this condition also helps the fire to spread further. In order to protect the built environment and residential areas it is unavoidable to move fire trucks in the field. In addition, I analysed the pros and cons of the use of an Extinguisher water backpack, an All-terrain vehicle (ATV), a Pick up and a Fire truck during the firefighting. By comparing the effectiveness of vehicles, I determined what types of interventions they could be used efficiency. I based my analysis on the approach to fire site, on the following types of routes: paved road, good quality dirt road, poor quality dirt road, forest path, forest trail, forest.

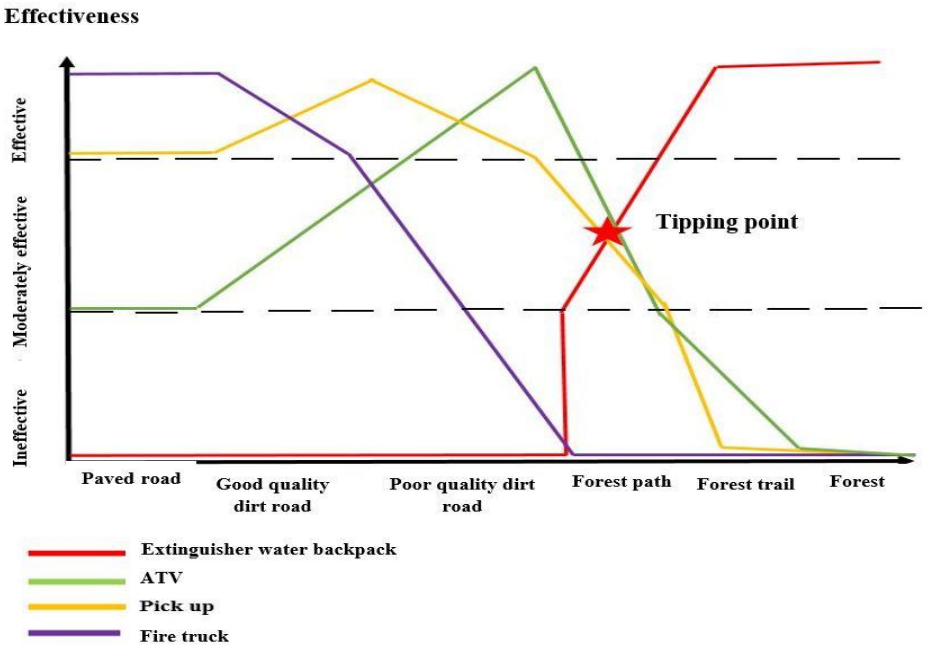

Figure 4- Illustration of logistical efficiency of vehicles and equipment on different types of roads.

Based on Figure 4, I found that as long as we can approach the fire site easily, the use of fire trucks is effective. However, this is changing as we move towards into the interior of wildland, where smaller vehicles like Pick up and ATV are a more effective solution, mainly because of their good off-road capability. I considered forest path to be tipping points in the efficiency of site approach, as this is the point where use of large fire trucks is no longer effective. On these types of routes, smaller firefighting vehicles are more effective.

4. Conclusion

As a result of my analysis of route combinations, I came to the conclusion that site approach on the dirt road results in time loss. As a result of it, interveners start firefighting at the fire site late. This also affects the lengths of the fire frontline, making the efficient firefighting more difficult. Intervention in time will also help save lives, and amount of damage will be less due to the shorter migration time. After examining the approach problem of fire site, my logical conclusion is that a calculation of time loss of migration should be made. In addition, it would be useful to widen and improve the quality of several dirt roads in the forest, in order to make these routes more walkable in case of a wildfire, thus reducing time loss. In many cases, fire site is covered with a large amount of reeds or grass, so much of the burned area can only be approached with the help of local people. Orientation can also be made with geographic information system (GIS), but in many cases this is not real-time and needs to be regularly updated (Burrough; Mc Donnel, 1998).

From logistical difficulties of fighting against wildfires, I drew conclusions that are suitable for detecting the time loss of migration and for establishing new methods and tools. Within this framework, I have dealt with effects of time loss caused by migration on poor quality roads. I not only characterized the problem of late arrival with time, but I related it to the increase in length of the fire frontline. To understand and illustrate this problem, I created a self-edited figure. Next, I analyzed advantages and disadvantages of an extinguisher water backpack, a firefighting ATV, a pick up, and a fire truck during the firefighting. By comparing the efficiency of vehicles, I determined what types of interventions they can be used efficiency. This was based on one of the most important factors in efficiency of vehicles, which is the approach to fire site. Consequently, I have concluded that, as long as we can approach the fire site easily, the use of large and high-capacity vehicles is effective. However, this changes as we move towards into the interior of the forest, the smaller vehicles are more effective because of their good off-road capability. I consider the forest path as a tipping point in the application efficiency between large and small vehicles.

Abstract

Forest fires are one of the main disasters that devastate many countries every year. The destruction caused by these phenomena generates social impacts putting at risk the population lives, environmental impacts due to the extreme deforestation and the high number of pollutants that are released to the atmosphere but also extremely important economic impacts caused by the destruction of a wide range of infrastructures and essential goods. Therefore, as it is impossible to remove all the infrastructures from the forest and from the wildland-urban interface, the development and installation of protection systems is essential. The main objective of this work is the development of a low cost protection system, with rigid panels, requiring a simple and easy installation, to protect outdoor infrastructures such as telecommunications stations, shelters, roadside enclosures, power cabinets, and other structures. A study was carried out on panels that could be used for the protection in order to determine whether the protective material would be more appropriate. Taking into account the fire resistance behaviour, thermal and structural properties and cost, the panels selected were the magnesium oxide fibreglass reinforced. The protection was constructed, installed on a telecommunication cabinet and experimentally laboratory tested in a wind combustion tunnel. To collect the data Infrared and video cameras, heat flux sensors and sheathed thermocouples were used to determine the fire propagation, heat flux and temperatures, respectively. The data obtained in the experimental tests show clearly that the simple low cost protection is effective for the protection of telecommunication cabinets and other similar infrastructures against forest fires.

1. Introduction

Forest fires are one of the main disasters that devastate many countries every year. The destruction caused by these phenomena generates impacts at several levels, whether social by putting at risk the population lives, whether economic through the destruction of a wide range of infrastructures and essential goods, or the environment. The forest fires that have been occurring in Portugal, and especially those in 2017, have highlighted the importance of infrastructures protection. In 2017, until October, 356 large forest fires (burned are larger than 1000ha) were recorded with an estimated burned area of 520,515 hectares (ANACOM, 2017). It was also in this year that the Pedrógão Grande fire occurred and it is known as one of the worst fires in Portugal and Europe. This terrible catastrophe took the lives of dozens of people, injured hundreds and caused a wave of destruction. During this fire, a lot of infrastructures were destroyed, including telecommunications stations, poles, copper and fiber optic cables, leading to numerous communication problems. “The failure of the communications system may have contributed to the lack of coordination of combat and rescue services, to the difficulty of people asking for help and to the worsening of the consequences of the fire” (Xavier et al., 2017). In the context of the high risk of forest fires in Portugal, a work has emerged whose objective is to develop a protection system applicable to infrastructures that are inserted in forest areas and that can be affected by forest fires.

According to (Andrade & Souza, 2015) the materials used for fire protection can be classified into three major groups: rigid and semi-rigid materials; intumescent paints; sprayed materials. (Takahashi, 2019) showed that the use of protective blankets made up of multiple layers of fibers allows the protection of infrastructures against fire. However, the application of this type of protection only becomes viable when the exposure time is relatively short, since for longer exposures, deterioration of the protection becomes evident. The work developed emerges

as a continuation of previous studies (Brinca, 2020), in which a fiberglass blanket coated with aluminium was used in order to protect a telecommunications cabinet. This protection, in addition to being effective in protecting against fire, also showed that the temperature inside the cabinet increased even when there was no exposure to fire. Thus, the author left open the possibility of using another type of protection. As forest fires are transient phenomena, thermal inertia of the protection is important to reduce the temperature increase of the protection and air inside the cabinets or enclosures. So, in this work, rigid panels will be used and applied to cabinet stations to test the fire resistance, in adverse conditions.

2. Experimental methodology

The first step of the work was the study and selection of the most appropriate material panel for the protection. The panels to be used in the protection must be impact resistant, fire resistant, resistant to climatic adversities and must have low thermal conductivity and high thermal inertia to withstand outdoor ambient conditions and forest fire transient effects. Several panels were identified and compared as shown in Table 1. The selected panel was the MAGOOX Board panel with 9mm thickness (MGOBoard, 2020) since that the boards are produced with thicknesses of 4 to 18mm being the thickness of 9mm an average value that does not turn the protection into a heavy structure. This material meets all the requirements for the protection material and it is non-toxic, has a low environmental impact and low price. The current approximate European price of the selected panel is 12€/m^2. This panel is composed of fiberglass reinforced magnesium oxide and has a fire resistance of 60 to 90 minutes. Generally, forest fire fronts have a residence time of no more than 15 to 20 minutes and they can reach very high propagation speeds (Raposo et al., 2018).

Table 1 – Commercial panels identified for the study.

Commercial name	DuraSteel	Promatec-XW	WeatherKem	SpeedPanel	MAGOOX Board	TriplacM
Composition	2 perforated steel plates and fiber reinforced cement core	Gypsum board with mat reinforcement	Mixture of cement, cellulose fibers and silicon-based binders	Cement core and galvanized steel cladding	Magnesium oxide reinforced with fiberglass mesh	Magnesium, fiber reinforced and other refractory materials
Thickness [mm]	9,5	15	6-18	51; 64; 78;	4-18	24-30
Fire resistance [min]	240	≤ 60	are completely non-combustible	Varies with thickness (60; 90; 120)	60-90	180-240
Resistance to climatic adversities	Yes	Yes	Yes	Yes	Yes	Yes
Impact resistance	Yes	Yes	Yes	Yes	Yes	Yes
Thermal conductivity (20ºC aprox.) [W/m.K]	0.55	0.264	0.24	Varies with cement densities	0.213	0.29

The protection was constructed and installed on a telecommunication cabinet as shown in Figure 1.

Figure 1- a) Telecommunication cabinet; b) Protected telecommunication cabinet.

To study the thermal behaviour of the cabinet and its protection, they were subjected to a series of tests carried out at the LEIF-ADAI facilities using the Combustion Tunnel 3 (CT3), which has two 35kW fans that can generate air speeds of up to 8m/s. This tunnel has dimensions of 8m length, 6m width and sidewalls of 2m height. The experimental apparatus is shown in Figure 2. The fuel bed area was defined by fixed length and width of 4m, corresponding to the 16m^2, with a fuel load of 1.5kg.m^{-2} of typical Mediterranean shrubs composed by a mixture of *Erica umbelatta*, *Erica australis*, *Ulex minor* and *Chamaespartium tridentatum*.

Figure 2- a) Combustion tunnel CT3; b) General view of the tests.

The existence or not of protection and the existence of side walls (which avoid lateral air entrainment promoting the arrival of a structured front, without edge effect) were tested. The list of tests performed and the respective variables are presented in Table 2 and they were performed in random order.

Table 2 – Conditions of the experimental tests performed.

Ref.	Wind speed (U [m/s])	Protection	Side walls
01	0	Yes	No
02	1	Yes	No
03	3	Yes	No
04	0	Yes	Yes
05	1	Yes	Yes
06	3	Yes	Yes
07	0	No	No
08	1	No	No
09	0	No	Yes
10	1	No	Yes
11	3	No	Yes

In the tests it was used an InfraRed FLIR Camera SC660, a heat flux sensor (Hukseflux sensor IHF01) and five sheathed K-type thermocouples of inconel with 1mm diameter. The referred equipment was used to determine the fire propagation, heat flux and temperatures. Additionally, at all the tests, two optical video cameras were used. One (Sony FDR-AX53) placed in a lift platform and the other (Sony HXR-NX30E) at ground level. Experimental setup is shown in Figure 3.

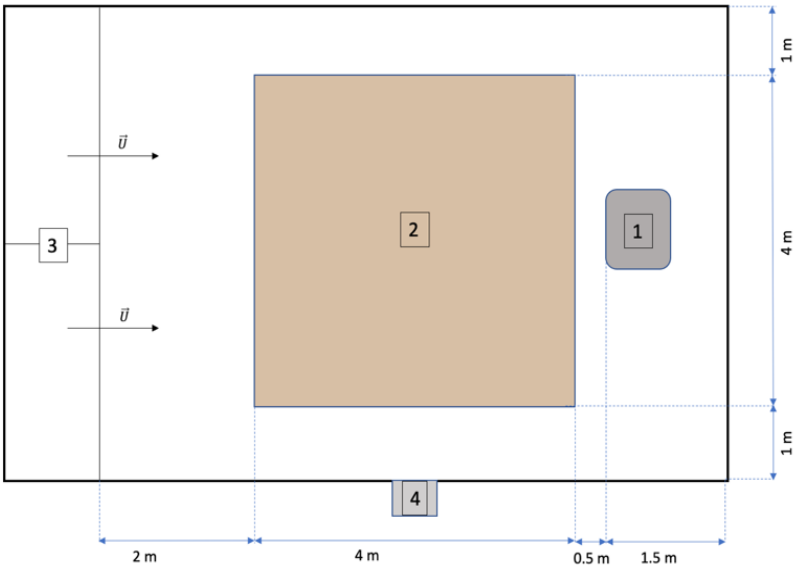

Figure 3- Experimental setup

(1 - Telecommunication cabinet, 2- fuel bed, 3- wind tunnel fans, 4- infrared and video cameras).

For the installation of thermocouples and heat flux sensor in the cabinet and respective protection, an acquisition board NI chassis cDaq 9174, a thermocouple board 9213, a voltage board 9211 and a computer with the *signalExpress* program with an acquisition frequency of 1Hz were used. The thermocouples and heat flux sensor were installed in the following positions:

Thermocouple 1(T_1): placed inside the cabinet (roughly in the center, about 1.30m from the ground) ;

Thermocouple 2 (T_2): placed on the inner front surface of the protection (about 1.30m from the ground) and in the tests carried out without protection, this was placed on the side of the cabinet;

Thermocouple 3 (T_3): placed on the outer front surface of the protection or cabinet (in absence of the protection), at about 1.30m from the ground;

Thermocouple 4 (T_4): placed behind the cabinet about 1m away in order to be able to assess the downstream air temperature;

Thermocouple 5 (T_5): placed on the sidewalls (when applicable);

Heat flux sensor: placed on the outer front surface of the protection (or of the cabinet, respectively, if testing with or without protection), approximately 1.30m from the ground. The flux and temperature values at the various points of the shield protection and cabinet were taken directly from the thermocouple data and converted into Microsoft Excel®.

3. Analysis and discussion of results

Figure 4 and 5 shows the temperature evolution in two tests performed with the protection applied to the telecommunications cabinet and 3m/s wind speed (highest wind tunnel speed which is the most critical situation tested and corresponding to the typical wind speeds of intense forest fires). Regarding the temperature inside the cabinet, it is possible to verify that the maximum temperatures do not exceed 30ºC, proving that the use of the protection under study is capable of protecting the cabinet against the high temperatures and heat fluxes of a forest fire.

Figure 6 shows the temperature evolution in the test performed without protection applied to the telecommunications cabinet and 3m/s wind speed. For this case, the evolution of temperatures is quite similar to that observed previously. However, there is a considerable difference with regard to the maximum temperature registered inside the cabinet, reaching a value above 60ºC. This value is considered critical for the normal operations of communication equipment.

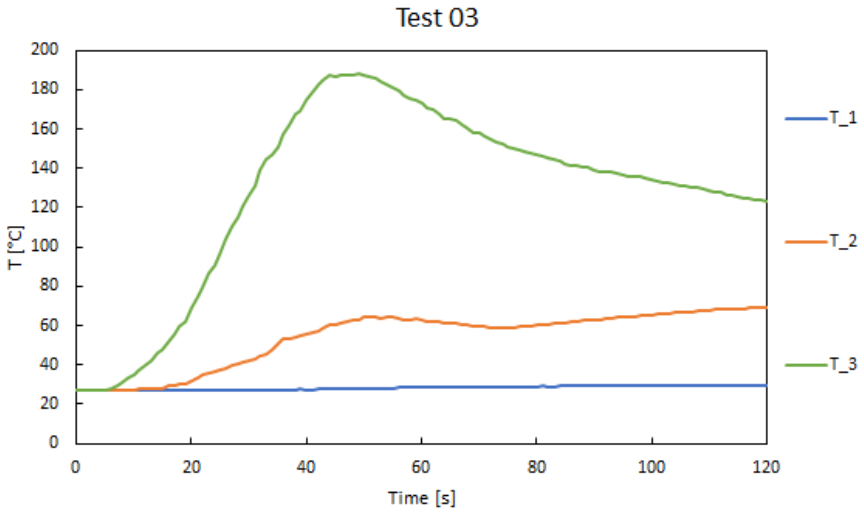

Figure 4- Evolution of temperatures in Test 03.

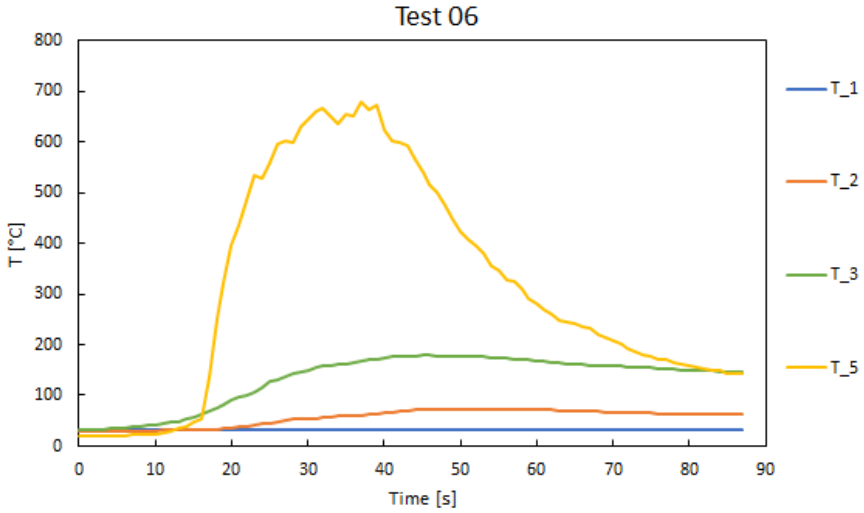

Figure 5- Evolution of temperatures in Test 06.

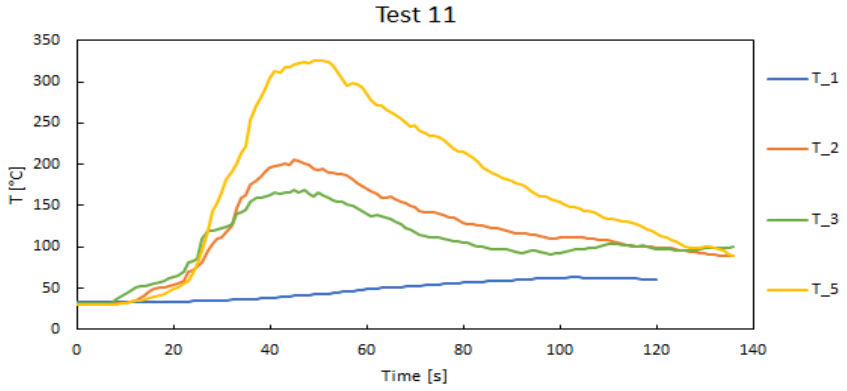

Figure 6- Evolution of temperatures in Test 11.

Table 3 presents a summary of the experimental results and it can be easily concluded that the protection system is effective as the maximum temperature inside the cabinet remains below 30°C, even with high fireline intensities.

Table 3 – Main results of the tests performed.

Test Reference	Protection	Wind speed [m/s]	Side walls	Max dimensionless rate of spread	Maximum fireline intensity [MW/m]	Maximum external surface temperature [ºC]	Maximum temperature inside cabinet [ºC]	Max Heat Flux [kW/m^2]
01	Yes	0	No	1.95	0.59	90.63	24.10	1.85
02	Yes	1	No	7.73	2.34	158.90	26.97	5.87
03	Yes	3	No	18.10	5.48	188.63	29.72	10.07

10	No	1	Yes	4.56	1.38	196.22	42.64	1.34
11	No	3	Yes	19.85	6.01	168.67	63.03	10.16

4. Conclusions

The data obtained in the experimental tests show that the simple low cost protection is effective to the protection of telecommunication cabinets and other similar infrastructures against forest fires. The protection avoided the high temperatures in the cabinet. The temperature obtained inside the cabinet, without protection, reached a value above 60ºC. This value is considered critical for the normal operations of communication equipment. Another great advantage of this protection is its low cost of material and labour for installation. In this case, the protection was built and installed at a cost of approximately 150 euros, increasing the protection of an asset that costs thousands of euros. Installing this type of protection does not compromise system operations at all. The access for maintenance or repairing is maintained since the plates are integrated in the movement of the openings of the cabinet.

Abstract

Nowadays climate change is one of the biggest challenges in the entire world. The average temperature on Earth is constantly increasing, and the distribution of seasonal precipitation is extreme. These factors together result in large fires and the new challenges require new solutions. The paper discusses the possibilities of developing the detection of outdoor fires with a camera. One of the objectives of the research is to prove the existence of a detection system by examining the detection conditions of outdoor fires and supporting them with practical examples. The research was determined to keep the costs of the examined developments below the value of properties they saved, so authors consider it a realistic aim to apply them in practice. Another objective was to demonstrate the time gain of the detection of remote sensing. In each case, the comparative analyzes of the authors show that citizen reports, i.e. the current, traditional solution, allow for a later alert than it would have been possible by using remote sensing. In the paper, wildfires were analyzed that were randomly recorded by video cameras. Authors have collected data on the specific fire from various official databases of the Hungarian Disaster Management. Taking into account the speed of fire propagation, it was determined that the burned area and perimeter of the fire are much smaller than the early detection when the firefighters arrive to the site. It shortens the length of the frontline to be extinguished. This predisposes to a lower force requirement for elimination and also significantly reduces the use of intervening forces along with the need for the used extinguishing agent. Overall, the intervention can be made more effective.

1. Introduction

In Europe, wildfires are most common during the summer fire season, due to the high average temperature and the quantitative distribution of precipitation. As a result of climate change, droughts have become common in the summer. In this case, no open flame is needed to ignite the dry fuel, a spark bursting from a machine can also do it. Combustion of accumulated combustible fuel releases enough thermal energy to cause even crown fire. Outdoor fires cause enormous damage to animals and wildland vegetation that can only be recovered in decades. By outdoor fires authors mean fires in the forest, wildlands, agricultural lands, grass, shrubs, forest litters, so they are talking about a collective concept.

The problems associated with fighting against forest fires are also very diverse, and their solution requires different tactics. If a fire already develops, it is important for everyone to put it out quickly and professionally with the least possible effort. Therefore, fast and accurate fire detection is very important for the efficiency. It is a negligent behaviour to rely solely on passive detection in case of outdoor fires. The later we become aware of fires in our environment, the more tools and forces we need to extinguish them successfully. The most effective solution for monitoring large areas is remote sensing. Nowadays, the presence of cameras is already common, it is no longer a big challenge for modern technology to produce devices suitable for high-quality images at minimal cost. All people have smartphones in their pockets whose cameras can take clear pictures. If the presence of cameras is so much part of our everyday lives, its benefits could also be used to support disaster management operations.

There are many papers focusing on camera based fire detection, some of them give a review of the technology (Alkhatib 2014, Mathi and Latha 2015, Yandouzi et al. 2022), others focus on the option of autonomous detection (Breejen et al. 1998, Liyang 2005, Saponora et al. 2018), the network system (Benzekril et al. 2020, Muhammad et al. 2018), the machine learning technology (Byongjun 2019, Xu et al. 2021) or the optimization of the detection (Restas et al. 2014, Quttineh et al. 2022).

The purpose of this study is to analyse the low-cost webcam videos of the locations where the fire occurred and then present the time difference between the occurrence of the fire alarm and the optional fire detection. Authors intend to demonstrate

even the difference between both the sizes of burnt areas and the lengths of perimeters in cases of active and passive detection.

2. Methods

We have examined and analysed the relevant literatures on the topic as well as the results of other authors. Part of the secondary research was the analysis of reports, data and webcam recordings of outdoor fires. The data on the alarm sheet provided by the fire service were studied and compared with the remote sensed recordings provided by the webcams. Using the timestamp of the recordings and the data on the alarm sheet, authors performed basic calculations from which comparisons were made and logical conclusions were drawn. In addition, authors analysed figures, signalling dates and damage descriptions through the statistical service of one of the online interfaces of the Hungarian Disaster Management. In addition to the practical experience of the authors, they received information about related examples during consultations with firefighting colleagues and experts, for which a remote sensing would have been very helpful.

3. Results

In this study 9 rural fires were analysed, all of them can be found in the 2021 year database of the Hungarian Fire Service. These fires were marked with A, B and C with 1 – 3. Authors summarized the data of these fires in the Table 1, where the time of fire alarm (T_p – passive fire "detection" that is reported by civilians), the time when fire could have been detected by the webcam video (T_C – optional detection time) and the time of the beginnings of the suppression (T_A – arrival time of the fire service) were provided. Based on these data authors could calculate the time of the free escalation of the fires (t_{dfree}), the time of marching of the firefighters (t_m), the fire development time of the fire supposed in case of webcam analysis (t_{dcam}) and the obtained time in case of camera based detection (t_w). In this study 1 minute was added to the cases of camera based fire detection as processing time. Based on the above data authors calculated the rate of fire propagation in all cases of passive detection (v_{tp}) and took also an average rate of spread for the further calculation (v_f).

Table 1. Data of fires analysed in this study.

	A/1	**A/2**	**A/3**	**B/1**	**B/2**	**B/3**	**C/1**	**C/2**	**C/3**

T_d [m^2]	9,253	74,510	3,079	1,374	148,876	3,295	11,374	8,480	3,178

Legend:

T_P : passive fire detection (fires, reported by civilians)	**v_{fp}:** assumed rate of fire spread based on passive detection
T_C: active fire detection (fires, can be seen on webcam)	**A_P :** burnt area at arrival in case of passive detection
T_A: arrival time of the first responders	**R_p:** the radius of the fire at arrival (passive detection)
t_{dfree} : time of fire escalation at real intervention	**K_p :** the perimeter of fire at arrival (passive detection)
t_m: marching time of first responders	**A_a :** burnt area at arrival (active detection)
t_p : assumed processing time of the automatic signal	**R_a :** the radius of the fire at arrival (active detection)
t_{dcam} : time of fire escalation according to the camera signal	**K_a :** the perimeter of fire at arrival (active detection)
t_w : time obtained by using automatic detection	**K_d :** the difference in the perimeter of fire
v_f : supposed rate of fire propagation	**T_d :** the difference in the area of fire

Database contains even the size of the burnt area reported officially by the firefighters after arriving to the fire front (A_P), and based on these the study calculated the radius (R_P) and the perimeter (K_P) of each fire. The authors also provided these data for webcam based active detections (A_A, R_A, K_A) and calculated the differences of the perimeter and the burnt area in case of each fire. The rate of the burnt areas in case of passive and assumed active detections presented in the Figure 1 as well as the time benefit between the passive and active detection.

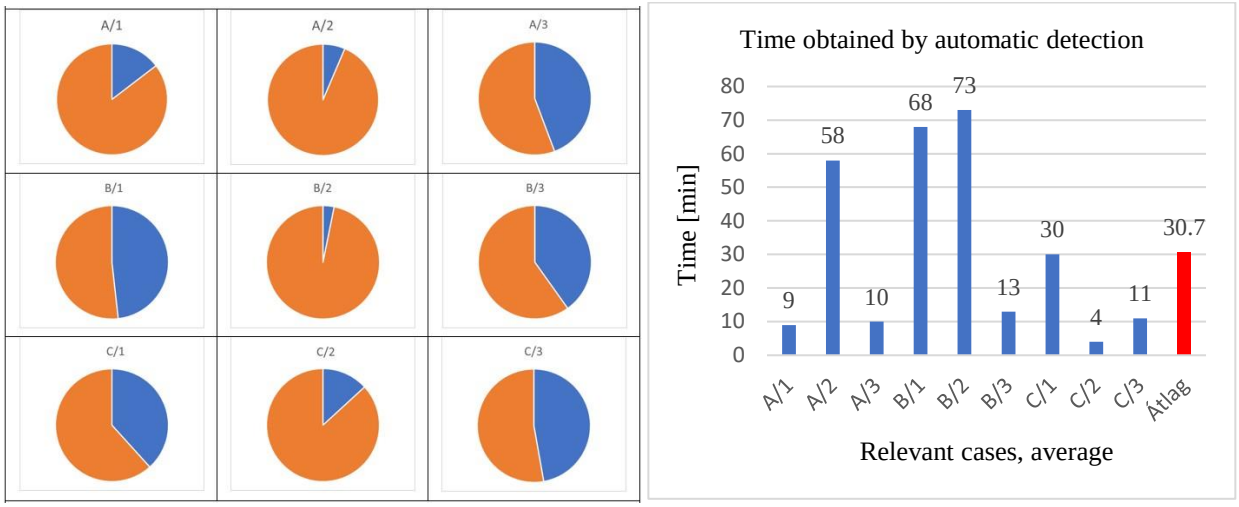

Fig. 1. The rate of the burnt areas in case of passive (orange) and active detections (blue) (left) and the time benefit between the passive and active detection (blue) with the average time benefit (red) (right). Created by authors.

Results show that in all cases using active detection firefighters would have had time gain, 4 minutes in the worst case (C/2) and 73 minutes in the best case (B/2), averagely more than 30 minutes (30.7 min). The burnt area would have been also smaller, with 1,374 m^2 in the worst case (B/1) and almost with 15 hectares in the best case (B/2), without the best case, averagely almost 1.5 hectares per fire. The perimeter, which is the fire front that firefighters have to suppress would have been shorter with 18 meters in the worst case (B/1) and more than 1 km in the best case (B/2), averagely 193 meters without the best case. Based on the above, authors state that the active fire detection can be effective even if fire service uses only the low-cost webcam solution for it.

4. Conclusions

It is very difficult to predict precociously the advantages of any early warning systems and camera based fire detection systems belongs to it too. Therefore, researches focusing on it have to take some simplifications and standard assumptions. This study generated by a random fire detection, however, authors could collect nine other cases to base the results. Even if this research focused on the saved area that can be achieved by the time difference between the traditional (reported by civilians) and camera based fire detection, authors found even some other results. One of these is, there was no fire to be reported earlier than staff could have been detected by cameras. All fires could be seen earlier by cameras than the fires was reported by civilians, averagely cameras could detect fire about 30 min earlier. The other is the standard deviation of the fire propagation is not essential in firefighters view; firefighters can calculate with 2.2 m/min fire propagation. Using surveillance cameras for fire detection can be a good opportunity in the future however more research is required to optimize its capability besides remaining even the original function. Summarizing the results, research demonstrates that, we can gain advantages even with a cheap and existing surveillance camera systems to reduce the burnt area.

Rural fires, transformative service research, value cocreation, wellbeing

Abstract

Socioeconomic changes have caused profound transformations in forest landscapes and increased abandonment of rural areas, leading to fuel accumulation and higher landscape homogeneity, and consequently, raising the rural fires risk. Rural fires risk is also fueled by climate change, due to heat waves and lack of precipitation. In this context, rural communities inhabiting forest areas are those who suffer the most, because rural fires, land degradation and climate change can disturb their food and economic strategy. These communities already suffer from underdeveloped rural infrastructure, and services, lack of labor and education opportunities, that trigger poverty and migration. Given this accelerating pace of change and increasing uncertainty, many fields of knowledge have been dedicated to contributing towards a more sustainable and inclusive future. In service research, transformative service research (TSR) literature plays a central role on understanding problems and finding solutions that improve well-being and create uplifting change through services. Similarly, the fire research field highlights the need for an integrated perspective to analyze all the aspects involved in rural fires occurrence, whether they are of an environmental or economic nature, or a sociological or demographic nature.

This study aims to explore transformative services oriented to cocreate value with forest-related rural communities, thus helping to manage forest areas and mitigate rural fires risks. A qualitative methodology was employed involving 28 participants related to fire management and forest areas and communities, including actors from industries, public entities, academics, the third sector. The data collected through individual interviews was transcribed, coded, and analyzed following a thematic analysis approach, with NVivo software support.

Overall, the study emphasizes the need for an endogenous and adapted set of services to cocreate value with vulnerable communities in forest areas, which consequently enable rural fires mitigation. Given the high level of land abandonment and accumulation of residual materials that increases the risk of rural fires, the development of valuing and recovery solutions is a priority. Finally, this research can also help decision-makers and stakeholders to generate and support services that cocreate value with rural communities to a sustainable, safe and inclusive future.

1. Introduction

Socioeconomic changes have caused profound transformations in forest landscapes and increased abandonment of rural areas since the 19th century. Land abandonment led to fuel accumulation and higher landscape homogeneity, and both contribute to raised rural fires risk (Mantero et al. 2020); also fueled by climate change, due to heat waves and lack of precipitation (Nunes et al. 2021). In this context, rural communities inhabiting forest areas are those who suffer the most, since they are especially vulnerable to land degradation and climate change (Shukla et al. 2019), which can disturb their food and economic strategy, exposing them to new social vulnerabilities and inequities (Miller and Mach 2022). These communities also suffer from the underdeveloped rural infrastructure, and services, lack of labor and education opportunities, that trigger poverty and migration (Lazarte 2017). So, increasing the land abandonment and rural fires risk, in a cyclical transformation of an ecosystem in increasingly poor health.

Given this accelerating pace of change and increasing uncertainty, many fields of knowledge have been dedicated to contributing towards a more sustainable and inclusive future. In service research, transformative

service research (TSR) literature plays a central role on understanding problems and finding solutions that improve well-being and create uplifting change through services (Anderson et al. 2013; Ostrom et al. 2021) in an inclusive way (Boenigk et al. 2021). Addressing how different stakeholders can share resources to achieve common goals (Ostrom et al., 2021) and how sustainability efforts require the active involvement of stakeholders throughout the service ecosystem (Field et al. 2021). Similarly, forest fire research field highlights the need for an integrated perspective to analyze all the aspects involved in rural fires occurrence, whether they are of an environmental or economic nature, or a sociological or demographic nature (Nunes et al. 2021). The increased risk of rural fires, due accumulation of biomass fuels in forests, motivated the launch of a set of legislative measures that seek to promote the management, cleaning, and control of these species. At the same time, it stimulates the study and research for more efficient and viable recovery alternatives, which allow the creation of value for these residual materials and the promotion of their sustainable management, thus mitigating the risk of rural fires. An example of this is the energy recovery of these species in local, small-scale processes, that is, increasing the value through planned actions (Nunes et al. 2021)

Considering the challenges presented, this article is bridging the service research field, namely, transformative service research (TSR) literature, with the forest fire research, through endogenous and adapted services that cocreate value with forest-related rural communities, mitigating rural fires risks. These services can foster value cocreation with the endogenous forest resources for commercial and non-commercial purposes, such as exploitation of natural resources (timber, pine resin, mushrooms, bee hives, etc), human nutrition, cultural and experience services. It can potentially contribute to the generation of jobs and income in rural areas (Weiss et al. 2020), as well as create more efficient and viable recovery alternatives for residual materials and promote their sustainable management, thus mitigating the risk of rural fires (Nunes et al. 2021). Thus, transformative services do not directly lead to well-being but serve as a mediating construct to promote greater well-being among individuals and collectives (Blocker and Barrios 2015).

Based on TSR approach in the improvement of individuals and ecosystems well-being and create uplifting change through services, this research aims to explore services to cocreate value with forest-related rural communities to mitigate rural fires risks. The following sections describe the method employed to answer this objective, as well as characterize main findings, discussion, and conclusions of this study.

2. Method

A qualitative methodology was undertaken to gain an in-depth understanding of how transformative service research can contribute to mitigating rural fires risks and increasing the well-being forest-related rural communities, through services. To ensure the holistic perspective of the research topic, 28 stakeholders with in-depth involvement and experience in Portugal forest-related areas and communities, and fire management, were individually interviewed. The sample included representatives from industries, public entities, academics, the third sector, from National Military Security Force, Volunteer Firefighters, National Emergency and Civil Protection Authority, National Guard, Agency for the Integrated Management of Rural Fires; National Institute for the Management and Conservation of Nature and Forests, forestry companies, electricity, and natural gas transport industries, multinationals that operate in telecommunications and other industries, associations, universities.

The data collected was transcribed, coded, and analyzed following a thematic analysis approach, with NVivo software support. Data analysis followed the Gioia approach (Gioia, Corley, and Hamilton 2013). Firstly, the interviews were initially coded following open coding procedures, in first-order codes, where the concepts were initially identified, and the properties and dimensions of these concepts were discovered in the data.

Afterwards, the codes were grouped, with continuous analysis of their subcategories, allowing the emergence of preliminary themes (second-order codes). These set of concepts were refined into “aggregate dimension”, that we named services to cocreate value with rural communities and mitigate rural fire risk, described in the following section.

3. Findings

From the data analysis a set of adapted services were identified with potential features to cocreate transformative value with rural communities and mitigate rural fires risk (Figure 1), such as associative and collaborative

services, ecosystem services remuneration, mentoring for smart use of land and management of its resources, rural industries and training and education services, as well as rural marketing and advertisement. Each identified service according to the stakeholders perspective will be reported in the following paragraphs.

Associative and collaborative services describe the collaborative effort to develop and protect local interests to overcome challenges of territory fragmentation, land abandonment, lack of land management and cleaning that increase the rural fires risk.

Ecosystem services remuneration consist of the landowner continually payment in exchange for guaranteeing the flow of ecosystem services, which is provided by nature and essential to survival, quality of life and well-being of society. These payments for ecosystem services can have different objectives and characteristics (e.g. payment for conservation, for active management of the landscape) and may favor a specific service (e.g. carbon sequestration), or a set of services provided by ecosystems (e.g. fertility of the soil, erosion control, hydrological regulation).

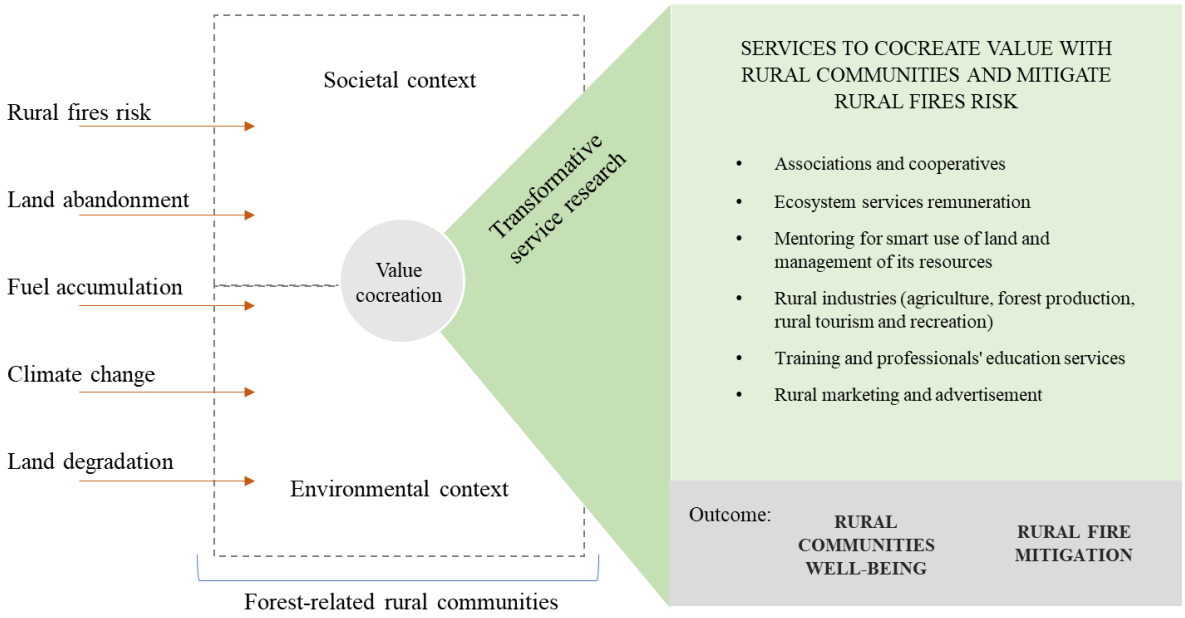

Figure 1- Services to cocreate value with rural communities and mitigate rural fires risk

Mentoring for smart use of land and management of its resources includes services oriented to active landscape management, sustainable manners to manage and promote the land and the resources, such as valuing residual biomass to energy recovery in local or small-scale processes, or recovery alternatives for residual materials. Rural industries encompass industries that run in rural areas, based on the utilization of local available resources, including agriculture, forest production, rural tourism and recreation.

Training and education services describe services to leverage knowledge in technical training in sustainable management of the land (suitable plant species to specific areas, valorization of natural materials, agrosilvopastoral system), and the professionalization of technicians in the forest clearing and safe fire use. These training and education services could be planned according to forest-related rural communities' profiles, such as local residents or technicians. And if oriented to young people, it can also contribute to attract them to rural areas. Lastly, rural marketing and advertisement services refers to foster and generate new social and economic dynamics to rural development through advertisement.

4. Discussion and conclusion

Rural communities' well-being in forest areas is linked to the recognition of the value of resources and the active and significant contribution of these territories to the mitigation of current challenges, such as rural fires (Nunes et al. 2021), land abandonment (Mantero et al. 2020), climate change (Nunes et al. 2021; Shukla et al. 2019), land degradation (Shukla et al. 2019) - that cannot be done without caring for the well-being of forest-related

rural communities. In other words, society needs rural areas and communities and the enhancement of the resources to face current global social and environmental challenges.

Moreover, the study demonstrates how transformative service research (TSR) favored forest fire research avenue, namely, to fire risk management with rural fires prevention, through a set of adapted services oriented to cocreate value with forest-related rural communities.

These services can improve the wellbeing of rural communities and, at the same time, foster active fuel management, promote the local economy and engagement of the community. Thus, mentioned services can foster value cocreation with the endogenous forest resources for commercial and non-commercial purposes (Weiss et al. 2020), contributing to sustainable land management and resources promotion, such as the possibility of valuing residual biomass (Nunes et al. 2021), generating new social and economic dynamics to rural development, such as jobs opportunities, income to local markets, and so avoiding land abandonment and encouraging the active land management. In a broader perspective, transformative services oriented to value cocreation with forest-related rural communities can also contribute substantially to poverty alleviation and the transition towards low-carbon and green economies. As previously said, transformative services do not directly lead to well-being but serve as a mediating construct to promote greater well-being among individuals and collectives (Blocker and Barrios 2015).

This study introduces an alternative lens to address the rural fires issue with a call for endogenous and adapted services oriented to value cocreation with vulnerable communities in forest areas. Given the high level of land abandonment and accumulation of residual materials that increase the risk of rural fires, the development of valuing and recovery solutions is a priority. Lastly, this research may inspire decision-makers and stakeholders to foster transformative services for a sustainable, safe, and inclusive future.

Wind speed; drag coeffcient; midflame wind; fire behavior; forest characterization

Abstract

Wind speed, that is strongly affected by terrain and vegetation, is one of the most important factors on fire spread. Fire simulators calculate wind speed as open 10-m wind speed multiplied by the wind adjustment factor (WAF). In forested sites, the sub-canopy wind speed plays a keystone role in low intensity fire or prescribed burn, and therefore, in prescribed burn plan. This research aims to estimate a WAF model based on in-stand wind speed at 2-m above ground and forests characteristics. Different sampling sites were established for WAF training and test. WAF range from 0.03 and 0.84, showing significant differences due to stand characteristics. Our findings showed canopy cover as the most influenced variable in WAF. On the one hand, the non-linear WAF model reached a coefficient of determination of 87.4%, including a second variable: the vertical distance between surface vegetation and the canopy base height. This approach proposes a novel method for the identification of WAF for prescribed fire implementation without the source of error could be generated using fixed WAF for each fuel model. The proposed model can be used to simulate different canopy management alternatives both fuel treatments and timber harvesting.

1. Introduction

Wind is affected by terrain, vegetation and the heigh above the ground (Andrews, 2012). The wind adjustment factor (WAF) has been widely used to identify a midflame wind from the 20-ft wind speed (Andrews, 2012). The midflame wind, which is used by several fire simulators, such as Behave Plus and FlamMap, is calculated as the product between 20-ft wind speed ("free wind") and WAF. In the case of Europe, weather station observations at 10-m height, clear ground, are used in opposition to 20-ft height following meteorological standards of the World Meteorological Organization (Brock, 2001). However, WAF depends on the vegetation characteristics and roughness (Mueller et al., 2014). The WAF, which is dimensionless (< 1), is reduced based on forest canopy and roughness (Albini and Baughman, 1979).

WindNinja software models wind speed according to terrain exposure and vegetation type. Other computational fluid dynamics (CFD) approaches, such as FIRETEC (Pimont et al., 2011) and WFDS (Mueller et al., 2014), can modify the wind speed based on fluid physical analysis. Although wind simulation using fluid dynamics is very realistic, a great time is required to run. Some approaches have been developed to simplify WAF calculation and to minimize the running time. Firstly, Deeming et al. (1977) assigned a mean WAF for each fuel model according to free wind at 20-ft height. Albini and Baughman (1979) proposed two mathematical models based on sheltered and unsheltered vegetation from the wind. Subsequently, Baughman and Albini (1980) modified the initial WAF for each fuel. Finney et al. (2011) proposed a WAF based on surface fuel bed depth.

Although wind speed profile is adjusted as a logarithmic function in open areas (Andrews, 2012), a complex wind profile is shown in forested areas due to the vegetation height, canopy cover and plant are density profile (Queck et al., 2010, 2012). Some authors (Gillies et al., 2002) have even proposed differences between species, but they suggested that is not be large enough to have a practical implication. However, a simplified wind profile simulation assumes a constant sub-canopy WAF when canopy gaps and topographical position could increase

wind speed due to Venturi effect (Molina et al., 2022). Therefore, WAF could be also affected by wind speed (Moon et al., 2019). All the above antecedents, subcanopy WAF plays a keystone role in surface fire spread in low intensity fires and prescribed fires, but a source of error could be generated using fixed WAFs for each fuel model.

This research aims to propose a mean wind adjustment factor (WAF) at 2-m above ground based on canopy characteristics. We attempt to find the relationship between reference wind (open area) and wind speed at 2-m height with different forests characteristics. In this sense, the identification of canopy characteristics that can affect wind speed and, therefore, fire intensity is essential for improving fire behavior models and prescribed burn plans.

2. Material and methods

2.1. Study area

Different forested sites were selected across southern Spain, covering two administrative regions (Andalusia and Castilla la Mancha) (Figure 1). Forested areas were dominated by *Pinus* species with and without understory. While 53.66% of the sampling sites were sheltered sites, 46.34% of the sampling sites were in unsheltered sites. One hundred meters was established as threshold to compare open wind speed and in-stand wind speed.

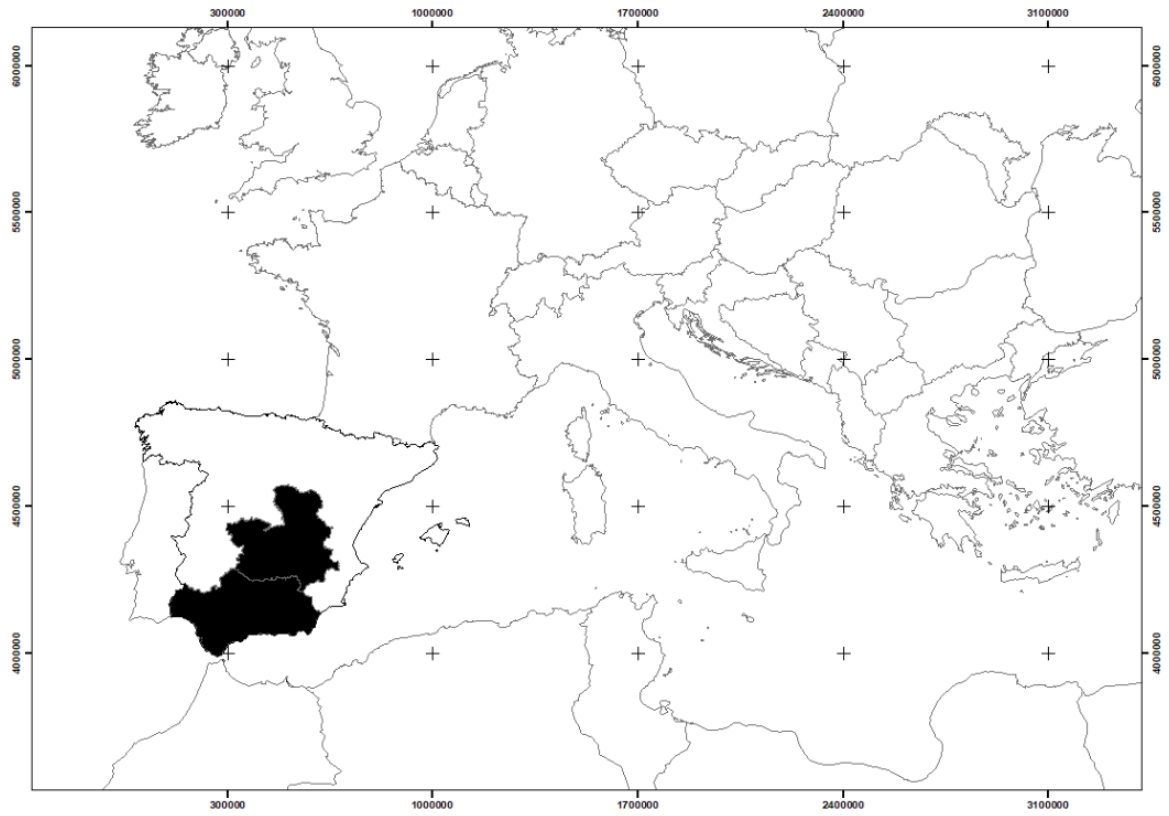

Figure 1- Study area location

Vegetation data was collected using circular plots of 20 m de radius. The vegetation inventory included variables such as stand density, stand height, canopy base height (live branch and dead branch), diameter at breast height, crown diameter and understory height. Basal area was calculated based on diameter at breast height and stand density. Canopy cover was estimated using the sum of tree crown vertical projection divided by the total area. The range of the vegetation characteristics was defined in Table 1.

Table 1. Range of the dependent and independent variables

Variable	Range
Wind adjustment factor	0.03 – 0.89
Wind speed (km/h)	0 – 47.2
Canopy cover (%)	10 – 100
Stand density (trees/ha)	10 – 1,205
Diameter at breast height (cm)	14 – 38.56
Stand height (m)	4.5 – 14.40
Basal area (m^2/ha)	13 – 65.53
Canopy base height (m)	4.5 – 15.3
Canopy dead base height (m)	0.1 – 71.91
Crown length (m)	0.44 – 7.57
Crown ratio	0.44 – 6.00
Undergrowth height (m)	1.10 – 9.01
Vertical distance between surface vegetation and the canopy base height (m)	0 – 7.57
Vertical distance between surface vegetation and the canopy dead base height (m)	0 – 5.63
Topographical stand position (unsheltered and sheltered stand)	1 = stand on flat or near base of mountain 2 = stand on high ridges

2.2. Wind speed measurements

Wind speed measurements were carried out from 2014 to 2020 using a meteorological vehicle and ThiesClima weather stations at open-canopy sites and guyed-mast with SkyWatch weather stations at sub-canopy wind speed (Figure 2). Wind speed was measured at height of 2 and 6 m (sub-canopy sites) and 10 m (reference open sites). Although the weather stations recorded data each ten seconds, the data were analyzed as ten minutes averaging interval to reduce effects of canopy cover. Our research has the limitations of the use of cup anemometer in-stand measures with turbulence patterns.

Figure 2- Weather stations used in this approach

2.3. WAF calculation

Although WAF can be modified by wind speed, this research identified an average WAF for a wide range of wind speed due to the reduced wind speed traditionally used for prescribed burns. WAF is calculated as the ratio between in-stand wind speed at 2-m of height (U_c) and open wind speed at 10 m above ground (U_o) (Equation 1).

$$WAF = U_c / U_o \quad \text{Equation 1}$$

2.4. Statistical analysis

Some statistical tests were performed using SPSS© software. Multi-linear and non-lineal models were tested to identify the best adjustment for WAF based on forest characteristics. A subsample of 70% of the dataset was

used for model training and 30% of the dataset for model test. The coefficient of determination, the mean absolute error (MAE), and the root mean square error (RMSE) were used to select the best model. Finally, a Wilcoxon test was used to identify significant differences in WAF based on canopy cover and unsheltered and sheltered fuels (< or > 50% of canopy cover).

3. Results

The wind adjustment factor (WAF) ranged from 0.01 to 0.84 for the different sampled sites. Canopy cover (CC) was the most related variable for WAF. Although basal area and stand density were the most important variables immediately following CC, they were strongly correlated with CC. The proposed model included two independent variables: canopy cover and the distance between surface vegetation and the canopy dead base height (z) (Table 2). While CC was negatively related to WAF, z was positively related to WAF. The coefficient of determination reached a value of 0.780 with only one variable. RMSE ranged from 1.21 m to 4.94 m and MAE was between 1.39 m and 5.85 m based on the training and test dataset, respectively.

Table 2. WAF model based on vegetation characteristics

Model	Parameter	Estimation	R^2	RMSE	MAE
WAF = a*FCC + EXP (b*CC)	a	2.594	0.780	0.29	0.11
	b	-0.033			

Note: FCC is the canopy cover (%) and CC is the canopy cover (%)

4. Discussion

Drag coefficient depends on wind speed, air density and contact area (Queck et al., 2010). Our findings observed higher WAF with light winds than heavy winds due to higher contact area like other studies (Queck et al., 2012). Considerable heterogeneity was found in vertical wind profiles based on vegetation structure and characteristics (Cassiani et al., 2008). Our findings showed canopy cover as the most influenced variable in WAF, like other approaches (Pimond et al., 2011). While some authors (Mueller et al., 2014) showed WAF range in canopies between 0.15 and 0.37, other studies (Moon et al., 2019) showed a wide WAF variation between open woodlands and dense forests. In our study area, WAF ranged from 0.03 to 0.89, showing differences more than nine times in dense stands than in open woodlands. Pimont et al. (2011) identified significant differences in treated areas with canopy cover lower than 25%, but they did not find significant differences with cover higher than 50%. We found significant differences with canopy cover lower than 30% and higher than 50%. Further studies would focus on the WAF adjustment based on the canopy fuel load.

There was a significant variation in the range of the WAF when they are compared to reference values or fuel model values used by fire simulators. We wonder that the limited sampling could be an issue here as possibly the adjustment could be different in different regions. BehavePlus offers the possibility to consider unsheltered o sheltered fuel models (Andrews, 2012). While fully sheltered WAF from BehavePlus varied from 0.1 (dense stands) to 0.2 (open stands), unsheltered WAF ranged from 0.3 to 0.4 from timber-understory and timber-litter fuel models. The reference WAF for canopy cover higher than 50% is like our WAF for very dense stands (cover higher than 90%) and other values found in literature from sheltered stands (Queck et al., 2012). Finally, although Baughman and Albini (1980) and NWCG (2006) performed significant WAF differences between shade-intolerant and shade-tolerant species, in our study are they were did not found due to the usual presence of Mediterranean mixed stands.

Wind speed at low canopy layer plays a keystone role in prescribed fire implementation. Canopy cover can be estimated by satellite images, hyperspectral images, and LIDAR data to improve economically the cartography required by WAF and fire simulation. With the help of LIDAR data and Geographic Information System, we performed WAF for different prescribed burns based on our test model. WAF variation implies a change in fire behavior, mainly in spread rate, flame length and fire-line intensity. A change in rate of spread and flame length would promote a higher fire-line intensity (Byram, 1959), and therefore, a higher scorch height and damages to trees (Molina et al., 2022). The wind speed modeling is a very complex phenomenon (Moon et al., 2019). Although computational fluid dynamics can precisely model the air flow (Pimont et al., 2011), forest managers

demand easy tools for use "in situ" or "on the fireline" for supporting changes in fire-ignition patterns of prescribed burns. The proposed model can be used to simulate different management alternatives and for discerning the most appropriate canopy cover to the achieve the trade-off between canopy fuel load and wind speed.

Airtanker, Aerial drop, Numerical simulation, Fluid mechanic, Liquid atomization

Abstract

Fighting wildland fires is a major issue for the protection of populations and environment with a need of more efficient means to fight fires. Airtankers are able to drop volumes of liquid (water or fire retardant) varying from less than 1m3 to several tens of m3, directly on fire or with the objective to form barriers of retardant to stop or reduce the fire propagation. However, the dynamics of a liquid dropped from an airplane has received few attentions in the scientific community, and related studies have mostly focused on Newtonian liquid jets injection in cross flow from millimetric injectors for combustion applications. For firefighting purpose, the liquid can be a retardant (a non Newtonian fluid) and the characteristic size of the delivery systems is of the order of a meter. The objective of this work is to demonstrate that Computational Fluid Dynamics (CFD) can be used to provide a deep understanding of the liquid fragmentation and dispersion when dropped from an aircraft. A numerical investigation is proposed for the analysis of airtanker performance and applied here to the biggest airtankers used in Europe: the Canadair CL-415 and the Dash-8. A numerical approach based on the Volume of Fluid method (VoF) is used to provide an accurate description of the tank discharge as well as to study the liquid ejection, fragmentation and atomization in air. The 3D unsteady resolution of the Navier-Stokes equations for both the liquid and the air allows us to provide a description of the main characteristics of the resulting liquid cloud, characterized by the vertical penetration of the liquid, its lateral expansion and the process of atomization.

1. . Introduction

Airtanker performances are usually tested with the cup & grid method (Suter 2000) developed by the USDA Forest service in USA and by the CEREN in France. Depending on drop conditions and systems, the resulting liquid deposit can present some irregularities resulting in zones of large concentration of product separated by zones of lower concentration offering a lower protection against fire (Plucinski *et al.* 2007). However, the dynamics of a fluid dropped from an airplane has received few attentions in the scientific literature with the development of simplified modelling (Amorim 2011; Legendre *et al*. 2014; Qureshi and Altman 2018), experiments in wind tunnel (Ito *et al*. 2010;) or numerical simulation (Rimbert 2003; Zhao *et al*. 2018). When considering airtanker the size of the delivery system doors is of the order of a meter, thus 3 orders of magnitude larger than millimetric injectors in combustion applications extensively investigated (Broumand and Birouk 2016), resulting in fragmentation and atomisation over a larger range of spatial scales making the experimental investigation more challenging. For that purpose, the use of Computational Fluid Dynamics (CFD) that allows to solve the liquid evolution after its exit from the tank can offer a promising tool. Indeed, all the information of the fluid evolution both in time and in space are available for a deep investigation. The objective of this work is to introduce the numerical approach proposed for the analysis of airtanker performance.

This study considers the aerial fleet of the French Civil Protection, more specifically the Canadair CL-415 and the Dash-8. These two airtankers are using different delivery systems. The Canadair CL-415 is made of two tanks incorporate in its fuselage and can drop a maximum of 6000 L of liquid. It has scoops on its belly, and can slide along a water surface to fill its tanks. The Canadair CL-415 is mostly used for a direct attack of the fire with water. The Dash8 is a fret plane reconverted with a tank attached under its belly and can drop a maximum of 10,000 L of liquid. Its tank is filled on the tarmac and this airtanker is used to provide line of

retardant in coordination with ground operations. A numerical approach based on CFD is used here to describe the liquid drop and atomization in air.

The paper is organized as follows. In section 2, the numerical method used for this study is presented. The liquid atomization and dispersion in air is then described in section 3.

2. Numerical methods

In this first approach we consider a Newtonian fluid (water) of density ρ_L and viscosity μ_L released at velocity U_L in air of density ρ_G, viscosity μ_G and relative velocity U_G. For that purpose, we solve the 3D unsteady Navier-Stokes equations for two incompressible and immiscible Newtonian fluids. Considering the Volume of Fluid (VoF) approach, the interface between the two fluids is obtained by solving the transport equation of the VoF function (or liquid volume fraction) α ($0 \leq \alpha \leq 1$):

$$\frac{\partial \alpha}{\partial t} + \nabla . \alpha v = 0 \quad (1)$$

The evolution of the fluids velocity v and pressure P are given by the conservation of mass and momentum

$$\nabla . v = 0 \quad (1)$$

$$\frac{\partial \rho v}{\partial t} + \nabla . (\rho v v) = -gradP + \nabla . \bar{\bar{T}} + \rho g \quad (2)$$

where t is the time, $\rho = \alpha \rho_L + (1-\alpha) \rho_G$ is the one-fluid density, $\bar{\bar{T}}$ is the viscous stress tensor expressed using the one-fluid viscosity $\mu = \alpha \mu_L + (1-\alpha) \mu_G$ and g is the gravity. The numerical solver of Star CCM++ has been used and turbulence has been modeled with a standard k-ε model. The meshes built for the simulations are described in the following sections. For each case, at least two meshes of different resolution have been considered in order to test the effect of the grid resolution on the results. The simulations have been performed on the regional Super computer CALMIP based in Toulouse.

The proposed numerical approach has two steps. First, CFD is used to describe the respective tank discharge in order to provide an accurate description of the discharge flow rate. For that purpose, the tank geometries of the CL-415 and Dash-8 have been designed and meshed. For the geometry of the Canadair's tank, a trimmed cell mesher has been used. The number of cells is around 810 000 and their size ranges from 1.10^{-2} m at the center of the tank to 5.10^{-6} m at the walls. For the geometry of the Dash tank, a polyhedral mesher has been used. The number of cells is around 1.9 millions, and their size ranges from 2.10^{-2} m at the center of the tank to 5.10^{-6} m at the walls. The resulting time evolution of the liquid velocity U_L(t) at the exit of the two tanks has recorder. The maximum velocity observed after 0.5s for the two tanks is around 6 m/s for the Canadair and 4.8m/s for the Dash8. The time to discharge the Canadair tank is around 1s while it is around 4s for the Dash8. This information is then considered for the second step to study the liquid drop and atomization in air. U_L(t) is imposed as inlet condition as described in the next section.

3. Liquid drop from Canadair CL-415 and Dash8

3.1. Domains and meshes

The second objective of the numerical approach is to simulate the dynamics of the liquid ejection, fragmentation and dispersion in air. The simulations are conducted in the frame of reference moving with the airplane. For each case, the air flow velocity is imposed at U_G=50 m/s at the domain inlet, which corresponds approximately to an operational speed for these aircrafts. Each belly of the studied airplanes has been meshed in an adapted domain. The domain is selected in order to observe the liquid fragmentation during its evolution in air while minimizing the size of the computational domain to reduce the number of cells. Several domain shapes have been tested and the selected ones are shown in Fig. 1 for the Canadair and the Dash-8.

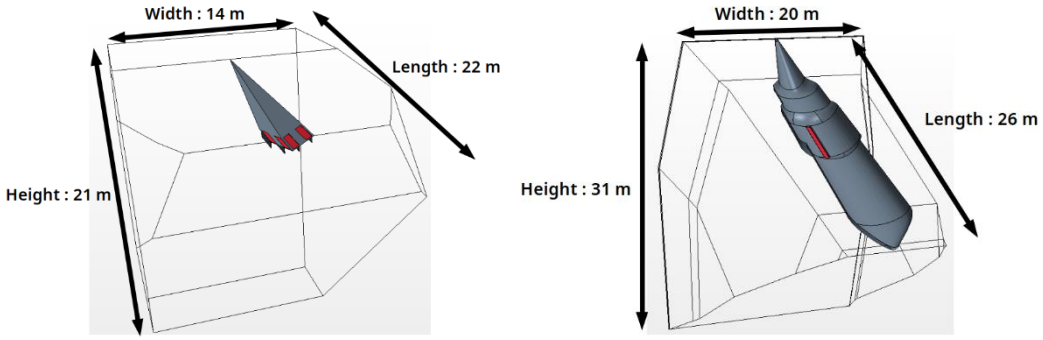

Figure 1 - Dimensions of the numerical domain. (left) under a Canadair belly with the four exits in red. (right) under a Dash8 belly with the exit in red.

Due to the complex geometry of the belly and the sharp angles on the corner of the domains, we have chosen in both cases a polyhedral mesher. The grid size ranges from 8.10^{-6}m at the walls to 8.10^{-2}m in the center of the domain. The total number of cells are 6.9 millions and 10.9 millions for the Canadair and Dash8, respectively. Parallel simulations made use of 180 and 720 processors, with computation CPU time of 18h and 40h, respectively. The liquid evolution in air is described in the following by considering its vertical penetration, lateral expansion and atomization. The liquid interface being tracked with the VoF model, we are able to select different values for the liquid volume fraction α for the liquid cloud inspection. "The liquid core" corresponds to $0.9 \leq \alpha \leq 1$, while the envelop of the liquid cloud can be described by considering $0.001 \leq \alpha \leq 1$.

3.2. Liquid vertical penetration

The liquid vertical penetration is defined as the evolution of the vertical distance *z* of the front of the liquid surface as a function of the streamwise distance *y*, red and black arrows in Fig 2, respectively. The shape of the corresponding curve indicates how the liquid front is deformed by the impact of the relative air flow. The liquid penetration *z* is compared for the Canadair and Dash8 in Fig. 2 at *t*=0.5s. As shown the penetration of the Dash8 and the Canadair are very close because the liquid velocity is of the same order of magnitude at *t*=0.5s. This confirm results observed for millimetric liquid jets where the penetration is controlled by the momentum ratio $q = \rho_L U_L^2 / \rho_G U_G^2$. Then the liquid penetration for the Canadair rapidly decreases and becomes less important than observed for the Dash-8.

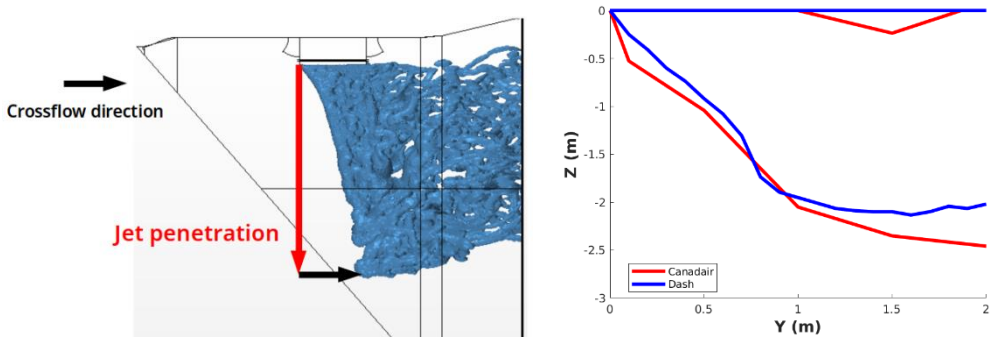

Figure 2 – Liquid penetration. (left) Visualization of the iso-surface of a=0.001 for the Dash8 at t=1s. (right) Comparison at t=0.5s of the liquid vertical penetration z as a function of the streamwise distance y for a Canadair (red) and a Dash8 (blue).

3.3. Liquid lateral expansion

The lateral (or transverse) expansion *x* is defined as the maximum width of the dispersed liquid as shown in figure 3. This parameter is important because its evolution controls the final width of the liquid deposit on ground. As shown in the figure, the lateral expansion is reduced for the Dash-8 compared to the Canadair, resulting in a more narrow liquid deposit on ground, and thus a higher liquid concentration.

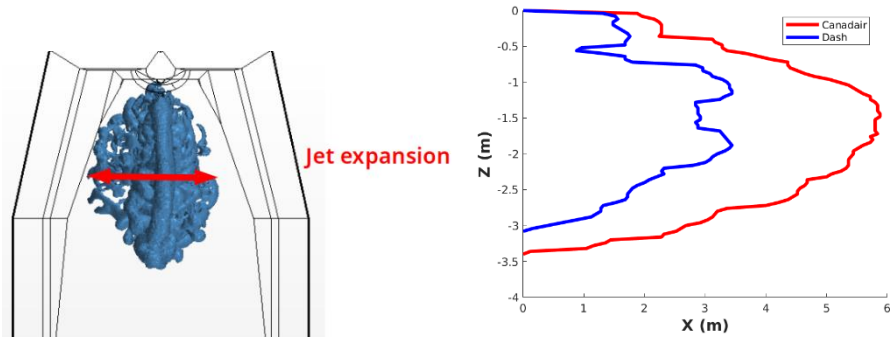

Figure 3 – Liquid lateral expansion. (left) Visualization of the iso-surface of a=0.001 for the Dash-8 at t=0.5s. (right) Comparison of the liquid lateral expansion x as a function of the streamwise distance y for a Canadair (red) and a Dash8 (blue).

3.4. Liquid atomization in air

One important aspect of the liquid evolution in air is related to the liquid fragmentation and dispersion. The objective is to finally obtain on ground a uniform liquid deposit. We consider here the evolution of the number and the size of produced droplets as illustrated by figure 4 with the observation of the formation of ligaments and droplets of large volume (several tens of cm). The shear stress from the air at the liquid surface tear off liquid ligaments, which are then fragmented into liquid volumes of different size. Their following dynamics may differ and result in different contributions to the ground pattern.

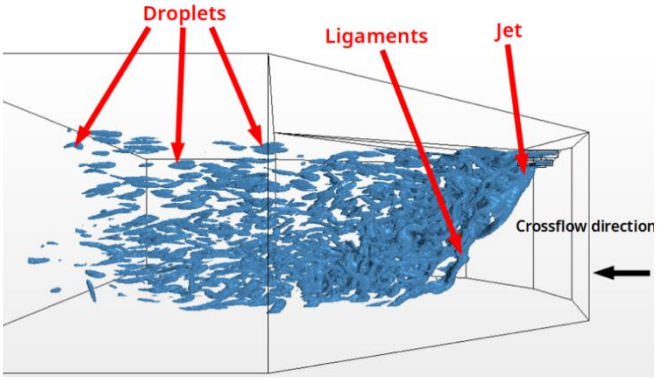

Figure 4 – Liquid atomization process for a Canadair CL-415 drop at t=1s. The iso-surface of the volume fraction is a =0.001.

A Matlab code has been developed to reconstruct the 3D liquid structures at each instant, to characterize their respective velocities and sizes. Figure 5 (left) reports the time evolution of the number of the identified liquid structures for the Canadair CL-415 for two thresholds for the detection: $\alpha \geq 0.9$ and $\alpha \geq 0.1$. The first one identifies droplets while the second one identifies volume of fragmented liquid in a more important number. Figure 5 (right) shows the distribution of droplets with their respective velocities for three different classes of size. The velocity components v_Z, v_Y and v_X, for the vertical, streamwise and transverse components, respectively, are reported. As shown the streamwise velocity is much larger because imposed by the relative airflow (50m/s), and the vertical velocity of lower magnitude is controlled by the velocity at ejection. The order of magnitude of the transverse velocity is around 1m/s, showing a significant liquid dispersion in the transverse direction.

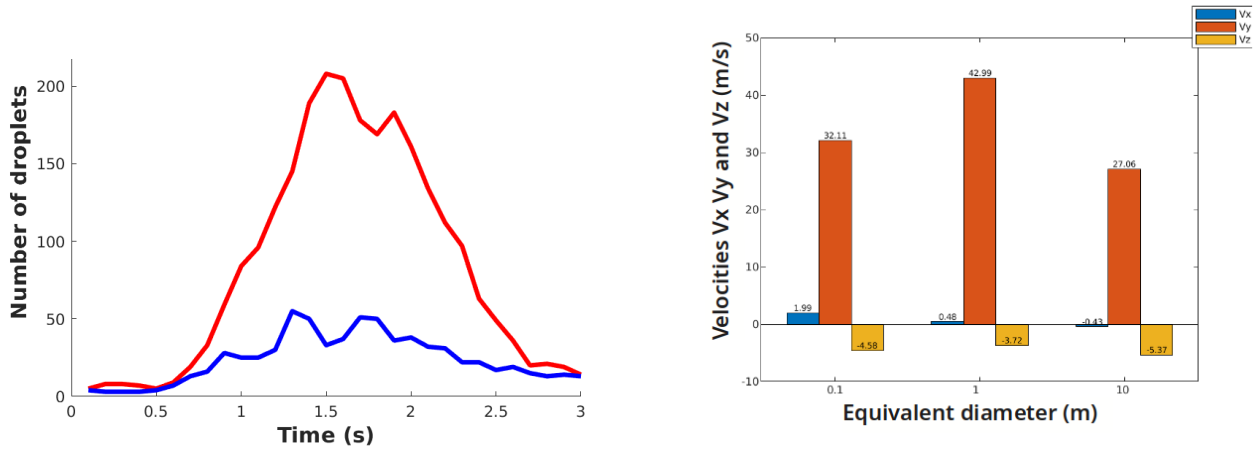

Figure 5 – Liquid fragmentation for the Canadair CL-415. (left) Time evolution of the number of identified fluid structures. Comparison for a detection using a liquid volume fraction a between 0.1 and 1 (red), and 0.9 and 1 (blue). (right) Repartition of the droplets with their respective velocities and size at t=1s for a detection with a volume fraction a between 0.1 and 1.

4. Conclusion

In this work, a numerical strategy has been proposed to deeply investigate the drop of a liquid from an airtanker. For this study, we have considered water drop from the Canadair CL-415 and the Dash-8. The 3D unsteady resolution of the liquid motion for both the liquid and the air allows us to provide a description of the main characteristics of the resulting liquid cloud. These liquid drops have been characterized through three main parameters: the vertical penetration, the lateral expansion and the structure of the liquid cloud during the atomization process. The next step will consist in extrapolating from these simulations the resulting liquid deposit on ground in order to make possible a direct comparison with the real tests performed using the cup & grid method.

5. Acknowledgments

This project is funded by Nîmes Métropole. It also benefited computation resources on the super computer CALMIP under the allowance 2020 – P20015.

Winter wildfires; field experiment; fire behaviour; physical fire model

Abstract

Field-scale experiments have been conducted on steep sloped terrains in Speluncatu and Letia, north-western and southern regions of Corsica. This work lies within the GOLIAT project framework and it was provided by the Fire and Rescue Service of North Corsica and the Corsican DFCI (Défense de la Forêt Contre l'Incendie) Group. This work reported high intensity fires propagating through shrub vegetation areas (*Genista Salzmannii*) lying between 60 cm and 85 cm. These sites were selected because of the density of the vegetation, the high slope angle values with a wind direction aligned with the main slope, which can generate a fire close to wildfire behaviour. A detailed experimental protocol is used in order to determine the propagation conditions and the fire behaviour using UAV cameras and heat flux gauges. In order to investigate the different phenomena encountered in these types of fires, numerical simulations were conducted using a complete physical fire model, based on multiphase formulation, namely FireStar2D. Numerical predictions were used to examine the fire front dynamics related to the fire's rate of spread and fireline intensity. Despite the unfavourable wind and humidity conditions, experimental results analysis showed that the fireline intensity was higher than 7 MW/m, which means that these fires fall into the category of the very high fire severity. Numerical results predicting the fire's rate of spread, fireline intensity and fire impact were in good agreement with the experimental data.

1. Introduction

Wildfires represent one of the main causes of the natural capital damage in the regions characterized by the Mediterranean climate like the Mediterranean basin, Chile, California, South Africa, and South and South-West of Australia. The Mediterranean climate is characterized by a high seasonality that can be summarized as hot, dry summers, and mild wet winters (di Castri 1981). Changes in climatic and weather conditions in these regions are one of the major reasons for the increase in wildfire risk, where they tend to be warmer and drier with more frequent heat waves (Benson et al. 2008; Sommers et al. 2011). Thus, in the presence of flammable vegetation, these climate conditions are prone to fire ignition and propagation. The real problem is that the Mediterranean region is witnessing a new wildfire context characterized by high intensity dangerous fires that present a real threat where their behaviour is unpredictable and uncontrollable.

In general, extreme fires are characterized by a high fireline intensity, and a high rate of spread, with the possibility of spotting or suddenly changing the fire behaviour (Alexander 1982). Firefighters know that beyond a threshold of 10 000 kW/m, a fire becomes erratic and incontrollable (Tedim et al. 2018). Indeed, fireline intensity has become one of the standard criteria by which firefighters estimate the difficulty of controlling a wildfire, and also the most appropriate descriptor of immediate fire effect on vegetation. The real problem is that extreme wildfire events tend to overwhelm suppression efforts, and cause lots of humans and economical

losses (Tedim et al. 2018; European Science & Technology Advisory Group 2020). This new context requires adapted policies to shift the focus from suppression to prevention that requires a good knowledge of the physical mechanisms governing fire behaviour like ignition, fire spread and fire impact. Many experimental fires have been conducted at the field scale (Cheney et al. 1993; Cheney and Gould 1995; Marsden-Smedley and Catchpole 1995; Vega et al. 1998; Viegas et al. 2002; Morandini et al. 2006; Mueller et al. 2018), but there are only few data for high intensity fires. Therefore, relevant experimental data on high-intensity wildfires is of paramount interest and experiments at the field-scale are highly valuable. Such fires are often subject to the vagaries of the weather and variations in the vegetation and land topography (Mulvaney et al. 2016). The interaction of these, and even with the fire itself, can result in seemingly capricious behaviour.

In this context the main purpose of this work is to present experimental data of the fires carried out at large scale fields, having important slopes, resulting in high fire intensities. This field-scale experiments have been conducted in two different regions of Corsica in March 2021 and 2022 and October 2021. In order to understand and investigate the different phenomena encountered in this type of fires, the experimental results are compared to the prediction provided by a complete physical model, namely FireStar2D (Morvan et al. 2009). In the next section the experimental method is described, followed by the modelling approach that was used. Finally, an analysis and a discussion of the relevance and the significance of the results are presented.

2. Experimental method

2.1. Site description and experimental protocol

Experimental sites were selected because of the structural homogeneity of the *Genista Salzmanni* vegetation with a coverage > 90%, and also because of the steep slopes that can generate high intensity fires. Slope values are obtained by measuring the coordinates of four poles positions as shown in Figure 1, using *a high-precision Global Navigation Satellite System (GNSS).* Concerning the experimental protocol, measuring devices were deployed in the field: Heat flux sensors and thermocouples were placed in the vegetation free area, video cameras were located on the sides of the plot, wind properties and ambient conditions were recorded using a weather station and fire propagation was recorded from above using a drone-mounted Visible-IR camera.

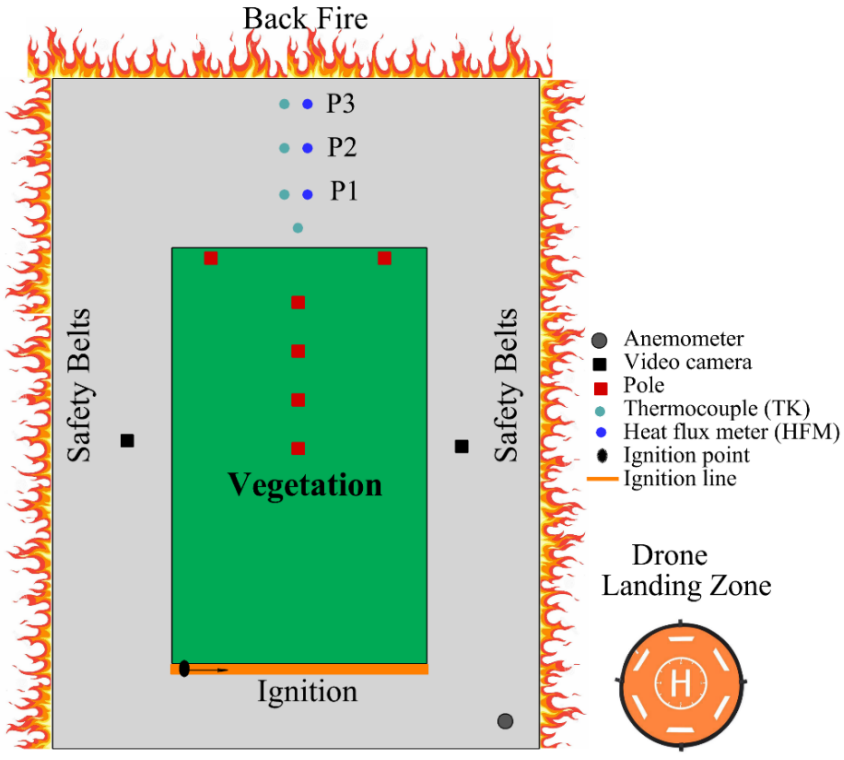

Figure 1- Schematic view of the experimental plot and the location of the measuring devices.

2.2. Characterization of the vegetation and meteorology

Physical properties of the vegetation are specific to the geographic area. Table 1 contains the main characteristics of the vegetation and meteorological conditions during the two burn campaigns. Fuel moisture content was evaluated after oven-drying fuel samples of dead and live fuel elements with diameter less than 6 mm at 60° for 48h (Awad et al. 2020). Fuel height was obtained after averaging 20 different measurements of the distance between the ground and the top of the vegetation. Ambient weather conditions were obtained less than 50 m away from the centreline of the plot, were a two-dimensional ultrasonic anemometer located at 3m above the ground recorder wind velocity and direction.

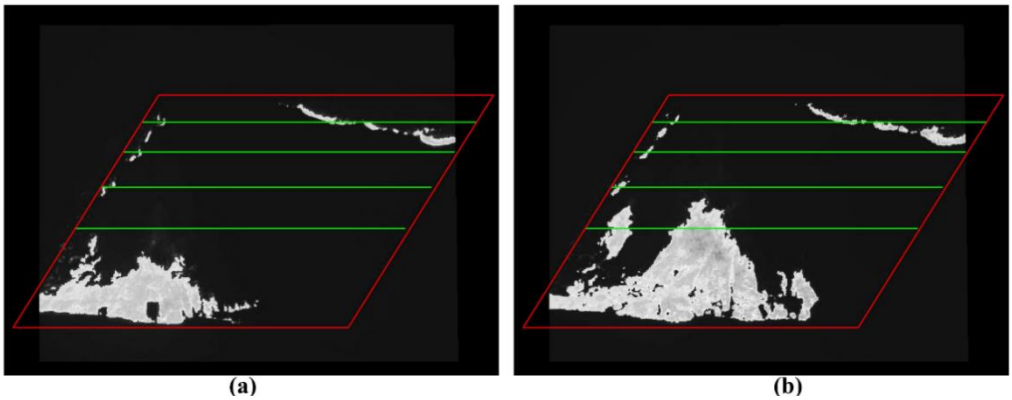
2.3. Experimental evaluation of fire parameters

2.3.1.ROS

The ROS represents one of the main parameters that characterize wildland fire behaviour. Fire front propagation is recorded using a drone located at a height of about 100 m, in order to determine the time needed by the fire to cross between the prefixed poles placed in the field. This allowed the evaluation of the ROS when the fire reaches a steady state propagation as shown in Figure 2.



(a) **(b)**

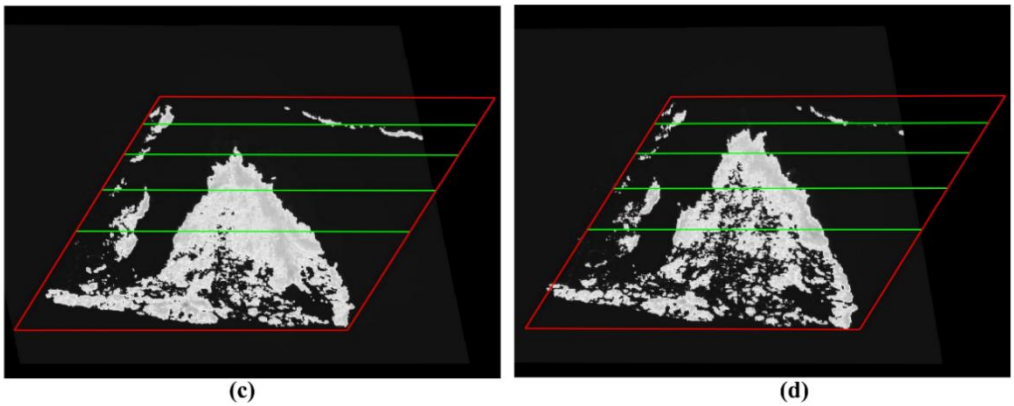


Figure 2- Infrared images of the fire front travel between equidistant positions (the green lines passing through prefixed poles) at different times.

2.3.2. Fireline intensity

Fireline intensity is estimated experimentally based on the Byram formulation: $I_{BExp} = \Delta H_c . w_a . ROS$, where $w_a = \mu\ \sigma$, with μ the percentage of the fuel weight actually consumed in the active flaming front and effectively contributed to fire propagation and ΔH_c represents the vegetation heat yield. This experimental method is often inaccurate because it is based on visual estimation of the burned vegetation during the fire (Alexander and Cruz 2020).

2.3.3. Heat fluxes

Concerning the fire impact evaluation, total and radiant heat fluxes were measured using three transducers (Figure 3) calibrated by the manufacturer in the range 0-200 kW/m^2, fixed on 0.5 m high supporting rods located at different positions from the upper limit of the vegetation plot.

Figure 3- Radiant and total heat flux sensors and thermocouple fixed on supporting rod and protected by aluminum foils.

3. Numerical method

3.1. Numerical modelling

Numerical simulations were conducted using a fully physical model, based on multiphase formulation, namely FireStar2D (Morvan and Dupuy 2001, 2004; Morvan et al. 2008, 2009; Morvan 2013; Awad et al. 2021). This model was validated from calculations carried out different scales and compared with experimental results, so it appears to be suitable for operational works since it provides valuable results and requires less simulation time compared to the 3D models. The main parameters of the computational domain and the vegetation layer is given in Figure 4. Both the solid-phase and the fluid-phase grids were characterized by cells sizes below the

radiation extinction length scale (Morvan 2011; Morvan et al. 2013) given by $4/s\beta$, in order to avoid fire extinction especially in the case of radiation-dominated fire propagation. Simulations were carried out for a 10 m open wind speed U_{10} by assuming a one-seventh power wind velocity profile. The domain inclination angle was specified through two non-zero components of gravitational acceleration: $g_x = -g\sin(\alpha)$ and $g_z = -g\cos(\alpha)$, where $g = 9.81$ m/s^2 is Earth gravity.

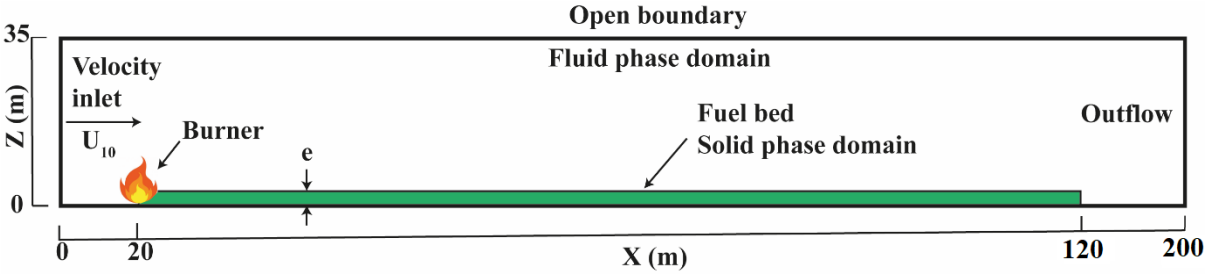

Figure 4- Computational domain and boundary conditions used in the 2D simulation of the experimental fire.

3.2. Numerical evaluation of fire parameters

3.2.1. ROS

Numerical prediction of the ROS using FireStar2D is obtained from the position of the pyrolysis front at the fuel-bed surface. It is the slope of the curve shown in Figure 5, once fire propagation had become steady.

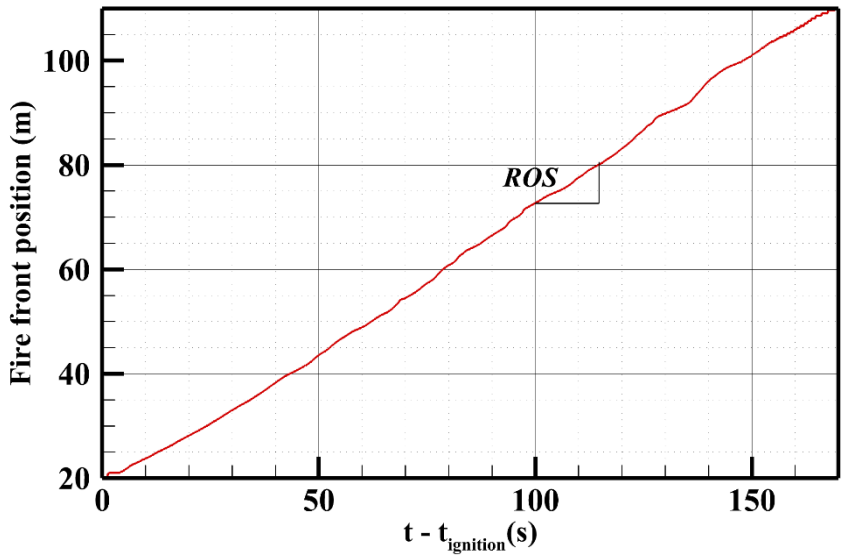

Figure 5- Position versus time of the furthermost point of the pyrolysis front at the fuel-bed surface obtained by FireStar2D after ignition at t = 30 s.

3.2.2. Fireline intensity

Numerical evaluation of fireline intensity is based on the following formulation: $I_{BNum} = \dot{m}\,.\,\Delta H_c$. Numerically, there is no difficulties to evaluate the vegetation degradation rate $\dot{m}$ as in the experimental method, where it is evaluated in this case by doing the summation of mass losses due to pyrolysis and charcoal combustion.

3.2.3. Heat fluxes

FireStar2D allows the evaluation of radiative and convective heat fluxes received by the targets, and assesses the heat fluxes recorded by the flux meters located ahead of the fire front. Convective heat flux is evaluated using Newton's law of cooling (Owen 2009), given by the following equation: $Q_{conv} = h_{\text{conv}}(T_0 - T_a)$, where $(T_0 - T_a)$ represents the difference between the gas mixture temperature and the target temperature (assumed to be the ambient temperature) and h_{conv} is the convective heat transfer coefficient.

4. Results and discussion

In this section, the results of the burns campaigns of Speluncatu and Letia will be presented. In this context, a comparison between experimental and numerical results concerning the ROS, and fireline intensity are shown in Table 2. Radiant and total heat fluxes received by the transducers located ahead of the vegetation area were registered when the fire front reached the end of the plot. During the burn campaign in October, backfires conducted by the firefighters to protect the burning zone were so close to the sensors, which have affected the measurements during fire. In this case, only heat flux measurements during March (2021) in Speluncatu and March 2022 in Letia were investigated, and compared with numerical predictions. Thus, time-averaged ratios (experimental and numerical) of the radiative heat fluxes to the total heat fluxes (i.e., convective and radiative), evaluated for the three flux meters are shown in table 3.

Table 2- Experimental and numerical results for the two burns campaigns in March and October.

	Speluncatu March (2021)		**Speluncatu October (2021)**		**Letia March (2022)**	
	Experimental	**Numerical**	**Experimental**	**Numerical**	**Experimental**	**Numerical**

Table 3- Time-averaged ratio of the radiative heat flux to the total one evaluated experimentally in March, and with FireStar2D at the different target positions.

	Speluncatu March (2021)		**Letia March (2022)**	
Position	**Q_{rad}/Q_{tot} FireStar2D**	**Q_{rad}/Q_{tot} Experiment**	**Q_{rad}/Q_{tot} FireStar2D**	**Q_{rad}/Q_{tot} Experiment**
1	0.796	0.845	0.91	0.94
2	0.993	0.971	0.95	0.99
3	0.961	0.93		

Concerning the rate of spread, results show an agreement between experimental and numerical evaluations with a certain difference may be due to numerical considerations: (1) numerically, a homogeneous fuel bed is considered; (2) in 2D simulations, the fire front is considered as a uniform thermal barrier, while the fire front is in reality structured as a succession of peaks and troughs, allowing for the air flow to find a way across it (Frangieh et al. 2020). Concerning heat fluxes evaluation, both numerical and experimental heat fluxes reported in Table 3, show the same order of magnitude for the calculated ratios and they both reveal the dominance of the radiation heat transfer contribution at different targets positions.

Concerning fireline intensities, results show that these fires conducted in winter and autumn are high intensity fires where fireline intensities (numerical and experimental) exceeds the value of 7 MW/m, despite the unfavorable conditions (low wind speeds, high FMC and RH). Knowing that the fireline intensity is an index to characterize fire severity rating, the considered fires fall then into the "very high" fire severity (Cheney 1981). Fire severity also depends on fire residence time (Cruz et al. 2013) related to the ROS. In general, due to the important slope, fire moves fast, and the residence time becomes relatively small, which does not allow reaching a high percentage of fuel consumption, especially for high fuel moisture content (>40%) (Dahale et al. 2013). These three experiments confirm the fact that a fire can exhibit a dangerous behavior of a high intensity fire, even in winter, because it occurs along a steep slope, and for a high fuel load especially for Letia experiment. The presence of a slope induces a pressure gradient between the burned and the unburned zone due to the changes in the capacity of air entrainment. The Coanda effect is a reaction to this pressure difference (Sharples et al. 2010), where the fluid flow tends to be attached to the propagation surface. Due to the important slope, the Coanda effect is reinforced by a component of the buoyancy force acting in the x-direction, g_x. Consequently, the flame becomes more inclined toward the ground, which increases the heat transfer between the hot gases and the unburned vegetation, resulting in a fire acceleration and higher intensity fire (Sharples et al. 2010; Sánchez-Monroy et al. 2019). In addition, fireline intensity estimation is directly related to fuel load that contributes to the fire front propagation. Thus, important values of slope angles and fuel loads can explain the high intensity fires obtained during these different campaigns despite the unfavorable propagation conditions.

Wildfire; Tactics; Perception; Incident commanders; Fire-fighting

Abstract

Unlike most regions with high-intensity wildfire potential, Sweden lacks specialized wildfire suppression organization. Instead, wildfire suppression is handled by highly decentralized and multitask municipal rescue services. This prompts the question how the incident commanders (ICs) perceive and interpret variation in fire behaviour and how they respond to wildfire incidents with regard to dispatching for initial attack and selecting tactics. To elucidate this, we exposed a spectrum of Swedish ICs to a questionnaire and round-table-exercises of different fire scenarios.

The informants had on average 13 years of experience as incident commanders and had on average managed 6 wildfires over the last 5 years. Despite minimal formal wildfire training the respondents showed reasonable consensus in rating of fire behaviour in response to fuels and weather, suggesting that their knowledge was built on personal and group experience. Likewise, they gave estimates on rate of production of hose-lays similar to published expert assessments from Canada. When exposed to a spectrum of fire scenarios, resource dimensioning by ICs was linearly related to the Canadian FWI-index, although most organizations did not have any preordained schemas or rules of initial dispatching resources to guide them.

Tactics employed were based mainly on accessing the fire from the nearest road and using direct attack with hose-line laid from the engine and water ferried on trucks. In a scenario where initial attack failed, suppression crews typically fell back on roads, which however would be breached by intense fire, and which also exposed the operation to risk of being outflanked. This response was in fact similar to that employed during a 2014 catastrophic wildfire in central Sweden and may indicate a fundamental flaw in tactics employed for large and intense fires.

The present structure of the Swedish wildfire suppression system developed during the second half of the 1900s and depends on rapid access to the fire by a relatively small number of firefighters. The study suggests a relatively high capacity for suppressing forest fires, despite that the organization is primarily rigged for other purposes and that ICs have minimal formal training in this area. Climate change-scenarios suggest longer fire season and more risk days in parts of the country, but the future wildfire scene may be even more sensitive to de-population and diminishing economic resources in heavily forested regions of the country.

1. Introduction

Swedish wildfires are handled by multipurpose rescue services organized at municipal level having extensive autonomy and no legally binding targets regarding resource levels or formal training of staff. Instead, the 290 municipalities (median population 16 300) are obliged to organize and pay for their fire protection, which should be capable of dealing with hazards based on a local risk assessment.

Wildfires constitute only a fraction of rescue services workload, the bulk being car accidents and structural fires. Most wildfires are easily contained, but some escape initial attack (annually 270 forest fires >0.5 ha and since 1996 a handful larger than 1000 ha (Sjöström & Granström, 2020). Fires are suppressed free of charge, but mop-up is the responsibility of the landowner.

Scandinavian climate-projections suggest increasing frequency of high-risk days (Yang *et al*, 2015). Future outcome will however depend also on preparedness and capacity of response organizations. Due to municipal

autonomy, no national wildfire-fighting doctrine or detailed tactics manual existed at the time of the study although a national guidance document was published in 2020 (Hansen *et al*, 2020). Here we elucidate perceptions of wildfire behaviour and tactics among Swedish ICs by interviewing and performing round-table-exercises of four wildfire scenarios from alarm to extinguishment.

Incident commanding typically evolve by deliberation/discussion/testing, but we focus on initial response and perceptions. Expert opinion has earlier been used to estimate fire-fighting variables e.g. situation-specific hose-lay production rates (Parker *et al*, 2007). The round-table-exercise scenarios presented operation pictures reflecting what an incident commander (IC) can encounter following an alarm call, and through this semi-realistic approach we elucidate normally concealed questions: Do ICs distinguish complexity levels regarding weather and other initial factors and does this reflect initial deployment? What tactics are employed, related to available resources and likely fire behaviour?

2. Methods

We interviewed 20 trained ICs with wildfire commanding experience from 8 municipalities (1-3 participants each). They were questioned regarding fire behaviour and suppression, e.g. estimated rates-of-spread (ROS) in two fuel-types given detailed weather (Figure 1) and hose-lay production rates, with/without simultaneous watering as well as individual experience/training and their organization's deployment capacity.

Scenarios spanned from simple (easily controllable) to complex (certainly escaping initial attack), based on weather, position, wind and access roads, containing at least one additional challenge (Table 1).

Table 1- Scenario weather and CFFWIS (Taylor et al., 1997) indices (ordered by increasing FWI-value, #-numbers refer to game chronology).

Case	**#3**	**#2**	**#1**	**#4**
RH (%)	48	42	33	31
Temperature (°C)	18	25	21	18
Windspeed (m/s)	1	2	3	6.5
FD-class	Moderate	Moderate	Very high	Extreme
FWI-value	11.4	16.4	22.4	35.3
DMC-BUI-DC	33-55-437	40–56–228	47–68–317	43–54–177
FFMC-ISI	88-3.9	89.9–6.1	91–8.0	92–18.6
Challenges	Poor road access	Steep slope impacts ROS/direction	Possible new head if flank not secured	Extreme conditions

Initial information offered: ignition time and point (on topographic maps), daily fire-danger (FD-) class (grouping FWI-values into e.g. *Moderate*=7-17; *High*=17-22; *Very high*=22-28 and *Extreme*>28) plus current weather (windspeed/direction, RH, temperature). Once the initial response crew arrived (30 minutes travel to nearest accessible road) burnt length/width and flame lengths was communicated and photos from real equivalent fires were presented, showing vegetation, smoke, flames etc. Fire behaviour was extracted from the Canadian FBP system (Taylor *et al*, 1997) using fuel type C-3 surrogating for *Pinus sylvestris*-dominated forests and S-1 for clear-felled areas.

Figure 1- Left: forest scenes (1-2) presented for grading potential fire-behaviour. Right: fire scenes (head - scene 1, backing – scene 2) for assessing ROS.

Informant knew they could ask for information they normally obtain from headquarters, such as CFFWIS indices or weather variables. CFFWIS was nationally employed 1996, but without nation-wide supplementary training efforts.

All scenarios occurred on forest-company land. If called for, companies could send a mop-up crew of six with basic equipment (shovels, pump, 500m hose) within 2 hours.

All decisions/actions were logged including respondents' comments. Tactical decisions (attack routes, water-sources, and hose-lays/crews/vehicles) were noted on maps. Scenarios were sequentially run as semi-directed interviews (Huntington, 2000) with follow-up questions upon ambiguities. E.g., if ICs asked headquarters for current weather prognosis, the facilitator first asked for which variables before delivering.

3. Results

3.1. Training

IC experience averaged at 12.6 years and 5.8 wildfire deployments last five years. Their average wildfire training during initial schooling was 4.6/2.4 days of theory/practice, without live fire-training in field. 44% had follow-up training averaging <1 day over five years. One informant had participated in prescribed burning.

3.2. Perceptions of fire behaviour and production rates

Respondents overestimated ROS in both fire scenes (Figure 1, A-B) while underestimating potential ROS in forests under given weather-scenarios (Forests 1-2) (Table 2). When asked in which forest (Figure 1-left) fire would spread the fastest, all identified Forest 1 and highlighted differences in fuel structure as main cause. Some specifically commented on structure and species ("*more lichens"*, "*Calluna dwarf shrubs"*, "*dead branches lower to the ground*").

Table 2- Informants answers concerning ROS and hose-line construction.

Question	**Respondent's average (range/σ)**	**Reference answer**
ROS: Fire scene A	5.4m/min (1-15)	2-3m/min (observed)
ROS: Fire scene B	1.7m/min (0.5-5)	~0.5m/min (observed)
Most fire intensity potential (1/2), Figure 1	Forest 1 (everyone)	1
ROS[1]: Forest 1 (RH=30%, Wind=5m/s)	12.7m/min (2-25)	25m/min (FBP C-4)
ROS[1]: Forest 2 (RH=30%, Wind=5m/s)	4.9m/min (1-15)	15m/min (FBP C-3)
Advance rate: 5-person crew laying a 500m 42mm hose-line, from engine, without watering.	24.9m/min (σ=12.3)	
As above including watering of hose	13.1m/min (σ=6.8)	
Advance rate: additional extension of 500m without ATV	8.6m/min (σ=5.5)	
Secure duration: wet-line a hot, windy day	1.6hrs (σ=0.7)	
Advance rate: re-wetting 500m	17.8m/min (σ=15.5)	
Advance rate: 2-person crew mop-up 5m wide belt	5.6m/min (σ=5.8)	

[1] After two precipitation-free summer weeks.

Production rates constructing hose-lays were relatively consistently estimated, ~25 min for 500m from the engine without watering and twice the time if watering. A wet-line was considered secure for nearly 2h (1-3h) on hot-windy days. Mop-up of a 5m belt along established hose-line: ~6m/min after prolonged drought (Table 2).

3.3. Deployment vs fire-danger

Initial deployment varied with fire-danger (indices/weather) and almost linearly with FWI-values (Figure 2). Typically, minimum 2 "units" (2 officer + 8 firefighters) from two different stations were deployed, each travelling with one engine (~3m^3, one pump and 500m hose), one tanker (8-10 m^3) and IC riding a separate vehicle. For severe cases, 1-2 ATVs were brought on trailers.

This basic initial deployment was increased by adding units. Initial deployment varied between respondents but even for the most severe scenario 45% initially deployed only two units, immediately requesting substantially larger forces once shown pictures of the smoke column.

Upon alarm, station officers contacted landowners and surveyed available helicopters. For case #4, helicopters were called early on and 1/3rd requested 40-50 people from the military. One informant had a local system how to mix these (1+1) with professional fire-fighters.

Generally, deployment sizes relied on IC judgement, based on FD-class or windspeed but two different municipalities had independently developed their own rule-based dispatching schema using FD-class for initial crew sizes.

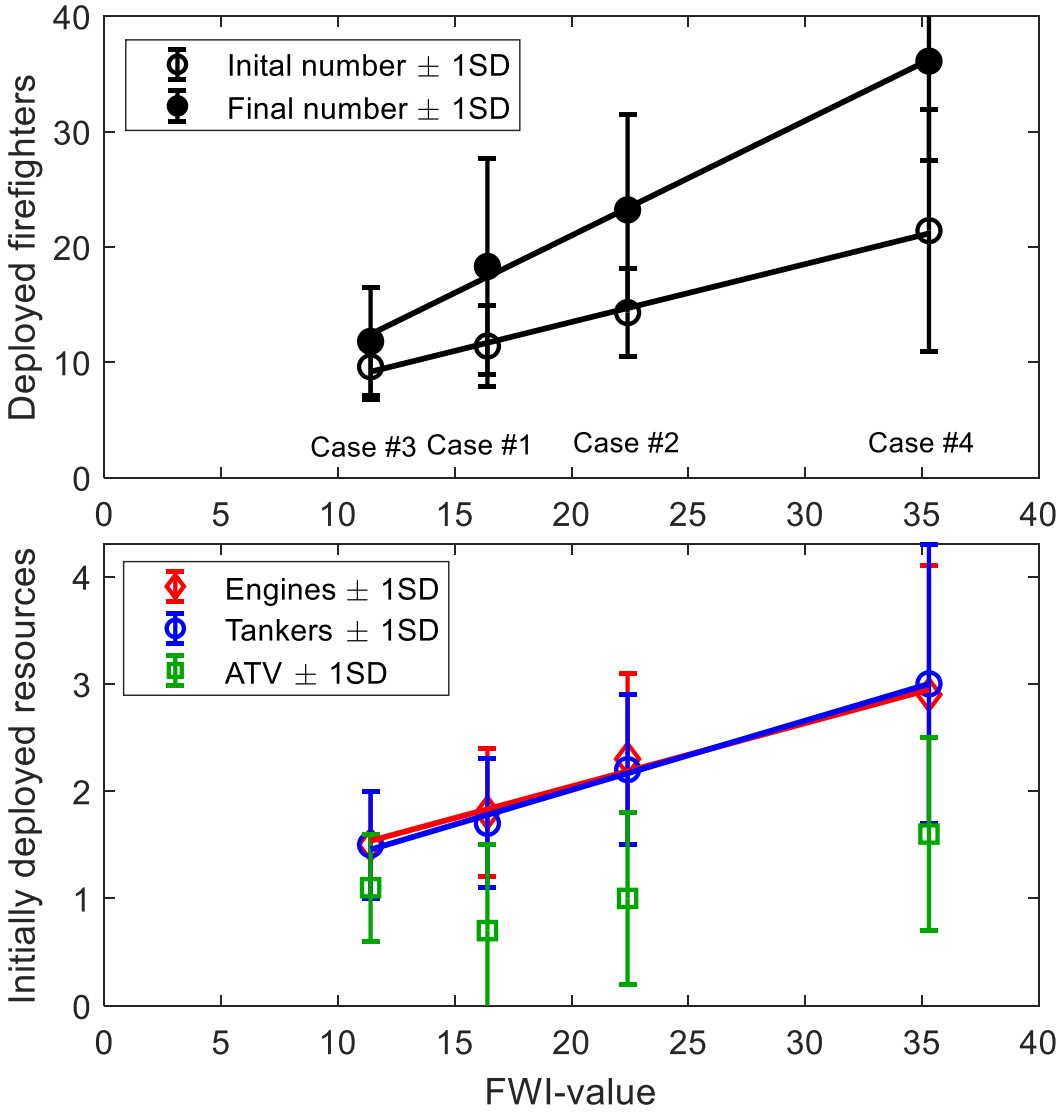

Figure 2- Initial resource deployment against scenario FWI-value (average ±1 standard deviation).

3.4. Suppression tactics

Standard procedure was driving to closest road position, sending 1-2 foot-scouts (sometimes with a drone), and start hose-laying from the engine once the fire location was verified (first 76-63mm hoses, transitioning to 42-38mm). Frequently, informants kept one unit at a distant staging point until engaging them from another direction. When fire was far from road access (2km, case#3), ATVs were often used for situational awareness and material transport. Hose-lay water supply was typically ferried by tankers from nearby accessible lakes, but occasionally smaller pumps were placed in nearby streams/lakes to feed hose-lines locally. Only two respondents used swatters/brooms on low-intensity backing and flanking flames. Landowner crews were not involved in the suppression stage.

Most respondents recognized/noted challenges such as slope-influence on ROS, or the danger of not controlling a flank early, allowing flames to circumvent a lake forming a high-intensity head fire. However, for the most severe scenario (#4), most respondents concentrated on the fire head, without securing the flanks from an anchor point. On this fire several respondents also worked exclusively along roads with hose-lays/watering from vehicles, setting up control lines far from the fire perimeter, thus adding risks in case of wind-shifts. As the high-intensity head reached the prepared lines, only two informants acted to control spot-fires. Two informants discussed expanding fire breaks using burn-out operations, but only one had relevant prior experience.

Mop-up time varied significantly, between 1-12h (case#1), after which landowner crews continued. Typically, hose-lines, pumps were precautiously left on site.

4. Discussion

Even in structured, hierarchical systems as in USA, variations occur among IC's risk perception (and McBride, 2013) but in decentralized Swedish organizations the competence is highly depending on individual- and group- field experience, developed through local rather than national organizational cultures. Most ICs had only a few days of formal theoretical/practical wildfire suppression instructions. Parallel to collective fire-knowledge in regions of active fire-use in land management (Johansson *et al*, 2012) the respondents did, however, exhibit considerable consensus in perception and judgement, suggesting reasonable degrees of field knowledge.

Initial deployments were rarely rule-based but depended on intuitive scaling of resources according to perceived fire behaviour, but with a two-units-minimum deployment. Most likely, ICs primarily based decisions on the 6-grade FD-class since few referred to FWI-values or its subcomponents. However, windspeed was also considered a separate risk factor and, on site, the colour and size of smoke columns were important signals.

Due to budget constraints, initial resources are weighed against the perceived risk of escaping initial attack (Lee *et al*, 2013), particularly so for helicopters, primarily called from the private sector (military helicopters are occasionally available at no cost for municipalities). Already, rescue service costs are 4X higher per capita in rural compared to urban regions (Anon., 2014). Another factor mentioned was resource conservation, to buffer for additional emergencies within the municipality.

Line construction rates have never been issued or discussed among Sweden's fire-fighting community, but our estimates were on par with previous Canadian results (Hirsh *et al*, 1998; 2004) and therefore one-crew hose-laying at 17m/min is a reasonable estimate for operational guidelines and modelling (Duff and Tolhurst, 2015). Reliable rates for hose-laying and re-wetting are important particularly as these often become limiting factors when fires escape.

The standard tactic of ferrying water by tanker is potentially vulnerable. First, the typical 76mm hose-lay from an engine means that its $3m^3$ capacity is emptied already by filling the first 660m. Then, to supply four nozzles implies one tanker (~$10m^3$) arriving each 30 minutes. Thus, one stationary engine and two rotating tankers can feed a hose-lay continuously but, will tie-up at least half of two-unit crew of 10.

Once fires were reached, the crews mostly proceeded to circle them close to the perimeter but sometimes well ahead of the fire, most evident for the worst-case scenario with high ROS and elongated perimeter. Here, no flanks were secured from safe anchor points, inviting outflanking risks. Further, strategies for controlling spot-fires were not planned-for. In fact, this scenario was based on a disastrous fire 2014 with similar response (Anon., 2015), suggesting results are indicative of typical response in case of fast-spreading and intense fires.

Time-to-initial-attack (median 25 minutes, 75% <30 minutes) vary greatly with population density within Sweden, and directly relate to likelihood of escape (Sjöström and Granström, 2020). The present-day system with few professional fire-fighters relies on Sweden's dense forest-road network (average distance <500m (1990), (Anon., 1991)). Road density correlates positively with fire occurrence and negatively with burnt area (Pinto *et al*, 2020). Median driving distance is 15 minutes and with 500m hose-lay within 20 minutes two standard 1+4-units may in fact be adequate for suppressing most low-intensity fires.

Though mostly adequate (89% of forest fires <0.5ha (Sjöström and Granström, 2020)), high-ROS or intense fires can quickly overwhelm such small forces. Even with helicopters, substantial ground crews are needed to secure perimeters. There are few stand-by firefighters in rural regions (Lindblad *et al*, 2015) and a deployment of as few as 40 fire-fighters (Case#4) drains resources over a large area. Additionally, tactics are vulnerable, e.g. relying on roads as fire breaks without burning off fuels ahead. This is, however, expected given that ICs seldom have been trained for or experienced complex wildfire scenarios.

Eruptive fire; physical model; fire induced wind;

Abstract

Eruptive fires are one category of extreme fire behaviour. They are characterized by a sudden and unpredictable change in the fire behaviour which represents an extreme danger for people involved in firefighting. The major point is about the mechanism that turns a usual fire behaviour into an eruptive fire behaviour. Among the different explanations found in the literature, the pioneering interpretation consisting in a feedback effect caused by the convective flow induced by the fire under wind and/or slope conditions, has never been disproved with an example of fire accident. The main goal of this work lies in proposing a physical modelling of this fire induced wind. This modelling attempt is derived from the brand-new version of the Balbi model, which is a simplified physical model for surface fires at the field scale that explicitly depends on the triangle of fire (fuel bed, wind and slope). This work is a first step to the modelling of fire eruption. The model tries to represent accurately the acceleration of the fire rate of spread propagating on different sloped terrain under no-wind or weak wind conditions. It is tested against three sets of experiments carried out at the laboratory scale without external wind and against a high intensity experimental fire spreading on a steep sloped terrain and conducted under weak wind conditions in the north-western of Corsica. Some statistical tools are used to compare predicted and observed rate of spread (NMSE, Normalized Mean Square Error and MAPE, Mean Absolute Percentage Error) and to understand the model's under-predictions or over-predictions trends (FB, Fractional Bias).

1. Introduction

A small part of wildfires (less than 2 per cent) (European Science & Technology Advisory Group 2020) has the most significant ecological and socio-economic impacts. These so-called extreme wildfire events ((Tedim *et al.* 2018) are characterized by very high fire intensities which lead to ineffective suppression capabilities. Eruptive fires are part of these extreme fire behaviours. If those eruptive fires are also known in the literature as flashover (in enclosed spaces, NFPA 921, 2011), blow-up (Butler *et al*. 1998) or generalized blaze flash (Chatelon *et al*. 2014), some slight differences remain between each definition. The definition of fire eruption has been proposed and characterized by Viegas (2004). It describes a fire with a sudden acceleration of the head fire rate of spread (ROS) in a very short time lapse with or without any changes in the topography, in the environmental conditions or in the vegetal stratum characteristics.

This phenomenon is very dangerous for firefighters and civilians because of its difficulty to be predicted and anticipated. Viegas and Simeoni (2008) reviewed the major mechanisms supposed to be the cause of a fire eruption triggering. For instance, from the firefighters point of view, an important release of VOCs (volatile organic compounds) is the main reason for a fire to erupt. Indeed, when a fuel is severely stressed, it releases VOCs that ignite a a lower temperature than the usual ignition temperature. The VOC's theory consists in assuming that a fire eruption is mainly caused by this gas release and is widely used in the literature (Chetehouna *et al*. 2014, Courty 2012). But the example of the Kornati fire accident (Viegas *et al*. 2008) refute this argument with a fire spreading across a grass fuel bed.

The pioneering interpretation proposed by Viegas (2004) consists in the presence of an air flow created by the fire itself which may significantly lead to a change in the fire behaviour, particularly for fires spreading upslope. The role of this induced convective flow is to bring fresh air and then oxygen to the flame in order to support the combustion. Viegas and Pita (2004) observed the importance of this air movement on the behaviour of fire spreads in canyons (at the laboratory scale and also during the field scale Gestosa fire experiments) and the accident occurred in Freixo de Espada-a-cinta (Viegas 2004) also support this interpretation.

So, a good modelling of the fire induced wind is the first step before trying to give a fire eruption physical model. In this work, the explanation provided by Viegas is selected and a first attempt of a physical modelling of this induced wind is proposed. It is based on a brand-new Balbi model formulation derived from (Chatelon *et al*. 2022) tested against more than 300 shrubland and grassland fires at the field scale with a very good agreement. This induced wind modelling is supposed to provide a good representation of a fire spreading upslope without wind (or with weak wind conditions). The model gives a new expression of the ROS that takes into account the pronounced acceleration of the fire spread with the increasing slope. It is tested against three different series of laboratory fire experiments (Butler *et al*. 2007, Liu *et al.* 2014, Liu *et al.* 2022) conducted without wind and in which the terrain slope angle varies ranges from 0 to 35° and against a field scale experimental fire conducted in Corsica across shrub species under weak wind and steep slope conditions (28°).

2. Physical modelling of the fire induced wind

2.1. Main equations of the new Balbi model

The Balbi model presented by Chatelon *et al.* (2022) calculates the ROS as the sum of three components (see fig. 1): (1) the radiation from the free flame F1 on the unburnt fuel (R_r), (2) the radiation from the flame base (the fuel burning particles area, R_b) and (3) the convection inside the vegetal stratum (R_c). The main equation of the model is the following:

$$R = R_b + R_c + R_r \tag{1}$$

The flame F2 is due to the flame base radiative and convective heat fluxes. All details and nomenclature can be found in (Chatelon *et al.* 2022).

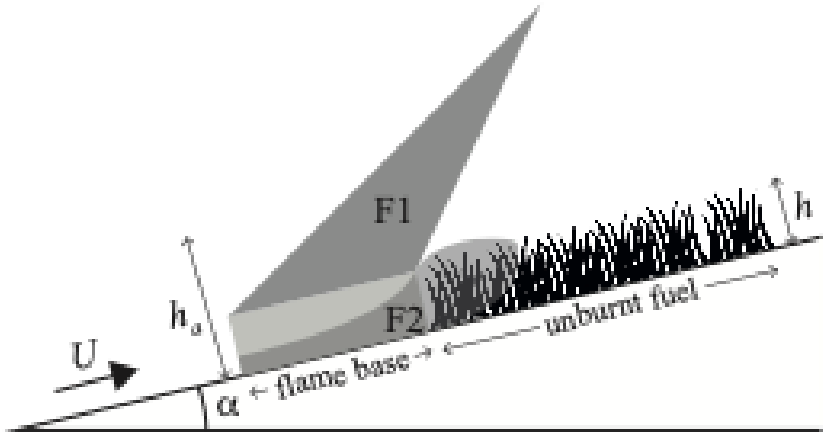

Figure 1- An idealized representation of the flaming zone combustion profile

As the convective and free flame radiative contributions to the ROS (R_c and R_r, see eq. 1) depend on the ROS, an iterative method is necessary to obtain the ROS. So, in order to obtain a formulation which is easier to implement into real time decision making tools, a new version of the Balbi model is developed in order to avoid the use of iterative methods for the calculus of the ROS. This new version is also presented in this IX ICFFR conference. In brief, the main equation (1) is replaced with the following:

$$R = \max(R_b + R_c\ ;\ R_r) \tag{2}$$

Where the component of the ROS due to the flame base radiative heat flux (R_b) is still defined thanks to a Stefan-Boltzman Modelling:

$$R_b = \min\left(\frac{S_t}{\pi}, 1\right)\frac{BT^4}{\beta\rho_v q} \quad (3)$$

And where the two other components are the following:

$$R_c = \min\left(\sqrt{\frac{b\,U}{K}}, b\,U\right) \quad (4)$$

$$R_r = s\,\frac{r_{00}}{u_0}\,(2A-1)(U-\,U_r) \quad (5)$$

If the drag forces law (K) is still a linear function of the packing ratio (β), the modelling of the radiative coefficient (A) and the upward gas velocity (u_0) are multiplied by a term τ_b which represents the fuel burning rate:

$$A = \min\left(\frac{S}{2\pi}; 1\right)\frac{\chi_0\Delta H}{4q}\,\tau_b \quad (6)$$

$$u_0 = 2\frac{(s_t+1)}{\tau_0}\,\frac{\rho_v}{\rho_a}\,\frac{T}{T_a}\min(S, 2\pi)\,\tau_b \quad (7)$$

Finally, the convective coefficient b is modelled as follows:

$$b = a\frac{\Delta H}{q\,\tau_0}\sqrt{\frac{s}{\beta}} \quad (8)$$

2.2. Modelling of the fire induced wind

As the flame needs fresh air for the combustion, it is assumed that this fresh air enters into the flame on a given height (denoted by h_a, see fig. 1). So, a simplified mass balance leads to:

$$\rho_a\,h_a\,U = s_t\,L\,\dot{\sigma} \quad (9)$$

After some simplifications, eq. 8 yields the expression of the fire induced wind:

$$U\ = \frac{R}{p} \quad (10)$$

Where p denotes the term:

$$p\ = h_0\,\frac{h_a\,h\sqrt{\beta}}{s_t\,\tau} \quad (11)$$

When the packing ratio β increases, there is less and less fresh air that could enter the flame base and then the given height h_a needs to increase. Thus, it is assumed that the given height is proportional to the square root of the packing ratio and the fuel height (h):

$$h_a\ = h_0\,h\,\sqrt{\beta} \quad (12)$$

Where h_0 is a scaling factor.

Finally, using eq. 12, the coefficient p is defined as follows:

$$p\ = h_0\,\frac{\rho_a}{\rho_v}\,\frac{1}{\sqrt{\beta}} \quad (13)$$

This modelling is possible thanks to the new formulation of the Balbi model whose main equation is defined by eq. (2).

2.3. The coupled model

Note that under zero wind conditions or when the ambient wind is not strong enough, the external wind U in eqs 2—8 is replaced by the fire induced wind.

When the slope angle (α) increases, the induced wind U increases as well and then the flame base cools. Consequently, the upward gas velocity u_0 decreases and the flame tilt angle γ increases. It therefore leads to a decrease in the vertical heat losses of the convective flow and to an increasing convective coefficient b through

the scaling factor *a* (see eq. 8). From a physical point of view, it means that the free flame F1 flattens the flame F2. So it is assumed that the scaling factor *a* linearly depends on the terrain slope angle α.

As the combustion rate τ_b decreases, the radiative coefficient *A* decreases as well and turns smaller than ½. Therefore, the free flame radiation can be neglected and $R_r = 0$. Finally, eq. 2 yields:

$$R = R_b + R_c \tag{14}$$

The expression of the ROS can be expanded according to two different induced wind regimes:

(1) For low induced wind values, $R_c = b\,U$ and using eq. 10:

$$R = R_b + b\,U = R_b + b\,\frac{R}{p} \tag{15}$$

Eq. 15 allows the characterisation of the ROS *R*:

$$R = \frac{R_b}{1-\frac{b}{p}} = \frac{R_b}{1-\frac{\alpha}{\alpha_\infty}} \tag{16}$$

Where α_∞ is a critical slope angle related to some fuel characteristics and model parameters:

$$\alpha_\infty = h_0\,\frac{\rho_a}{\rho_v}\,\frac{1}{\sqrt{s}}\,\frac{q\,\tau_0}{a_0\,\Delta H} \tag{17}$$

(2) For high induced wind values,

$$R = R_b + \sqrt{\frac{b\,U}{K}} = R_b + \sqrt{\frac{b}{p}\,\frac{R}{K}} \tag{18}$$

After some calculations, eq. 18 yields:

$$R = \frac{\alpha}{\alpha_\infty\,K} \tag{19}$$

The final expression of the ROS is obtained in merging eqs. 16 and 19:

$$R = \begin{cases} \frac{R_b}{1-\frac{\alpha}{\alpha_\infty}} \;if\; \alpha < \alpha_\infty \\ \frac{\alpha}{\alpha_\infty\,K} \;if\; \alpha \geq \alpha_\infty \end{cases} \tag{20}$$

3. Numerical results and discussion

The model given by eq. 20 is tested against three sets of laboratory experiments conducted under zero-wind conditions. The set of experiments conducted by Butler *et al*. (2007) aims at studying the fire spread on slope. An excelsior fuel bed with three different heights (and packing ratios) and six different slope angles ranging from -17° to 43° were set. The second set of experiments was performed by Liu *et al*. (2014). Fires spreading on 10 different values of the slope angle (from 0 to 32°) across a dead pine needles fuel bed were monitored. The last set of laboratory experiments carried out with the same pine needles fuel bed is composed of four series of fires spreading upslope (slope angle ranging from 0 to 40°). Each series differs from another by the dimensions (the height) of the lateral walls of the bench.

All the ROS measurements in the three sets of experiments suggest two different types of fire behaviour. Up to a specific value of the slope angle (which is different from one experiment to another), the fire growths slowly with a very low to moderate ROS. Beyond this threshold value, a dramatic acceleration of the ROS is observed.

The numerical results obtained by the proposed model against the experiments performed by Butler *et al.* (2007), and by Liu *et al.* (2014, 2022) are plotted in figs. 2 and 3, respectively. Note that Butler and his co-authors (2007) calculated the normalized ROS (ratio between ROS and ROS0, obtained for zero-wind and zero-slope) in all their set of experiments.

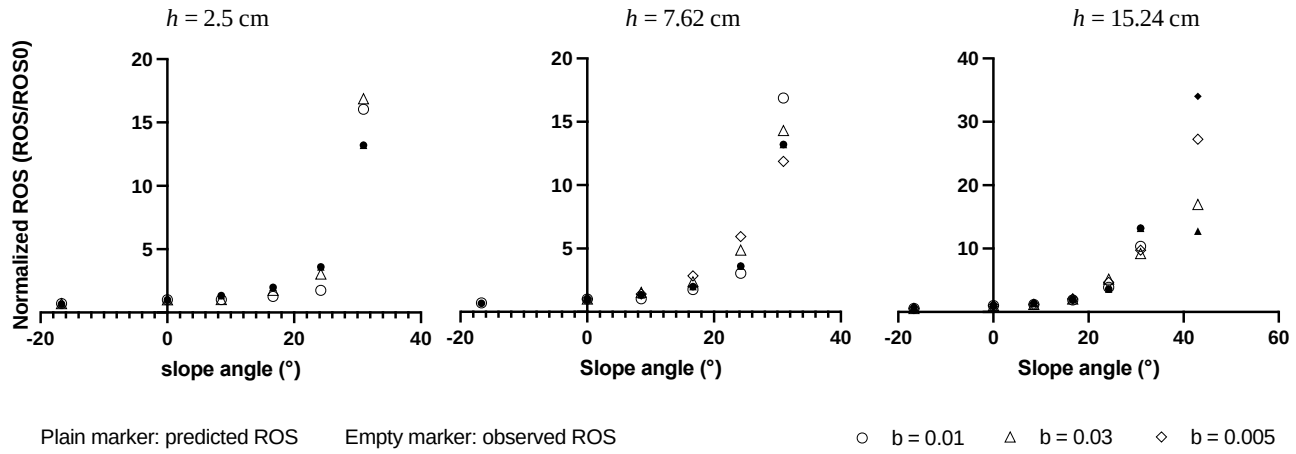

Figure 2 – Comparison between observed ROS (empty markers) and predicted ROS (plain markers) for three different fuel heights (2.5, 7.62 and 15.24 cm) and three different packing ratios (0.01, 0.03 and 0.005) in the set of experiments carried out by Butler et al. (2007)

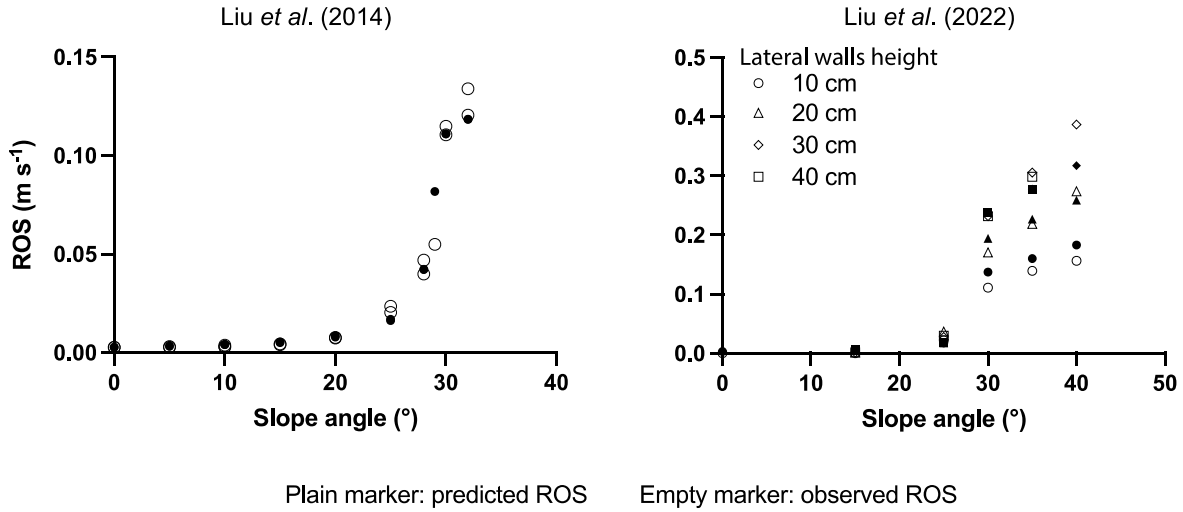

Figure 3 – Comparison between predicted ROS (plain markers) and observed ROS (empty markers) in the set of fire experiments conducted by Liu et al. (2014) (left plot) and by Liu et al. (2022) (right plot). Liu et al. (2022) measured several propagations with only a change in the height of the lateral walls of their experimental bench.

The agreement between observed and predicted rate of spread is assessed using three statistical tools whose results are presented in table 1. Both Normalized Mean Square Error (NMSE) and Mean Absolute Percentage Error (MAPE) are useful for estimating the overall deviations and the Fractional Bias (FB) allows to understand if a model shows under-predictions or over-predictions. An ideal model is obtained for a zero NMSE, MAPE and FB.

Table 1- Agreement between observed and predicted rate of spread estimated with three statistical tools (NMSE, Normalized Mean Square Error, MAPE, Mean Absolute Percentage Error and FB, Fractional Bias)

Set of experiments	*NMSE*	*MAPE*	*FB*
Butler *et al*. (2007)	0.25	18%	0.08
Liu *et al*. (2014)	0.04	16%	0.07
Liu *et al*. (2022)	0.02	58%	0.29
Winter high intensity fire (unpublished)	0.03	20%	0.18

According to figs. 2 and 3, the ROS predicted by the proposed model seems to match well the trends of the ROS against slope angle. The slow increasing of the ROS for small values of the slope angle and the ROS acceleration

are correctly reproduced. This visual impression is confirmed by the error results (table 1) with low NMSE and MAPE, except for the last set of laboratory experiments. Indeed, 58% is a quite high value for the MAPE but this result is mainly due to the two first values (where the slope angle is equal to 0° and 15°) with a practically zero ROS (order of magnitude smaller than a millimetre per second). If these two first values are removed from the calculation, the MAPE falls to a value of 17%.

The model has also been tested against an experimental shrubland fire conducted in the north-western of Corsica in march, 2021. The plot was approximately 150 m (length) x 30 m (width) and was burnt on a steep sloped terrain (slope angle ~ 28°) upon winter environmental conditions (ambient temperature ~ 6°C, weak wind velocity ~ 1.3 m s^{-1}). This fire fell into the very high fire severity (Cheney, 1981) with a fireline intensity close to 10 MW m^{-1} and a very fast ROS (0.45 m s^{-1}). As the Balbi model (Chatelon *et al.* 2022) does not include any fire induced wind sub-model, it provides poor results with a predicted ROS equal to 0.1 m s^{-1}. The ROS calculated with the proposed induced wind model (eq. 20) is equal to 0.54 m s^{-1} and is clearly a good approximation of the observed ROS. Indeed table 1 provides small errors (NMSE = 0.03 and MAPE = 20%).

The three sets of laboratory experiments exhibit the same ROS behaviour, consisting in a very slow increase of the ROS up to a threshold value of the terrain slope angle. Below this threshold value, without external wind, the fire spreads as on flat terrain, where the main heat transfer mechanism is the radiation from the fuel burning particles area. Beyond this value, the ROS highly accelerates in an exponential way for Liu *et al.* (2014) and Butler *et al.* (2007) or in a quite linear way in the experiments carried out by Liu *et al.* (2022). The slope angle threshold value seems to be different for each fire experiments series but approximately ranges from 20° to 30°. For these steep slopes, the flame is more tilted on the ground and creates a convective airflow in order to compensate the draft caused by the hot gases moving upwards. This feedback accelerates the ROS and in certain cases, an equilibrium is not obtained, causing a fire eruption. The proposed model (eq. 20) suggests two different behaviours splitted by a threshold slope angle calculated with the model. The numerical results shows a quite good agreement for these sets of laboratory experiments and for the winter fire at the field scale.

4. Conclusion

An accurate modelling of the convective flow induced by a fire spreading on a steep sloped terrain is the first step towards the modelling of eruptive fires. This work is a first attempt to give a physical formulation to this fire induced wind phenomenon. If the tests against three sets of laboratory experiments and against a field scale shrubland fire are very encouraging (with quite small deviations), the proposed model needs to be confronted to much more laboratory and field experiments in order to improve the physical formulation.

Abstract

Wildfires in Mediterranean Croatia have increased in recent decades, raising concerns about the adverse effects of fire and the rate of soil and water degradation. Post-fire management techniques, such as mulch application, are commonly used after high to moderate wildfire severity. Local, site-specific solutions are needed to mitigate wildfire effects in this context. This research aims to study the effect of mulches (from on-site sources) on soil and hydrological properties. We hypothesised that mulch application would increase soil quality and reduce erosion and runoff yield. During July 2019, about 900 ha of *Pinus halepensins* Mil. forest, abandoned grazing and agricultural olive groves (*Olea europea* L.) were affected by a moderate to high wildfire in the hinterland of Šibenik City (Croatia, 43°45'N 15°56'E, 105 m a.s.l.). Twenty-five days after the wildfire occurrence, unmulched (UM, control) and two mulch treatments (*Olea europea* leaves (OM) and *Pinus halepensis* needles (PM) were applied for post-fire stabilisation on *Cambisols*. One treatment covered an ~10 m^2 area with 0.5. kg m^2 mulch application which was measured on the experimental plots. Prior to mulch application, 15 (5 per treatment) metal rings (0.2 m^2) with connected plastic collectors were set up on sloped terrain (~9°) to monitor erosion and runoff yield. Soil samples were collected every three months, and erosion and runoff yield after major precipitation events during two years. The studied soil properties were: soil water repetency (SWR), soil hydraulic conductivity (SHC), mean weight diameter (MWD), water stability of aggregates (WSA), soil organic matter (SOM), total carbon (TC), total nitrogen (TN), extractable potassium (K_2O), and available (P_2O_5). Our results showed that both mulch treatments reduce runoff generation in addition to UM treatment. The erosion yield was not occurred due to natural soil conditions. A linear decreasing trend was noted for SWR in all treatments. Overall, PM was showed higher efficiency in increasing soil aggregate stability (MWD and WSA), SHC SOM, and TC. OM has mostly increased soil nutrients such as TN, P_2O_5, and K_2O. Bot mulch treatment increased soil quality, but the effect was variable due to the different chemical compositions of the material. The use of native mulch can be recommended because it improves soil quality and reduces runoff ratio. However, consideration should be given to whether they are available in the areas affected by wildfire.

1. Introduction

Wildfire is a common phenomenon and part of the Mediterranean ecosystem. However, in recent decades, the number and intensity of wildfires over the entire Mediterranean area have increased related to the long drought periods and intense high temperatures (Pausas et al., 2008). In addition, land abandonment, depopulation of rural areas, reduction of pastures, accumulations of flammable vegetation contribute to the spared of wildfires frequency and magnitude (Moreira et al., 2011; Pausas and Keeley, 2009). In the Mediterranean Croatia, such cases are often pronounced in the hinterland of large cities, especially in areas where landscape management and land use are not properly implemented (Delač et al., 2020, 2021). One of the main consequences of wildfires is the complete removal of vegetation and litter, which exposes topsoil to the risk of erosion and degradation of soil's physical and chemical properties. Soil affected by wildfire will experience degradation of primary functions, at least for some time (Certini, 2005; Pereira et al., 2019). The post-fire management is often implemented in the wildfire affected area to rehabilitate and stabilise the upper soil profile. Very often, mulch is applied to burned areas during post-fire restoration (Díaz-Raviña et al., 2012). Mulch is a common technique to inhibit soil erosion and encourage faster soil recovery after the passage of fire. Moreover, these treatments, known as emergency rehabilitation treatments, reduce rainwater's impact, favour the infiltration process, mitigate soil degradation, and prevent runoff and soil sediment removal after a wildfire. Moreover, mulching

with organic plant residues has improved the soil structure, mainly due to an increase in stability of soil aggregates, soil porosity, and improvement in soil hydraulic conductivity (De la Rosa et al., 2019). Although depending on the fire severity, soil organic matter (SOM), total carbon (TC), total nitrogen (TN) and available and extractable nutrients such as phosphorus (P) and potassium (K) can increase, decrease or remain unchanged. (Caon et al., 2014). The mulch addition and the compounds that have not been volatilised in the form of ash and charred residues are incorporated into soil increasing nutrients content (Caon et al., 2014). However, there is a lack of research about their manner after applying different types of mulch materials. In addition, there is a need to observe runoff and erosion behaviour after application on native mulch materials. This research aims to study the effect of Pinus halepensis and Olea europea mulches (from on-site sources) on soil and hydrological properties. We hypothesised that mulch application would increase soil quality and reduce erosion and runoff yield.

2. Material and method

The study was carried out in the Dalmatia region on the Adriatic coast (Croatia) in a hinterland of Šibenik City, (5 km from the Coast, 43°45'06.0"N 15°56'02.9"E.; Fig.1.). Elevation ranges between 50 and 200 m a.s.l. and the aspect is NE. According to Köppen classification, the study area's climate is Mediterranean Csa (warm temperatures with dry and warm summers). The mean annual temperature is 15.8 °C, and the annual precipitation is 800 mm (Šibenik meteorological station) (Kottek et al., 2006). The soil type is classified as *Cambisol*. Vegetation belongs mainly to *Pinus halepensis* Mil., forest and cultivated olive groves (*Olea europaea* L.) and fig tress (*Ficus carica* L.). In the study area, the wildfire occurred on 28 July 2019 and affected an area of about 900 ha (Delač et al., 2020, 2021) and it lasted three days until local firefighters stopped the fire. The first intervention to the burned area was 25 days after wildfire occurrence due to safety reasons and recommendations from local firefighters. The severity of wildfire was moderate to high, which was evident in partially burned canopy places. The area provided natural organic materials for usage and implementation. For covering burned soil surface, two different mulch treatments were applied. One was composited of *Pinus halepensis* needles (PM) the other one of mulch of *Olea europaea* leaves (OM). These mulched were used due to on-site availability and the valuable input of native plants on the soil. The mulches were applied in 0.5 kg m^2 on 10 m^2 each treatment. The erosion equipment to measure runoff and sediment yield were set-up on the same treatments. The studied soil properties were: soil water repetency (SWR), soil hydraulic conductivity (SHC), mean weight diameter (MWD), water stability of aggregates (WSA), soil organic matter (SOM), total carbon (TC), total nitrogen (TN), extractable potassium (K_2O), and available (P_2O_5). The effect of wildfire without any human intervention (unmulched, UM) was monitored next to mulch treatments to assess the impact of both mulches. The soil sampling campaign was conducted during two years: 25 days after fire (DAF), 3 months after fire (MAF), 6, 9, 12, 15, and 24 MAF. Soil samples (0–3 cm) were collected in each treatment in 5 repetitions after litter removal (105 in total). The runoff and erosion yield were collected after major precipitation events.

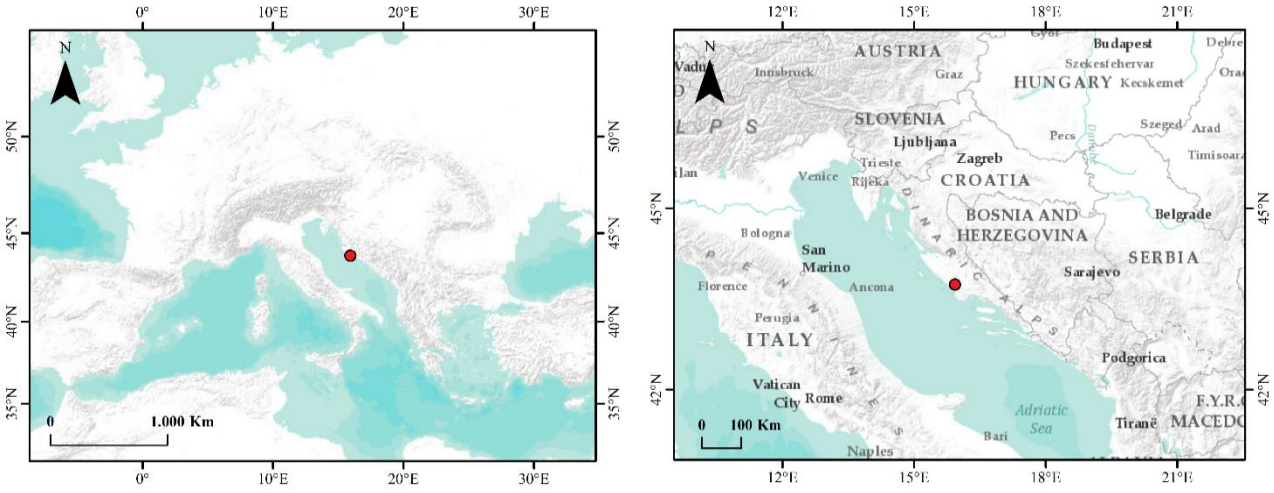

Figure 1. Study area (red dot shows experimental location)

3. Results and conclusions

Post-fire management is typically a trade-off between the cost and potential effectiveness of applied treatment and the potential damage to valuable resources from unmitigated erosion. Mulching is a technique that belongs to emergency stabilisation techniques, as it immediately stabilises the soil of the burned area and reduces additional damage to the fragile bare soil which confirmed our results. After a wildfire, there is a mosaic of low, moderate, and high soil burn severity conditions, but the cost of mulch material and the energy required to apply it must be considered. Preference should be given to local and available on-site material. Our results showed that both mulch treatments reduce runoff generation in addition to UM treatment. The erosion yield was not occurred due to natural soil conditions. A linear decreasing trend was noted for SWR in all treatments. Overall, PM was showed higher efficiency in increasing soil aggregate stability (MWD and WSA), SHC SOM, and TC. OM was mostly increased soil nutrients such as TN, P_2O_5, and K_2O. Bot mulch treatment increased soil quality, but the effect was variable due to the different chemical compositions of the material. The use of native mulch can be recommended because of its effect on improving soil quality and reducing runoff ratio, however consideration should be given to whether they are available in the areas affected by wildfire.

Standardization, symbology, wildfire, tactical, mapping

Abstract

During the onset of a crisis, a wide range of local, regional, national and sometimes international authorities generate maps using proper symbols to support coordination and communication during a potential disaster, such as a large forest fire. In this context, it is essential that all stakeholders can readily understand the information shown on these maps to respond in a prompt and adequate manner. The standardization of a set of symbols, which could facilitate the efficiency of the operations in the field and at the same time optimize the coordination between all the command chain levels during the fire crisis, is conducted in context of the European research project STRATEGY, which aims to build and implement a Pan-European pre-standardisation framework for improving the interoperability of crisis management solutions.

The pre-requisite for standardization is a concrete pre-standardization activity aiming to describe and document the subject of the standardization as well as the purpose and the context of use. This is achieved through a properly organized pre-standardization procedure known as CEN/CENELEC Workshop Agreement (CWA), with the active involvement of interested organizations. In the envisaged case of wildfires, the organization is represented by the entities involved in the fire operations and the service provided is firefighting. In this direction, the relative pre-standardization initiative further described in this paper, aims to introduce a standardized set of tactical symbols that can be used by the responsible public safety agencies across EU and worldwide for the graphical presentation of mission critical operational information, based on SITAC approach. SITAC is a set of tactical symbols for wildfire managers, initially developed by the French Fire Service, used since 2000, further adopted and operationally used by the Fire Services in Italy and other EU Member States. SITAC, consists of tactical symbols, displaying graphic and textual information about an object at a single geographic position at a particular point in time.

The SITAC CWA shall deliver clear, concrete, and adequate instructions and guidelines for the visual description of the field operations during forest fire incidents in a predefined, formal way. Information related to the characteristics of the affected area, the evolution of the fire, the intervention measures as well as current or planned actions, are encompassed by the proposed symbology. This will play an important role during large and very large fire events where several organizations and actors need to cooperate and exchange information in common, such as incident commanders, fire officers, forest managers, personnel of the civil protection agencies and emergency services. Furthermore, in the case of cross-border incidents the use of a standardized symbology, familiar and known to international firefighting teams and modules, will facilitate to overcome the language barrier and to optimize the response to the crisis. Finally, such standardization will push the EU security industry, dealing with the development and deployment of related Command & Control systems and solutions, to follow formal visual communication guidelines, enhancing the communication and cooperation of the organizations in charge of managing wildfires and the organizations supporting the field operations.

1. Introduction

Conveying spatial information plays a very important role in efficient emergency response where maps are the most solid basis for direct representation of this spatial information. During the onset of a crisis, a wide range

of local, regional, and national authorities need to generate maps using proper symbols to help communicate information, respond to, and recover from a potential disaster such as a large forest fire. In this context, it is essential that all stakeholders (national and potentially international according to the incident) can readily understand the information shown on these maps to respond in a prompt and adequate manner. In this regard, a concrete symbology, in the sense of a visual language displayed on the map, is needed to share the operational message in a concise and clear way to all responsible decision makers.

The standardization of a set of symbols, which could facilitate the efficiency of the operations in the field and at the same time optimize the coordination between all the command chain levels during the fire crisis situation, is conducted in context of the European research project STRATEGY (https://strategy-project.eu/). STRATEGY aims to build and implement a Pan-European pre-standardisation framework to improve the interoperability of crisis management solutions, based on a gap analysis initially implemented within the project, given the expertise of involved end-users.

Base on the gaps identified, a standardized approach for visually communicating operational messages, using a commonly agreed and understood symbology among the actors of wildfire management is currently missing. This fact limits the effectiveness of coordinating the response effort of the resources involved in the incident. Having each organization in the various EU member states to use diverse processes, procedures, and symbols for communicating situational information during large fire incidents and crisis management operations can't be effective. This is more evident in case of cross-border crises where such peculiarities and differences may cause confusion among the first responders, often wasting the assistance offered between the Union's Member States. More specifically, in the case of large-scale forest fires in a cross-border context and with multiple authorities and modules from foreign countries engaged, the sharing of operational information and the common understanding of the situation becomes crucial. Therefore, establishing a common symbology which can be used by the fire services and the public safety agencies involved in wildfire management, is essential for the efficient and effective management of situations as mentioned before.

2. Methodology

2.1. Standardization and CWA

Standardization is a framework of agreements to which all relevant parties in an industry or organization must adhere to ensure that all processes associated with the creation of a good or performance of a service are performed within set guidelines. In the envisaged case of wildfires, the organization is represented by the entities involved in the fire operations and the service provided is firefighting. The pre-requisite for standardization is a concrete pre-standardization activity aiming to describe and document the subject of the standardization as well as the purpose and the context of use. This is achieved through a properly organized pre-standardization procedure known as CEN/CENELEC Workshop Agreement (CWA).

A CEN/CENELEC Workshop is considered as a body with a short-term task specified in its project plan. If the proposed scope calls for a long-term activity, the possibility to propose a Technical Committee should be explored. A CWA is a deliverable, which may take various forms such as text file or computer code, developed and agreed by the participants in a temporary working group (CEN/CENELEC Workshop). It is designed to meet an immediate need, can be quickly developed and can be used as fast track to future standardization activities. The stakeholder involvement is limited to those directly interested in the subject. The direct participation of interested parties, the possibility to indicate the participants and their organizations in the foreword and the rapid development process offered by a CWA, are particularly attractive for European research and innovation projects, which must deliver results within the limited duration of their project lifetimes.

In the case of the CWA presented in this paper, which concern the pre-standardization of the wildfire management symbology for mapping purposes during large scale fire crises the participants comprise representatives from fire and forest organizations, industry, research and technology organizations and standardization bodies. The standardization community is represented in the SITAC workshop by the National Romanian Standardization Organization (ASRO), which acts as the link with the European Standardization Committees and Technical Groups.

2.2. SITAC CWA

The CWA mentioned in this paper refers to SITAC (Standardization of Firefighting Tactical Situation Management), a set of tactical symbols for wildfire managers, initially developed by the French Fire Service (Sapeur Pompiers) being in use since 2000. The set of symbols that was originally developed included all type of hazards. SITAC literally stands for SITuation TACtique, an acronym corresponding to a schematic representation of an intervention of the Fire Brigades. It is part of the Operational Management and Command tools, which are implemented during a disaster to best organize the return to initial conditions or in a preeminent situation, a way out of the crisis.

The last decade, the original set was adopted by the "Corpo Nazionale dei Vigili del Fuoco (CNVVF)" in Italy and several other fire service agencies in EU Member States and the part of the symbology related to exclusively to wildfire management was marked out to be used operationally. This specific set is the focus of the respective CWA mentioned in this paper.

SITAC, as any set of tactical symbols, can be used by the respective agencies across EU and worldwide for the graphical presentation of mission critical operational information during operational missions. A tactical symbol displays graphic and textual information about an object at a single geographic position at a particular point in time. The graphic displayed is typically a screen icon with supplemental text and graphics surrounding the icon. In general, the graphic displayed depends on the symbology set a tactical symbol belongs to. Information related to the characteristics of the affected area, the evolution of the fire, the intervention measures as well as current or planned actions, are encompassed by the proposed symbology.

The CWA focuses on a specific set of symbols that can be used by public safety agencies for the depiction of operational information against a cartographic background during forest fires incidents. In this context, information related to (among others) the characteristics of the affected area, the advancement of the fire, the intervention measures / available equipment and actions that need to be taken, will be encompassed by the proposed set of symbols. Given its simplicity, its operational maturity and its acceptance in several EU countries, the SITAC set of symbols (known as) sets the basis for delivering a standardized way to share forest fire management information in paper and electronic maps during fire response operations. Its use in training sessions can further facilitate familiarization and efficiency during real operations.

The use of the graphics makes it possible to schematize using a normalized code, the main operational information related to an ongoing crisis. The objective is to facilitate the collection, transmission and understanding of information exchanged by the different levels of the command chain. Saving time and being aware of the real operational situation is essential for the wildfire managers when lives or property are threatened by an active fire. In addition, the standardization of means and actions considerably reduces the risk of misunderstanding and improves the accuracy of actions.

This paper presents the approach and the expected results of the standardization of the SITAC set of symbols, incorporating the feedback on several countries approaches deriving from the CWA members, to generalize its use by the EU public safety agencies for depicting operational information against a cartographic background (either digital or paper based) during forest fires incidents. The SITAC CWA aims to gain consensus from many of the EU wildfire management organizations for using a common approach to graphically symbolize the elements (means, operations, assets) of wildfire management operations, in an agreed manner building on the SITAC approach. It should be kept in mind that firefighting is a particular case of operations, where a variety of organizations are involved (not exclusively the fire brigade but forest services and forest fire fighting organizations as well). Due to the large extent of the incidents and the large number of the organizations involved (services and agencies), specific equipment and operations are used, and the coordination is often challenging. In case of large wildfires, it is a common practice that civil protection modules are deployed from one EU country to another. In such case the use of standardized symbols for planning, monitoring, and coordinating cross-border operations in the field will be even more beneficial for the effectiveness of the coordination.

Hence, this document is intended to benefit the cooperation among the EU and global wildfire management community, comprising incident commanders, fire officers, forest managers, personnel of the civil protection agencies and Emergency services. At the same time such standardization will push the EU safety and security industry dealing with the development and deployment of related Command & Control systems and solutions.

In this direction, the document will provide formal visual communication guidelines to support the communication and cooperation of the organizations in charge of managing wildfires and the organizations supporting the field operations (e.g., police, ambulance services, coast guard, etc.).

The SITAC symbology organizes the information to be shared in several groups depicting a. the environment i.e., the wind, the vegetation type and the slope b. the fire i.e. the type of the fire and its current and expected progression c. the operating area i.e. landscape type and infrastructures such as lifelines, water sources, helispots d. fire operations (ground, aerial and special e.g. backburn) and the forces (ground and aerial) deployed or planned to be in the field.

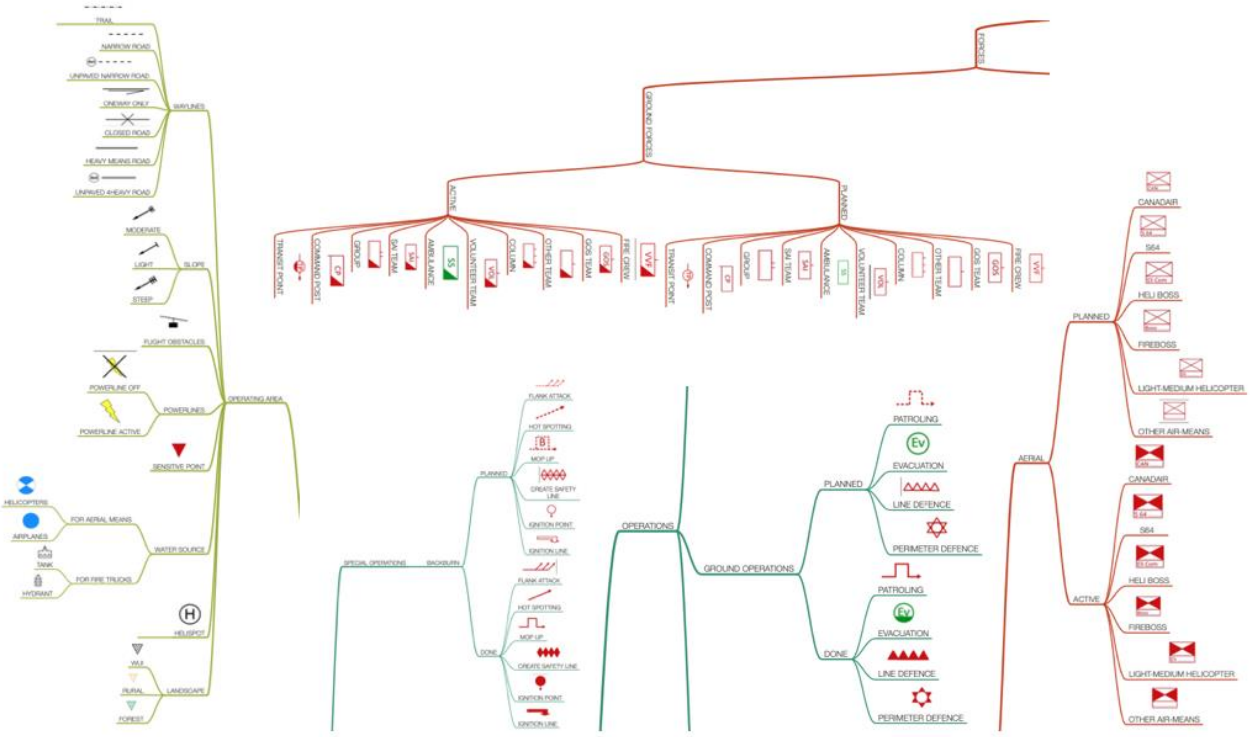

Figure 1- Groups of SITAC symbols for wildfire management information sharing

The SITAC symbols are kept simple to be easily drawn on paper maps in the field while semantic to be easily perceived and interpreted in the command post.

3. Results

The SITAC CWA shall deliver clear, concrete, and adequate instructions and guidelines for the visual description of the field operations during forest fire incidents in a predefined, formal way. This will allow to organize efficient and effective information sharing among all the operational actors involved in the fire management command chain. This will be important during large and very large fire events where several organizations need to cooperate and exchange information in common. Furthermore, in the case of cross-border incidents the use of a standardized symbology, familiar and known to international firefighting teams and modules will facilitate to overcome the language barrier and to optimize the response to the crisis.

4. Discussion

The outcome of the work presented here shall benefit the cooperation among the EU and global wildfire management community, comprising incident commanders, fire officers, forest managers, personnel of the civil protection agencies and Emergency services. At the same time such standardization will push the EU security

industry, dealing with the development and deployment of related Command & Control systems and solutions, to follow formal visual communication guidelines, enhancing the communication and cooperation of the organizations in charge of managing wildfires and the organizations supporting the field operations.

5. Acknowledgments

The aforementioned pre-standardization activity is currently performed within STRATEGY project that has received funding from the European Union's Horizon 2020 Research and Innovation programme under Grant agreement No 883520. Please see https://strategy-project.eu for more information.

Pyrocumulonimbus, Fire-generated thunderstorms, Fire-weather prediction

Abstract

Pyrocumulonimbus (pyroCb) clouds are difficult to predict and can produce extreme and unexpected wildfire behavior that can be hazardous to fire crews. Many forecasters modify conventional thunderstorm diagnostics to predict pyroCb potential, by adding temperature and moisture increments to represent smoke plume thermodynamics near the expected plume condensation level. An alternative approach is to anticipate the minimum firepower required to generate pyroCb for a given atmospheric environment.This concept, termed the pyroCb firepower threshold (PFT), requires only atmospheric information, removing the need for subjective estimates of the fire contribution. A simple approach to calculating PFT was presented by Tory and Kepert (2021) that incorporates only basic plume-rise physics, and yields an analytic solution for the minimum heat flux required to enter the base of the plume for pyroCb to form. This version takes into consideration the magnitude of any inversion or stable layer the smoke plume must penetrate, the height the smoke plume must rise before sufficiently buoyant cumulus clouds form in the smoke plume, and it incorporates the impact of wind on plume rise via the Briggs plume-rise model. This PFT also offers important insight into plume behavior and pyroCb formation.

Many assumptions are made to close the equations and to maximise simplicity. Two of these assumptions are questioned in this paper following the investigation of two deep, moist pyro-convection cases that occurred during 'Black Summer' (southern Australia, September 2019—March 2020). The first assumption, consistent with many thunderstorm diagnostics, is that the moist (cloudy) plume is non-entraining, and the second assumption is that the plume is positively buoyant when it saturates and remains buoyant until it rises beyond the -20 ℃ level of the atmosphere. The first assumption underpredicts the fire-power required and the second assumption can overpredict the necessary firepower, since a vigorous plume may have sufficient kinetic energy to penetrate stable layers or capping inversions. Procedures are introduced to address these limitations.

1. Introduction

When intense smoke plumes develop on wildfires, the so-called plume-dominated fires, fire behaviour can become erratic, unpredictable and the fire ground can become highly dangerous for fire fighters. Strong updrafts can transport burning embers downwind, amplifying firespread through the ignition of spotfires ahead of the fire front. The formation of deep cumulus clouds with strong vertical motion in these plumes may amplify the dangerous fire behaviour, and introduce additional hazards separate to the fire such as extreme winds from evaporative downbursts, and tornadic-strength vortices. When conditions are favourable the fire-induced deep, moist convection can produce lightning with the potential to ignite more fires. These fire-generated thunderstorms (FGT) are also known as pyrocumulonimbus (pyroCb).

A procedure for identifying atmospheric conditions that favour deep, moist plume growth in wildfire smoke plumes, termed the Pyrocumulonimbus Firepower Threshold (PFT, Tory and Kepert 2021) was tested in a real-time trial (Tory 2020) during Australia's 'Black Summer' (southern Australia, September 2019—March 2020). The procedure estimates a theoretical minimum heat flux (or firepower) required for deep, moist plume growth. This version of the PFT (hereafter PFT1) takes into consideration the magnitude of any inversion or stable layer the smoke plume must penetrate, the height the smoke plume must rise before sufficiently buoyant cumulus clouds form in the smoke plume, and it incorporates the impact of wind on plume rise via the Briggs plume-rise model (e.g., Briggs 1984). Below the condensation height it is assumed that the smoke plume can be described

by a Briggs plume rising through a neutrally stable layer of constant background wind. Above the condensation height, it is assumed the rising moist plume can be described by simple parcel theory (non-entraining, as applied to common thunderstorm forecast products such as Convective Available Potential Energy, CAPE).

During the real-time trial PFT1 forecast maps provided excellent guidance for predicting deep, moist pyro-convection (hereafter DMPC). A selection of interesting DMPC cases were investigated in detail, using a manual PFT1 analysis method applied to thermodynamic diagrams, yielding important insight into plume behaviour, which has inspired further development and tuning of PFT products. In this short paper, two such cases are presented.

2. PFT

The full PFT1 derivation is provided in Tory and Kepert (2021), as well as an approximated form designed for estimating and visualising PFT1 manually on a thermodynamic diagram,

$$PFT1 \sim 0.3 \times \left(z_{fc}\right)^2 \times U \times \Delta\theta_{fc}. \qquad 1.$$

Here z_{fc} is the free-convection height in units of km (the minimum height the plume must rise to initiate deep moist pyro-convection), U is the average velocity magnitude of the mixed layer horizontal wind, units ms^{-1}, and $\Delta\theta_{fc}$ represents how much warmer the plume needs to be than the mixed-layer potential temperature, units ℃ (or K). These units yield PFT1 in GW. An example from the evening of the disastrous Black Saturday fires of 2009 is shown in Fig. 1. The mixed-layer potential temperature (thick red line) and specific humidity (thick cyan line) represent the average thermodynamic properties of air entrained into the plume. The saturation point curve is approximated by a straight line representing a 15:1 ratio of temperature to moisture increments (units $K/g\ kg^{-1}$, blue line) produced by the fire (Luderer et al. 2009, Tory et al. 2018). It represents a range of possible positions on the diagram where the plume can reach saturation. The minimum-buoyancy plume-path that freely convects to a level cooler than -20 ℃ is indicated by the gold curve. The free-convection height (z_{fc}) is the height at the base of the gold curve. Here the plume must be at least $\Delta\theta_{fc}$ warmer than the mixed-layer potential temperature (thick red line), and the average mixed-layer wind, U, can be estimated from the wind barbs highlighted in green.

In theory, the fire must be able to produce enough firepower for the plume to rise to at least a height of z_{fc}, while maintaining an average plume temperature of at least $\Delta\theta_{fc}$ warmer than the mixed-layer potential temperature, while battling the wind, U, which inhibits the plume rise by stretching the plume out downwind and exposing it to more dilution from entrainment.

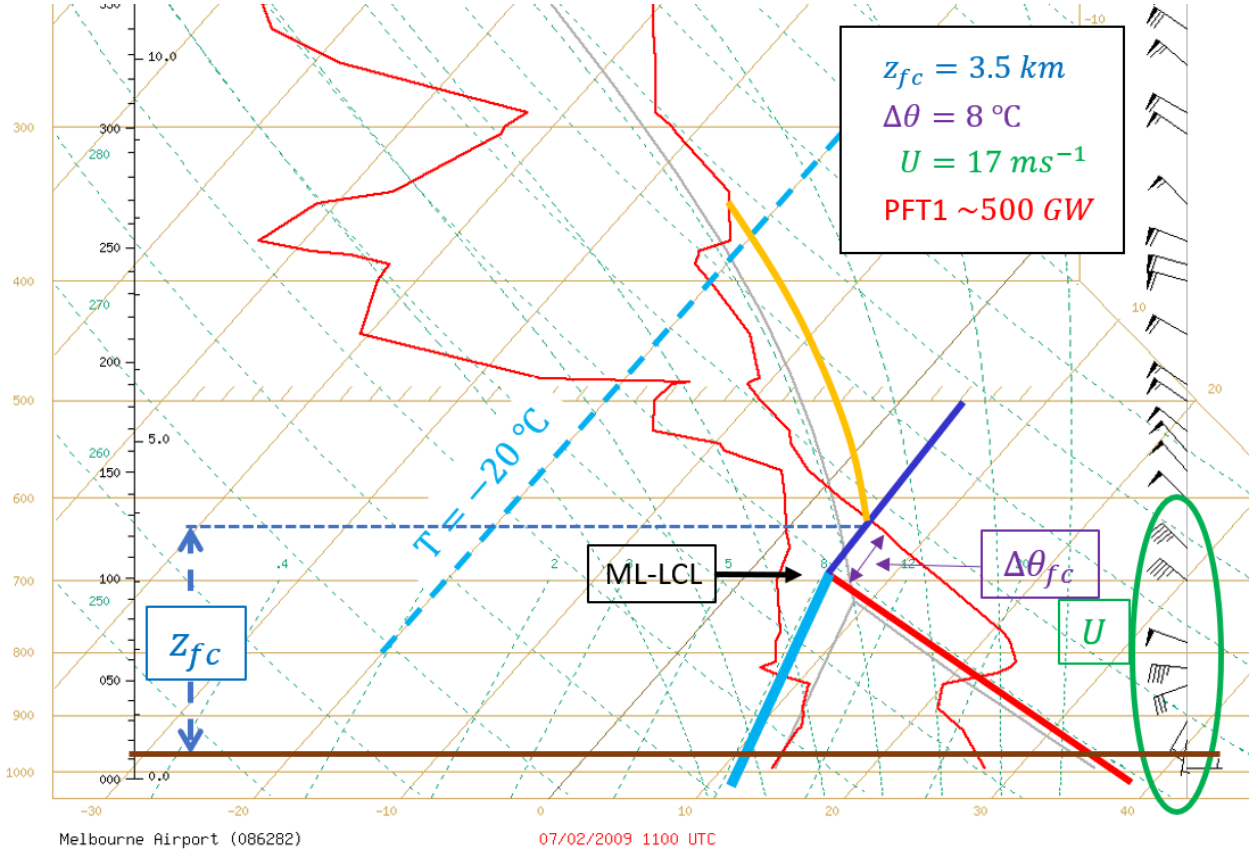

Figure 1- Melbourne Airport sounding 1100 UTC, 7 February 2009 (10 PM local time), with markers used in the manual PFT calculation (Eq. 1). Thick red and cyan lines represent the mixed-layer potential temperature and specific humidity respectively, with the mixed-layer lifting condensation level (ML-LCL) marked at the apex of these two lines. The saturation point (SP) curve (approximated by the blue line) identifies the potential plume condensation positions. The minimum-buoyancy plume-path is indicated by the gold curve. The free-convection height (z_{fc}) is the height at the base of the gold curve. The plume must be at least $\Delta\theta_{fc}$ warmer than the mixed-layer potential temperature (thick red line), and the average mixed-layer wind term (U) can be estimated from the wind barbs highlighted in green.

3. Case study events

One focus of forecasters during the trial was the prediction of lightning in DMPC because lightning is generally well observed and offers a clear distinction between towering pyrocumulus and pyrocumulonimbus clouds. Cloud-top temperature (CTT) observations from satellites are readily available that enable near-real-time assessment of DMPC maturity, and an indication of when the convection has penetrated the typical charge separation layer (-15 to -25 ℃) above which lightning might be expected to develop. However, it was common for DMPC to develop with CTT much cooler than -25 ℃ without lightning. Then on Sunday 2 Feb 2020 forecasters were confounded by lightning that developed in DMPC when the CTT only reached -15 ℃. This was unexpected, especially given that on the previous day DMPC with CTT of -45 ℃ developed on a fire nearby, with no lightning.

To try and understand these differences, a PFT1 analysis was performed for each case, with both identifying scenarios where assumptions used to simplify PFT1 need to be reconsidered. The first of these simplifying assumptions is that a rising plume-parcel is always buoyant, i.e., it is assumed a parcel cannot penetrate a capping inversion unless it is warmer than that inversion. The second simplifying assumption is that the moist plume is non-entraining, i.e., it does not lose buoyancy from dilution and cloud moisture evaporation when cooler drier air is mixed into the plume from outside.

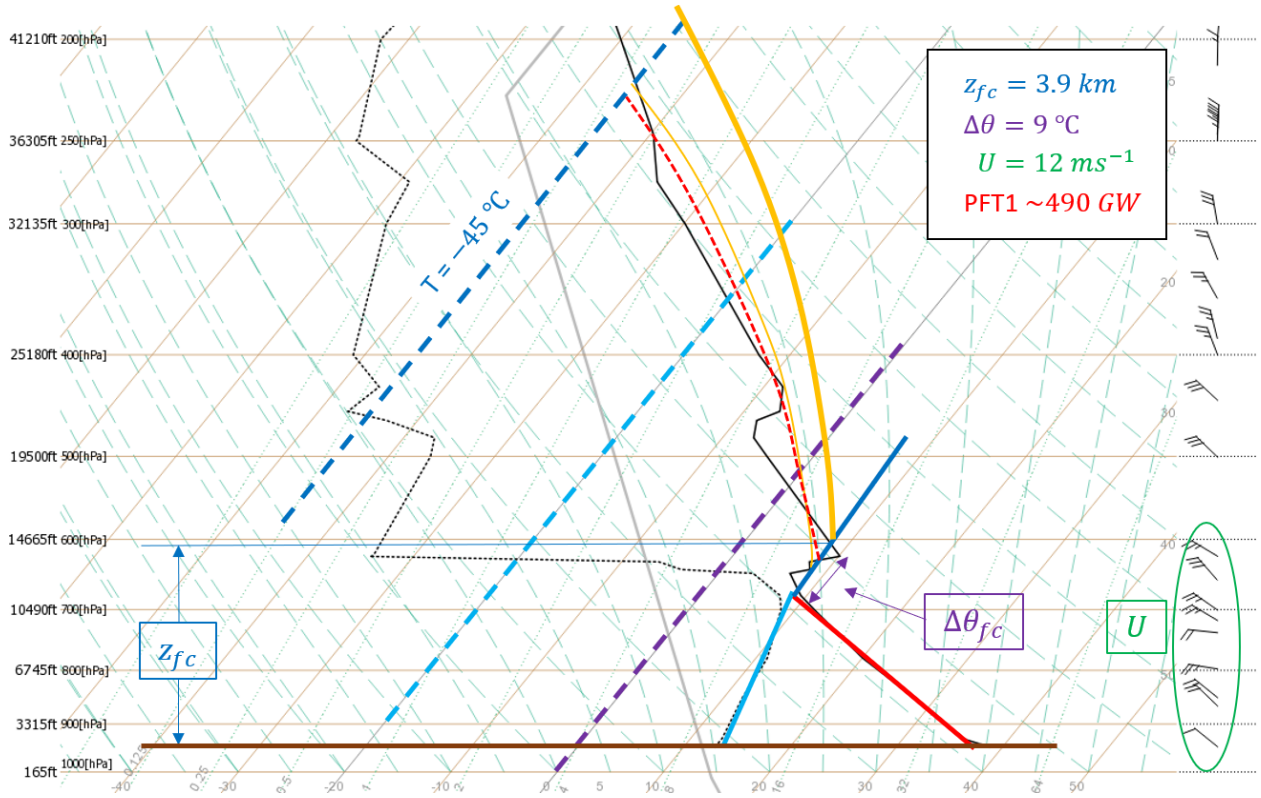

Figure 2- Canberra sounding 1 PM local time (0200 UTC) Saturday 1 Feb. The solid and dotted black lines represent temperature and dewpoint temperature respectively. The 0, -20 and -45 ℃ temperature lines are indicated by purple, cyan and blue dashed lines respectively. The solid red and cyan lines show a mixed layer temperature and dewpoint temperature of constant potential temperature and specific humidity that represent the average quantities entrained into a hypothetical plume rising through the mixed layer. The solid blue line is an approximate Saturation Point curve. The gold lines are moist parcel paths emerging from the SP curve, one with minimum buoyancy just able to breach the capping inversion and exceed the -20 ℃ level (thick, used in PFT1), and the other (thin) represents a non-entraining parcel path corresponding to the observed cloud-top temperature of -45 ℃. The red dashed line is a hypothetical parcel path that reaches the observed cloud top temperature with some overshooting, takes into account buoyancy losses associated with entrainment, and assumes sufficient vertical kinetic energy to penetrate the lower temperature inversion (between 650 and 610 hPa). The three ingredients for a manual PFT1 calculation are illustrated, and their estimated values shown in the legend.

The PFT1 analyses used to explore the two events are presented in Figs 2 and 3 respectively. Dark blue dashed lines corresponding to the observed CTT, and corresponding non-entraining moist-plume parcel paths (thin gold lines) have been added to highlight the discrepancy between the observed, and minimum-predicted equilibrium levels. On both days the minimum-predicted equilibrium level (top of the thick gold line) is much colder (-60 ℃ and -50 ℃ respectively) than the observed CTTs (-45 ℃ and -15 ℃ respectively). However, the zero-entrainment parcel paths matching the observed CTTs (thin gold lines) both have regions of negative buoyancy, which is counter to the PFT1 assumption of positive buoyancy everywhere.

In the first case (Fig. 2), negative buoyancy is encountered when the thin gold line penetrates the capping inversion near 600 hPa, and it also approaches zero buoyancy near 450 hPa. If this parcel path is realistic, it implies that the plume had sufficient kinetic energy to penetrate the capping inversion.

A theoretical kinetic energy can be calculated from the Briggs plume-rise equations, which, with a few simplifications (not shown), becomes,

$$E_k \sim 4.3 \times \Delta\theta_{SP} \times z_{SP}. \qquad 2.$$

Here E_k is the vertical kinetic energy of a plume parcel in units of Jkg^{-1}, the subscript SP refers to a point on the SP curve (blue solid line), and $\Delta\theta_{SP}$ and z_{SP} are analogous to $\Delta\theta_{fc}$ and z_{fc} (same units). Importantly, Eq. 2 shows that the larger $\Delta\theta_{SP}$ and z_{SP}, the larger the plume kinetic energy.

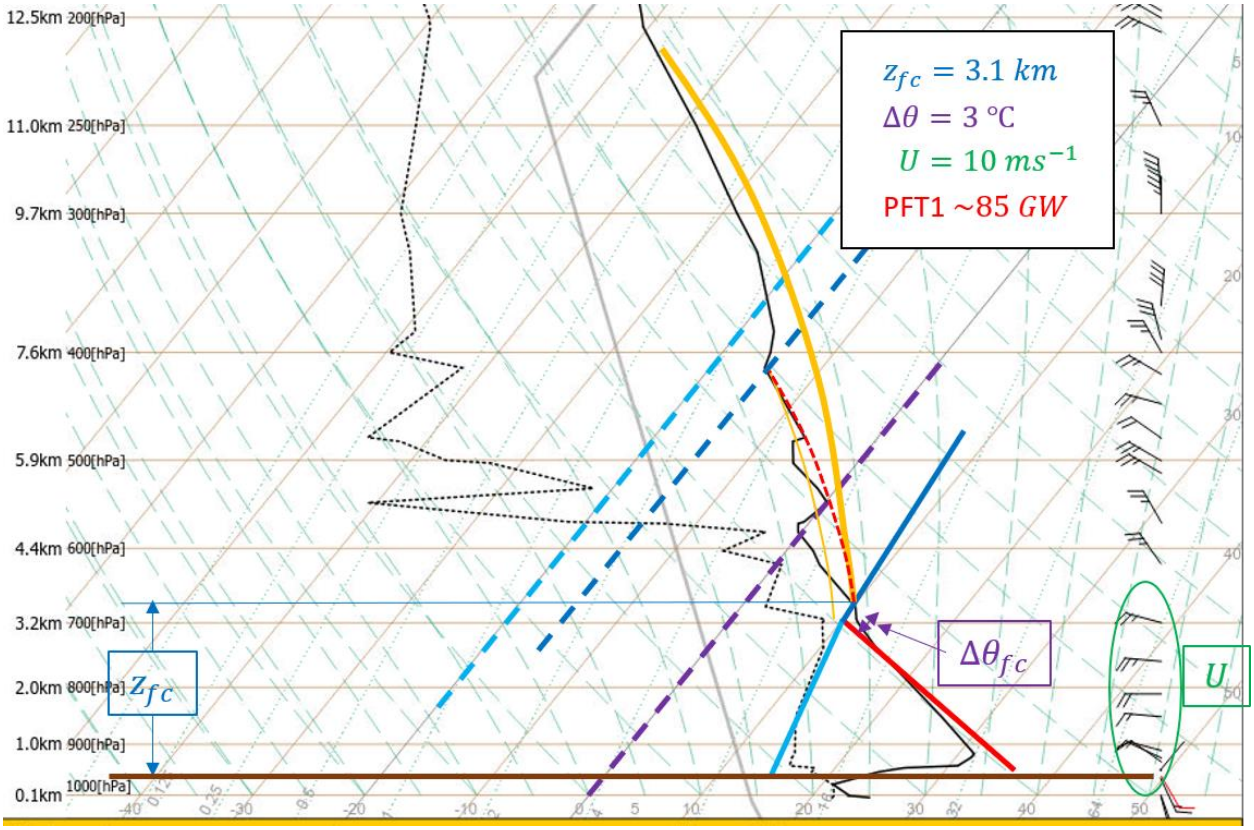

Figure 2- As in Fig. 2 but for the Sydney sounding 2 PM local time (0300 UTC) Sunday 2 Feb. Observations from a PAWS (RF55) located at Faulconbridge (elevation 410m, 20 km north of the fire) were used to estimate the actual conditions below 1.0 km.

In the second case (Fig. 3), the negative buoyancy regions encountered by a parcel on the thin gold line are more substantial than the first case. These include a stable layer just above the ML-LCL and two inversions near 550 and 470 hPa. Furthermore, the corresponding $\Delta\theta_{SP}$ would be close to zero or even negative, suggesting any plume elements at the base of the thin yellow line would not only have negative buoyancy, but no vertical kinetic energy prior to plume condensation. It follows that the real plume parcel paths must have had $\Delta\theta_{SP} \geq 2$ to have reached the observed CTT (assuming the temperature trace represents the fire environment), which implies they would have had vertical momentum at saturation, and were probably buoyant too. However, any non-entraining parcel paths (moist adiabats) matching these $\Delta\theta_{SP}$ values would rise well beyond the observed CTT levels. It follows that any plume parcel with $\Delta\theta_{SP} \geq 2$ that reaches equilibrium at -15 ℃ must have lost buoyancy while ascending. The most likely cause of buoyancy loss is entrainment of cooler and drier air. The warmer plume is diluted by the cooler entrained air, and the evaporation of cloud water by the entrained dry air further cools the plume.

Hypothetical entraining-plume paths, are included in Figs 2 and 3 (red dashed lines). Entrainment is often expressed as a dilution fraction per km of ascent. While the entraining interface between the plume and environment is more turbulent in rapidly rising plumes (which enhances entrainment), plume elements spend less time ascending and hence less time entraining, with the net effect that rapidly rising plumes experience less total entrainment than slower rising plumes (e.g., Gregory 2001). It follows that as a general rule, larger (smaller) $\Delta\theta_{SP}$ would relate to greater (smaller) ascent rates and thus smaller (larger) entrainment rates.

On both days very dry air was located above about 600 hPa, indicating entrainment would be particularly detrimental to plume buoyancy. However, the $\Delta\theta_{SP}$ values corresponding to the hypothetical entraining plume paths (difference in potential temperature between the SP and mixed-layer value) are about 7 ℃ (Fig. 2) and 3 ℃ (Fig. 3) respectively, suggesting the former would have ascended more rapidly and thus experienced less entrainment than the latter. Furthermore, it suggests entrainment may only be significant for cases with relatively small $\Delta\theta_{SP}$.

4. Summary and Discussion

The two cases presented suggest the PFT1 assumptions of non-entraining moist plume paths that are everywhere buoyant from condensation to the -20 ℃ isotherm (thick gold lines in Figs 2 and 3), may not always be reasonable. Plumes with non-trivial $\Delta\theta_{SP}$ are likely to have sufficient vertical kinetic energy to penetrate some stable layers and inversions, and plumes with smaller $\Delta\theta_{SP}$ will likely experience greater buoyancy losses from entrainment. However, the associated errors from ignoring these effects will partly cancel, since the plume-kinetic-energy omission yields a PFT1 over-prediction and the entrainment omission yields a PFT1 under-prediction.

A manual procedure for estimating the minimum $\Delta\theta_{SP}$ of a plume capable of penetrating a stable layer is under development. The plume kinetic energy is estimated using Eq. 2, and the integrated buoyancy force it will encounter is estimated from the area between the parcel path and the environment temperature trace, similar to the calculation of convective inhibition (CIN) used in CAPE calculations. Where the E_k and CIN balance, the plume is deemed to just have sufficient kinetic energy to penetrate the stable layer. Estimating entrainment rates is considerably more complex. It may be necessary to add 1—3 ℃ to $\Delta\theta_{SP}$ to account for buoyancy losses due to entrainment, with a larger increment added if the initial $\Delta\theta_{SP}$ is relatively small and a smaller increment if it is relatively large (suitable increments are yet to be determined). Finally, the updated $\Delta\theta_{SP}$ along with a matching z_{SP} can be fed into Eq. 1 to calculate an improved PFT. There will be many cases in which these modifications will have no or negligible impact on the PFT result. It is anticipated that users will soon identify environments in which taking these additional steps will yield improved PFT estimates.

Peat Fires, Forest Fire GS Mark III, Spray length, Pressure. Fire suppression

Abstract

Anthropogenic interventions and global warming are normally the cause of Malaysian peat fires. Fire suppression methods and techniques have garnered the attention of innovators. In the current study, a series of field experiments were undertaken to quantify the effectiveness of an invention of fire-fighting equipment called Forest Fire GS Mark III (patent pending). A number of hoses and water pumps, as well as accessories, are also integrated into the GS Mark III configuration. The installation of equipment only considers single hoses line with several lengths from an open water source. This involved three field tests using a single pump, an end-to-end pump, and series pumps. Both the end-to-end pump and the serial water pump were found to have significant performance with longer spray length and consistent water pressure. Further, according to the present invention, the area covered during extinguishment is about 18,000m^2 or 4.45 acres or 1.8 hectares within 50 minutes by mains off the end-to-end pump or serial pump installation. Conversely, the pressure and length decreased when the number of hoses increased. This study makes a good contribution to the firefighter community by providing the initial design of fire extinguishment methods under better conditions.

1. Introduction

Forests are extremely valuable because of their ability to trap rainwater, produce oxygen, store carbon, and provide habitat for a wide variety of animals. Haze is commonly caused by major forest fires, which can spread significant distances and blanket extensive areas. People's respiratory systems, health, livelihoods, and lifestyles can all be negatively impacted by air pollution, and in extreme circumstances, the pollution can even force schools and airports to close. Firefighter put their lives on the line in order to extingto fires.

The use of fire retardants, fire barriers, rewetting peatland, water bombing, and cloud seeding are s the strategies that are now being utilized to stop forest fires. However, these approaches can be risky, expensive, time-consuming, depending on the weather, and ineffectual geographically remote and inaccessible areas. A significant amount of study has been carried to cut carbon emissions, respiratory health problems, and economic loss brought on by forest fires and the smoke hat they produce.

In the earlier studies, fire suppression models (Duff and Tolhurst, 2015), stochastic fire simulation model (Riley et al., 2018) and the species, momentum, and energy conservation equations (Huang et al., 2015) have been used to model the decision-making process for a significant portion of fire costs and for a large portion of

impacts to describe drying, thermal, and oxidative degradation during the smouldering combustion in previous studies. However, these models have significant drawbacks when it comes to simulating the spread of a fire.

The other solution was also proposed by the previous researchers to overcome the suppression method. Suppression chemicals which proposed by Plucinski, (2019) is not a promising alternative since the scale and purpose that they are considered. Kalabokidis, (2000) also reported that the chemical usage showed major impacts, on the environment, which may be through the adverse effects on water quality, and subsequently to aquatic ecosystems.

On wildfire suppression equipment, only a small amount of research and development work has been done. In 2018, Bartenev et al. developed a combined machine for putting out forest fires and using soil to create fire-break makers. This machine works by removing the upper fire-hazardous cover, which is made up of plant residues. Drapalyuk et al., 2019 proposed fire-fighting soil-thrower machine which provide better preventive and fireproof work in conditions of heavy soils, saturated with roots of the tree. Kasymov et al., (2017) have been presented backpack motorized fire extinguisher too minimizes the damage caused to the environment but limited for extinguishing low and medium intensity forest fires. However, the aforementioned machine do not extinguish for large fire especially involving ground or peat fire where the thickness of the burned layer is should taken into account. In addition, when a layer of organic soil ignites, it burns steadily without flaming and eventually spreads through the soil (Rein et al., 2008). Smouldering in peat soil can go days undetected Zaccone et al., 2014). During a peat fire, the temperature at ground level can reach 400 degrees Celsius, while temperatures 5, 10, 20, 30, and 40 centimetres below ground level can reach 200 degrees Celsius, 90 degrees Celsius, 50 degrees Celsius, and 45 degrees Celsius, respectively (Rinaldi et al 2019). Since peat soil has high water content, it is hard for firefighters to walk on it. Efforts to extinguish fires on peatlands is strenuous, wildly if the fire has penetrated the deep layer of peat, only heavy rain can effectively extinguish it (Rosita, 2018). In this regards, this paper intends to propose new suppression equipment for forest fire particularly peat fire which merge three suppression techniques ; direct attack and fire break, and total flooding.

2. Methodology

2.1. Forest Fire GS Mark III,

The Forest Fire GS Mark III (patent pending) comprise a sprinkler; connect to the 1¼ ” upper pipe; and it is attached to stop valves to allow and close the water flow to the sprinkler. The upper pipe are mounted to the Cross tees – four - steam divider. On the bottom of the cross tees divider, a ½” stop valve will be mounted to allow and close the underground water flow. An underground pipe ½” in size will be attached and a ½” round cap is fix at the end of the underground pipe as pipe cover. (The detailed of the aforementioned equipments is patent pending).

The Forest Fire GS Mark III as claimed in previous pragraph characterized in that a male coupling and female coupling which working as a connector to the hose, will connected on the left and right side of the cross tees four steam divider. Water supply will flow over to the upper pipe for water spraying and lower pipe for total flooding.

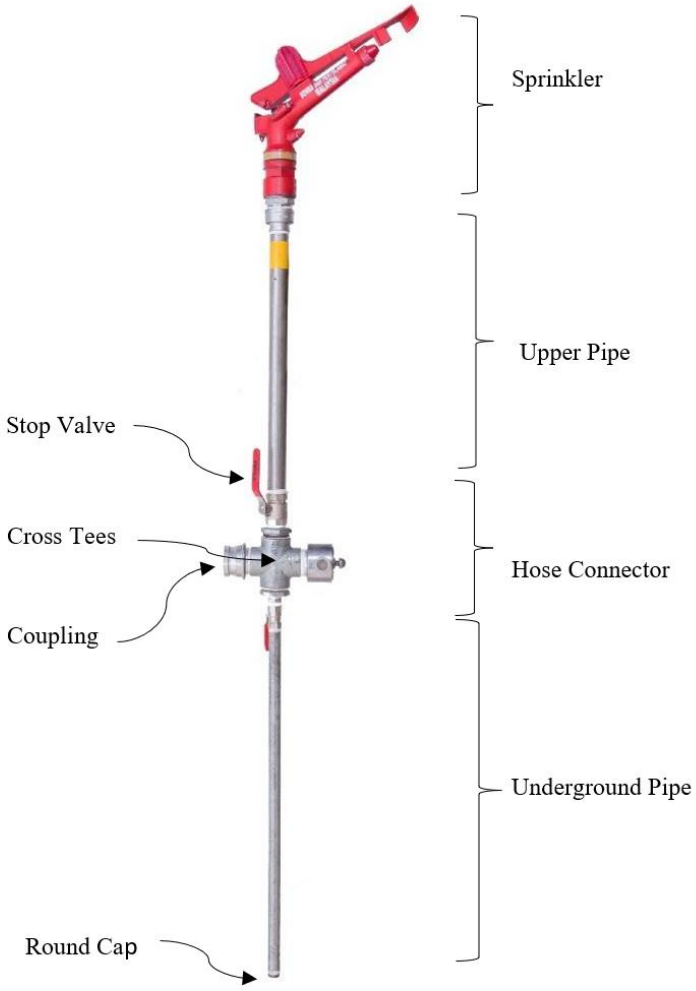

Figure 1: Forest Fire G.S Mark III

The Forest Fire G.S Mark III testing were conducted in an open area. Table 1 shows the apparatus needed in this study.

Apparatus	**Utilization**
Forest Fire GS Mark III	Water outlet
Water pump	Pump water to hose
Collecting Breeching	two water feed hoses supplying one outlet
2 ½ inches hose	Deliver water to outlets
Flowmeter	measuring nonlinear or linear flow rate
Wajex Hose c/w nozzle	Water outlet

Table 1: List of apparatus and its utilization

2.2. Experimental Set Up

The Forest Fire GS Mark III comprises a sprinkler, an upper pipe, a hose connector, and an underground pipe. The total length is 90 inches and weighs 9 kilogrammes. The diameter of the upper pipe is 1 1/4 inches, whereas the diameter of the underground pipe is 1/2 inches. The size of the discharged outlet at the sprinkler and the underground pipe is different. The discharge outlet of a sprinkler, which is regulated by a nozzle tip, is adequate for 10mm particles. In addition, the subsurface pipe initially consisted of four 4.6mm outlets. The stop valves are fitted on both the above- and below-ground pipes. During a fire suppression operation, these functions are employed to shut off a water supply for maintenance i an emergency.

In order to run the Forest Fire G.S Mark III, a water pump is equipped and positioned near water sources such as rivers, temporary ponds, and lakes. For water supply, hard suction hoses are laid from the water source to the water pump. The delivery hoses are fitted every 30 or 60 metres using Forest Fire G.S Mark III from the water

pump. With these two installation alternatives, firefighters can make choices based on the severity of the fire. In the event of a peat fire, the installation of G.S. Mark III equipment at a distance of 30 metres is necessary to raise the groundwater level more quickly, which is equivalent to the technique of total flooding. Moreover, the distance of water spray radius covered between adjacent G.S Mark III. In cases other than peat fires, it is recommended to install G.S Mark III equipment every 60 metres because water spray can reach to a 30-meter radius around the fire.

Currently, the spray type of the Forest Fire GS Mark III sprinkler can be selected using either a static or rotating technique. With the rotating option, the sprinkler's water spray can be changed to 180 degrees or 360 degrees, depending on the fire suppression strategy and local fire scenario. In reality, the installation of Forest Fire GS Mark III along the hoses created a fire break zone to prevent the impacted fire area from spreading to the adjacent region.

2.3. Experimental Configuration

2.3.1. Single Pump Approach

Knowledge of the Forest Fire G.S Mark III in the performance of the water pumping sprinkler systems is important to maximize its effectiveness in extinguishing the peat fire. Forest Fire G.S Mark III is the latest design from its model. The design concept is similar to the sprinklers

There are two designs conducted for a single pump approach. The **first** type of test utilized six Forest Fire GS Mark III while for the **second** design, three Forest Fire G.S Mark III and three Wajex hoses were employed. The field test conducted was to evaluate every design performance base on the pump's pressure. Flowmeters were placed in each test designs.

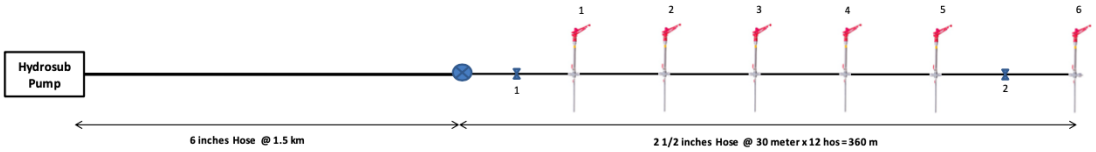

Figure 2: First design

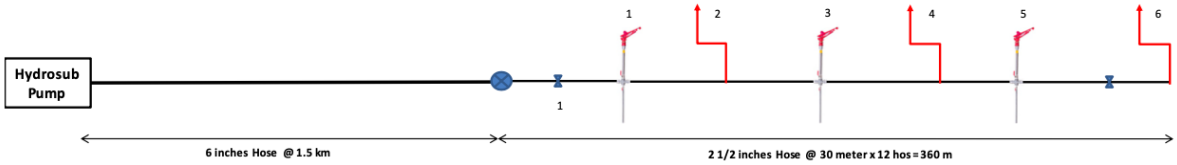

Figure 3: Second design

2.3.2. End-to-End Approach

The test were carried out in a real peat fire test in Tanjung Sepat, Kuala Langat Selangor on 6th March 2021 during the drought season.

The hoses were connected to two portable water pumps between end to end from a different water source. So, the water is put under pressure along the hoses. This test involved laying approximatle of 300m hoses or 10 rolls of delivery hoses. Every 30m, Forest Fire GS Mark III and Forest Fire GS Mark II were installed alternately.

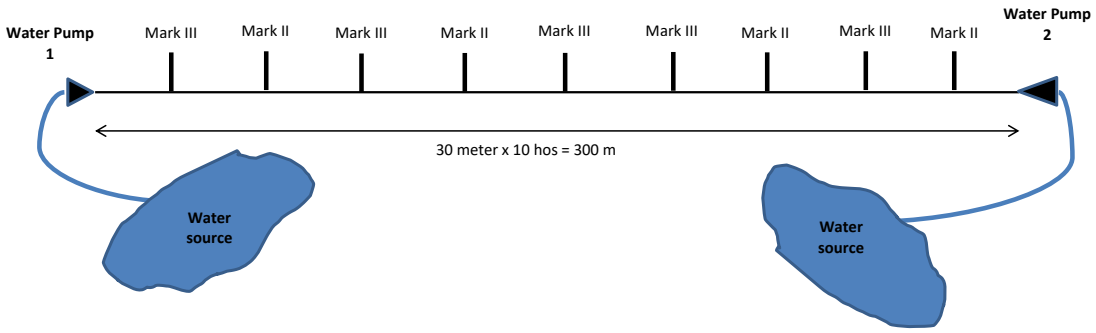

Figure 4: End-to-end pump

2.3.3. Serial Pump Approach

The first rule that should be applied in serial pump approach is the pressure at the second pump should be lower than the first pump. In the same way, the GS Mark III installed before a second pump should not have a pressure drop. Pressure is considered dropped as a spray length at that point is lower than spray length at the next point.

To execute the serial pump approach, a water pump, 16 hoses (480 meters) and 8 units of Forest Fire GS Mark III were set up. Two hoses from the water pump were connected to the hose line using a collecting breaching.

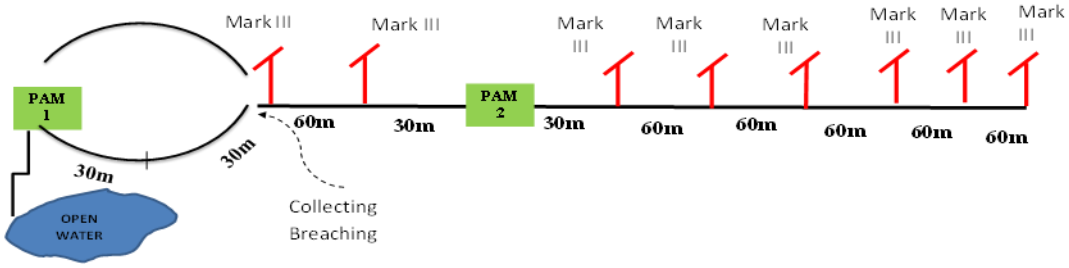

Figure 5: Serial pump arrangement

3. Results and Discussion

3.1. Single Pump Approach

During the test, the environment condition where the test is taken place is very important to get accurate data. This test was conducted place in the open environment, and the weather is not windy. The following table present data from the test conducted to test the performance of Forest Fire G.S Mark III. The result of test 1 and test 2 are as follow:

Table 2: Result for 1st Design

Hydrosub pump pressure (Bar)	Flowmeter 1		GS Mark III					Flowmeter 2		GS Mark III
			1	2	3	4	5			6
	Pressure (Bar)	Flowrate (L/Min)	Spray Length (Meter)					Pressure	Flowrate (L/Min)	Length
5	5.01	1070	24.19	17.17	10.9	6.28	5.09	0.43	80	4.23
7	6.1	1210	28.87	23.93	18.45	9.42	7.83	0.62	110	7.5
9	7.72	1370	29.41	19.93	19.26	11.96	11.11	0.84	130	8.69
11	8.35	***1440***	31.9	28.86	23.91	17.22	13.43	0.99	147	12.08

Table 3: Result for 2nd Design

Hydrosub pump pressure (Bar)	Flowmeter		GS Mark III + Wajex Hose					Flowmeter		Wajex Hose
			1	w	3	w	5			W
	Pressure (Bar)	Flowrate (L/Min)	Spray legth (Meter)					Pressure (Bar)	Flowrate (L/Min)	Length
5	3.86	850	22.3	13.88	8	6.58	5.5	0.15	12	2.6
7	5.55	1100	28.89	17.43	10.66	8.34	8.18	0.84	70	4.26
9	7.3	1300	30.75	23.19	16.45	14.13	14.95	1.02	117	10.99
11	9.03	1440	29.46	20.56	19.56	17.76	15.92	1.34	128	12.69

The data of design 1, and 2, show that increasing the hydrosub pump pressure increase the flow rate and the spray length. The pressure reduction from the first output station to the last output station. The length of spray also reduces from every output station to output stations.

3.2. End-to-End Approach

The installation of the equipment took about one hour. The area covered during extinguishment about 18, 000m2 or 4.45 acres or 1.8 hectares within 50 minutes.

3.3. Serial Pump Approach

The result of testing is elaborated as follows:

Table 4: Result for Serial pump

Field Test	Pump 1	Spray Length		Pump 2	Spray Length					
	Pressure (Bar)	GS Mark III	GS Mark III	Pressure (Bar)	GS Mark III	GS Mark III	GS Mark III	GS Mark III	GS Mark III	GS Mark III
		1	2		3	4	5	6	7	8
Test 4	7 bar	19.62	19.96	5 bar	21.92	21.24	19.26	17.65	17.54	17.20

The test performance showed the spray length remained nearly similar even though the hose line increased to 480 meters. Using a collecting breaching technique, the water flow rates remain maintained along the hose line. For a longer hose line, a powerful water pump should be used to get a longer spray length and keep the flow rate along the hose line. The performance also showed that any Forest Fire GS Mark III could be changed to be an attack hose (with nozzle) for direct attack purposes.

4. Conclusion

To extinguish traditional forest fires, the Forest Fire G.S Mark III is also designed to extinguish peatland fires where the source of the flame is buried deep underground. The most successful and capable means of extinguishing a peat forest fire, according to the experienced firefighters involved in peat forest fire operations, is watering or flooding the area until the underground water layer is raised. Using Forest Fire G.S Mark III equipment, the spray of water flowing out of the underground pipe can permeate the peat soil's pores, flooding the peat layer under the surface. In addition, spraying on the higher pipe and rotating sprinklers assist in saturating the upper and lower soil surface layers.

With the development of G.S Mark III technology, extinguishing operations can be conducted constantly for 24 hours (including at night). Firefighters need just monitor the portable water pump at the fire scene. The method and application of G.S Mark III equipment are highly effective at preventing the spread of fires, hence avoiding considerable forest destruction and losses for all parties. In addition, firefighters are protected from a variety of perils, including pit falls, wild and toxic animals, and even pre-war munitions. This method of extinguishment can also restrict the exposure of firefighters to harmful plants, water-borne infections, and mosquito-borne disorders.

Further, according to the present invention, the area covered during extinguishment about 18,000m^2 or 4.45 acres or 1.8 hectares within 50 minutes by mains off end to end pump or serial pump installation.

Abstract

The merging of two linear forest fire fronts that intersect at a small angle creates an accelerating fire in a relatively short time. In the majority of cases during the interaction, the fire fronts are non-symmetric. In Pedrogão Grande on the 17th June 2017, two-fire front merged and the propagation of the fire was influenced by the interaction of these two non-symmetric fire fronts. This forest fire motivates us to study the Junction Fire with two non-symmetrical fire fronts. The analysis of the interaction of two fire fronts and the angle between the bisector of the fire lines and the maximum ROS (γ) is of particular relevance. We found that with these preliminary laboratory tests, the non-ROS of intersection fire fronts for small rotation angles (δ) depends on the slope angle (α) and the initial angle between fire fronts. For the higher slope angles, the non-ROS is the highest influence by the convection process, and the angle γ where the maximum ROS occurred, increases when δ increases. However, for the lowest slope angles, the radiation process is dominant and influences the non-ROS. For these cases, the angle γ is near to the bisector of the fire lines.

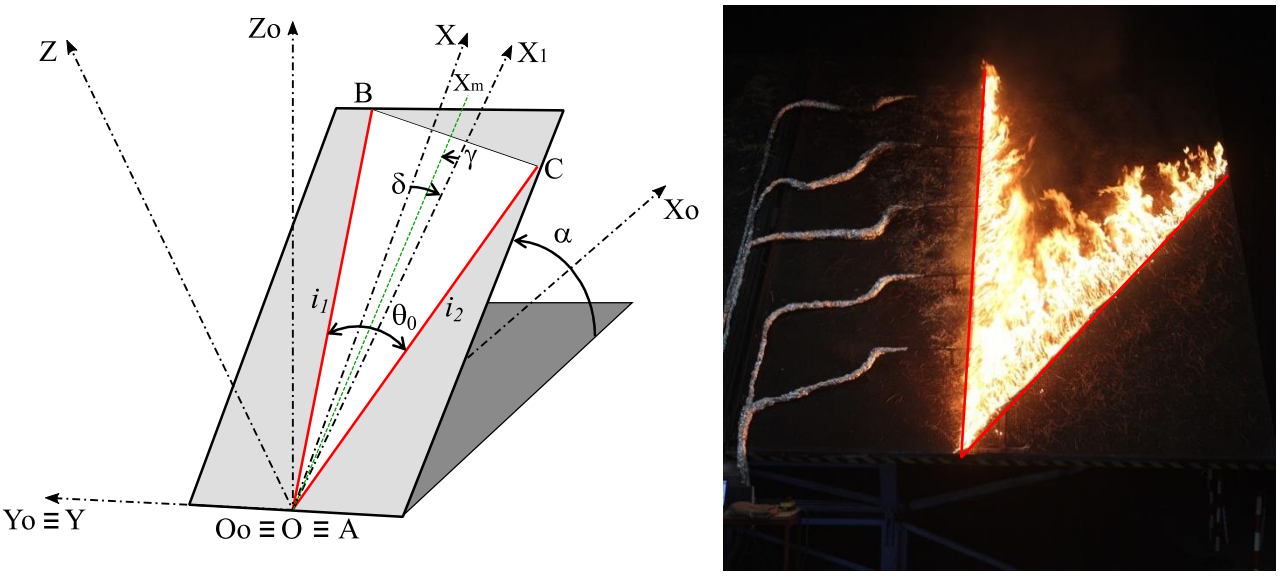
1. Introduction

The merging of two fire fronts that intersect at a small angle induced very high values of the Rate of Spread (ROS) and fire intensity of their intersection point, and followed a gradual velocity decrease in the course of the time when the angle between fire fronts increases. This problem was studied in the past by Viegas et al. 2012, initially described this phenomenon as a Jump Fire, and developed a conceptual analytical model for the vertex "V" ROS. After the initial project, numerous research works experimental, analytical, and numerical simulation were followed (Viegas et al. 2013; Raposo et al. 2015, 2018; Sharples et al. 2013; Hilton et al. 2016; Thomas et al. 2017; Sullivan et al. 2019; Filkov et al. 2020). The fire fronts were always symmetrical in relation to the vertex "V" and there was no fuel bed to burn outside of linear straight fire lines. The results showed that the ROS of the vertex "V" has a great relationship in which the initial angle between the merging fire fronts and the ROS increases sudden zero to values of the order of one hundred times the basic ROS. A real fire situation occurred in the merging of two large fires: one near Canberra on the 18th January 2003 and, more recently, in Pedrogão Grande on the 17th June 2017.

On 17th June of 2017, the Pedrogão Grande fire starts at Escalos Fundeiros by 14:30h, and there was a second ignition in Regadas by 16:00h, local time, according to Viegas et al. 2017. The distances between those two ignitions were 2.6km and at 19:30h the two-fire front merged and the propagation of the fire was influenced by the interaction of these two non-symmetric fire fronts. This forest fire motivates us to study the Junction Fire with two non-symmetrical fire fronts.

2. Physical Problem

In the present study, it is assumed that two straight fire lines intersect at point ***A*** with an initial angle θ_0 between them and spread in a uniform fuel bed layer on a flat surface making an angle α with the horizontal datum $O_oX_oY_o$. Cartesian coordinate system $O_oX_oY_oZ_o$ is considered, in which O_oZ_o is perpendicular to the ground. Point ***A*** coincides initially with the origin of the reference cartesian frame with axis ***OX*** parallel to the slope gradient. The axis OX_1 represents the symmetry line of the fire configuration and can be defined by the angle δ that represents the angle between the bisector of the fire lines and the line with the highest slope. However, for each angle α and δ the maximum ROS happened according to axis OX_m and this axis is rotated some angle γ that represents the angle between the bisector of the fire lines and the maximum ROS. The fuel bed area is defined by ***ABC*** and is covered by a uniform layer of forest fuel able to support the spread of a surface fire. The merging of two linear fire fronts is illustrated schematically in Figure 1 a).



a) b)

Figure 1- a) Schematic layout of the merging of two non-symmetric straight fire lines making an initial angle 0 between them. The axis OX is parallel to the slope gradient, the axis OX1 represents the symmetry line of the fire configuration and the axis OXm, defined by the green dashed line, represents the maximum ROS happened. b) View of the Canyon Table DE4 of the Forest Fire Laboratory of the University of Coimbra.

We consider two linear fire fronts defined by two straight lines (***AB*** and ***AC***), non-symmetric in the OX axis, as shown in Figure 1 a). Henceforward, the linear fire lines ***AB*** and ***AC*** will be referred to as i_1 and i_2, respectively. In this study, it is assumed that the ambient air is still in accordance with the experimental conditions at the laboratory and at time $t_0=0s$, the fire lines are simultaneously and instantaneous ignited.

3. Material and Methods

3.1. Laboratory Experiments

Laboratory experiments were carried out at the Forest Fire Research Laboratory of the University of Coimbra using the Canyon Table DE4 and that has a useful area of $6.0x8.0m^2$ with a slope (α) that can be changed in the range of 0^o to 40^o. The initial angle θ_0 between the two fire lines was 30º. In Figure 1 b) typical performance conditions of these tests are shown.

During the preparation of each test, the conditions of the fuel load and bulk density were controlled, and the air temperature (^oC), relative humidity (%) and fuel moisture (m_f) were monitored. The fuel bed for the experiments was composed of dry particles of dead pine needles (*Pinus pinaster - PP*) with a constant load of 600g.m^{-2} (dry basis) (Viegas and Pita 2004; Xie et al. 2014; Raposo 2016; Raposo et al. 2018; Rodrigues et al. 2019; Viegas et al. 2021). The fuel bed height (h_f) was measured in five aleatory positions and on average it was 5.2cm. The basic rate of spread R_o (cm.s^{-1}) of a linear fire front in a fuel bed with the same properties was measured for

each series of tests using a 1x1m^2 horizontal fuel bed without slope and wind. The ignition of the two fire lines was made by two persons to assure that the lines started burning simultaneously and two wool threads soaked in a mixture of petrol and diesel fuel were used. A summary of the main test parameters is provided in Table 1.

Table 1 – Parameters of the tests.

3.2. Evolution of the ROS

The instantaneous position x_A of the intersection point A along the axis OX_m was the main object of the present analysis and it is associated with the overall evolution of the fire fronts. The displacement velocity R_A is defined as:

$$R_A = \frac{\partial x_A}{\partial t} \tag{1}$$

In order to compare results performed with different fuels we use the non-dimensional displacement velocity R'_A defined by:

$$R'_A = \frac{R_A}{R_o} \tag{1}$$

where Ro is the basic ROS.

4. Results and discussion

4.1. Rate of Spread analysis

The evolution of the fire front during tests performed was recorded by IR camera and frames with pre-defined times were used to measure the ROS of point A. The area between two fire fronts is burned by the advance of the intersection point A.

Results of R'_A from a series of tests performed as a function of the time are shown in Figure 2. In general, the evolution of R'_A, for $\alpha=10^o$ and $\alpha=20^o$, happens with a market acceleration when the fire lines are ignited, but, during the time, a deceleration phase happens. Otherwise, for $\alpha=30^o$ and $\alpha=40^o$, the evolution of R'_A has a market non-monotonic behaviour, but after the R'_A reaches the maximum value the deceleration phase happens. For the angle δ and slope angle α performed, there is no marked difference between the R'_A for each combination. For $\alpha=30^o$ and $\alpha=40^o$, the R'_A for $\delta=0^o$ (JF151530_1 and JF151540_1, respectively) on average during the time is quite similar to the δ values performed.

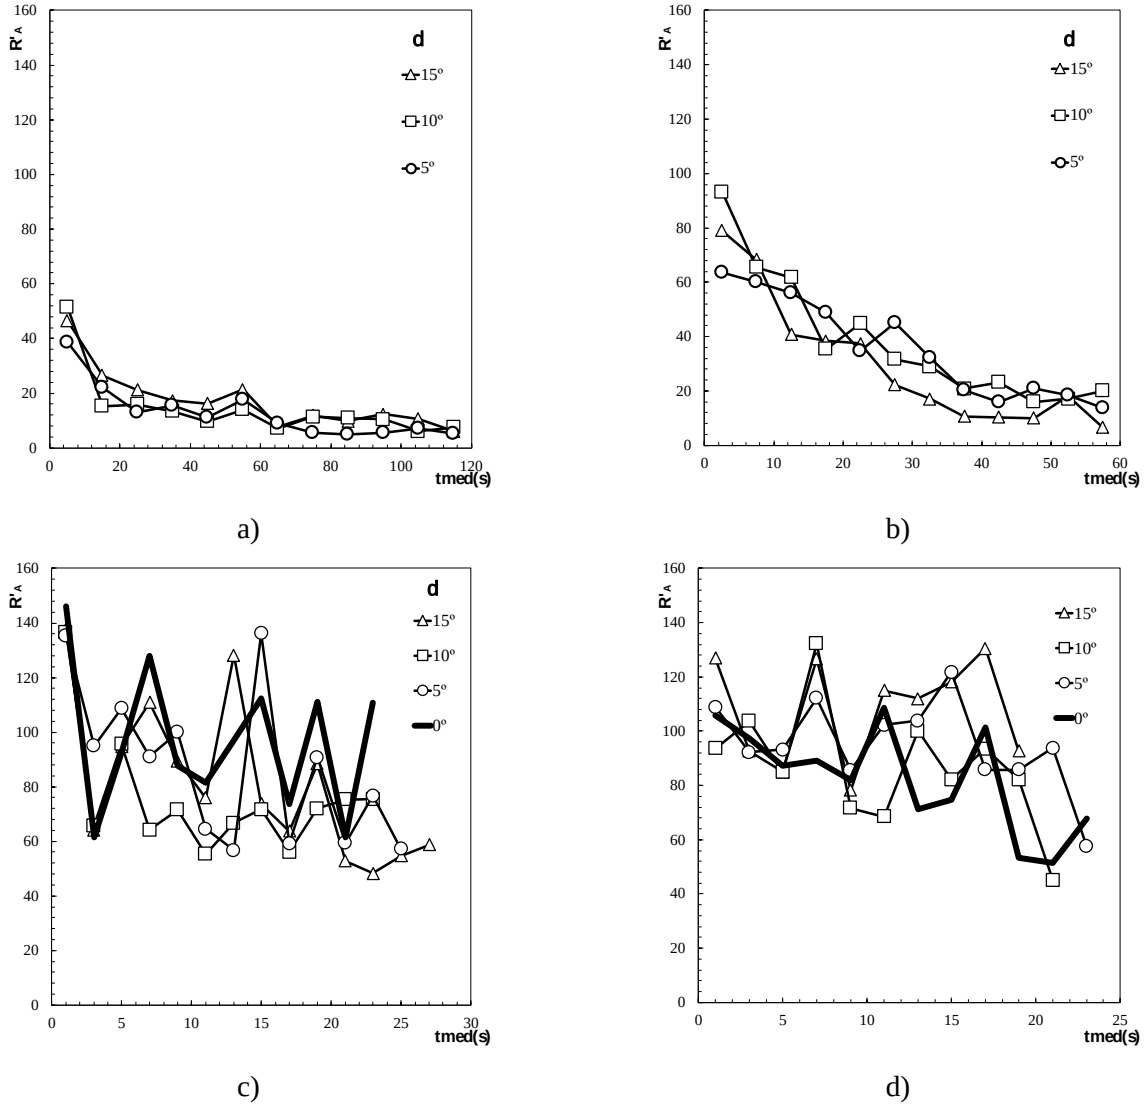

Figure 2 - Non-dimensional ROS R'_A of the intersection point A as a function of the time. The angle δ=5º, 10º and 15º were plotted in all analysis and, for α=30º and 40º, the angle δ=0º was added. a) α=10º; b) α=20º; c) α=30º and d) α=40º

4.2. Angle of the maximum ROS

In order to assess the overall role of the parameters α and δ, the angle γ for each set of parameters was measured. These values are plotted in Figure 3 as a function of the angle between the bisector of the fire lines and the line with the highest slope (δ), for all tests performed. As can be seen, for the highest value of the slope (α=30º and 40º) the angle γ has a similar trend and, in those cases, the axis, where happens the maximum ROS, is influenced more by the convection process. However, for the lower values of the slope the values (α=10º and 20º) the angle γ tends to decrease and the maximum ROS happens near the bisector of the fire lines. In that case, the radiation process in the vicinity of point ***A*** is dominant relative to the convection process.

The dashed lines, in Figure 3, represent the fitted linear regression of the data values for each slope angle (α) and the correlation coefficient R^2 for this fitting is for $a=10º$, $R^2=0.864$, and $a>10º$, $R^2=0.991$.

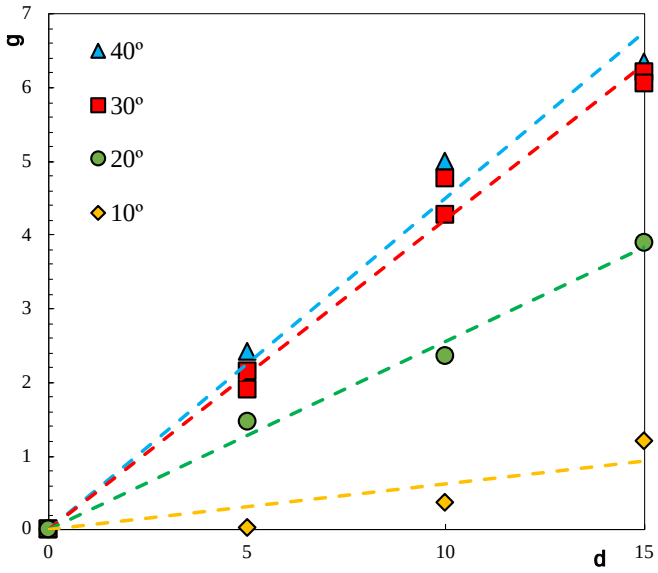

Figure 3- The angle between the bisector of the fire lines and the maximum ROS (γ) as a function of the angle between the bisector of the fire lines and the line with the highest slope (δ). The dashed lines represent the fitted linear regression of the data values for each slope angle (α).

5. Conclusion

Analysis of the Junction Fires with non-symmetric linear fire lines based on laboratory scale experiments was performed for different inclined terrain, ***α=10º, 20º, 30º*** and ***40º***. The evolution of the fire front consists mainly of the advance of the intersection point ***A***, with an initial angle θ_0***=30º*** between fire lines. For the δ angles performed, the non-ROS R'_A is quite similar for each slope angle and, for ***α=30º and 40º***, similar with symmetric condition ***δ=0º.*** With these preliminary laboratory tests, we conclude that the non-ROS of the intersection point ***A*** for small rotation angles depends on the slope angle and the initial angle of the fire fronts. However, for the highest slope angles, the convection process is dominant and changes the angle γ where the maximum ROS occurred but, for the lowest slope angles, the variation angle γ is lower and near to the bisector of the fire lines.

This study must be complemented by more tests to reduce experimental errors and to explore other conditions, different fuel bed types and scale effects.

Extreme fire weather, Europe, ERA5, trends, change-points

Abstract

This work summarizes preliminary results of a spatiotemporal analysis focusing on changes in the occurrence of fire danger extremes in Europe between 1980 and 2019. Extreme danger days were defined based on the daily severity rating exceeding the locally defined 95th percentile. For the 2001 – 2019 period, we show that extreme fire danger days and total burnt area have a positive relationship across Europe, albeit stronger in the eastern half of it. Trend analysis results indicate that extreme fire danger days have overall increased in Europe, with the largest increases found in the north-eastern regions. Further, we illustrate that these increases may be related to abrupt shifts in the means, especially over the south-west Mediterranean, and central and north-eastern Europe. These shifts took place primarily during the 1990s, marking large increases in the mean annual number of extreme fire danger days before and after the years of change. It is hypothesized that these abrupt shifts in fire danger extreme means could be associated with changes in the large-scale circulation of the atmosphere. Overall, the approach followed in the present study is novel as it has not been implemented in previous studies focusing on fire weather extremes. In that view, it complements existing studies and provides new insights into the spatiotemporal variations and changes of fire danger extremes in Europe.

1. Introduction

According to the European Forest Fire Information System, the 2021 fire season in Europe was the second worst on record since 2000 (San-Miguel-Ayanz et al., 2021). Large and extreme wildfires burnt more than 500,000 ha across 22 EU27 Member States, with Mediterranean countries experiencing the most damages. These wildfires are the latest in a series of catastrophic events that affected Europe in recent years. Some of the worst cases include the wildfires that occurred in Portugal (2003, 2005, and 2017), Spain (2006 and 2017), Greece (2000, 2007, and 2018), and Sweden (2018). Researchers argue that the frequency and intensity of such events have been increasing due to the more frequent occurrence of extreme fire weather (e.g., Abatzoglou and Williams, 2016; Bowman et al., 2017; Jolly et al., 2015).

In this work, we present preliminary results of a spatiotemporal analysis focusing on the occurrence of fire danger extremes in Europe between 1980 and 2019. Our analysis is based on the daily severity rating (DSR), a sub-component of the Canadian Forest Fire Weather Index System (CFFWIS; Van Wagner, 1987) that indicates fire suppression difficulty. Trend analysis was conducted to quantify long-term changes in the occurrence of fire danger extremes in Europe. In addition, we applied statistical change-point detection methods to identify and quantify abrupt changes in the occurrence of extreme fire danger days.

2. Data and methods

Daily, gridded DSR data were retrieved from the 0.25^o x 0.25^o spatial resolution GEFF-ERA5 reanalysis dataset of the CFFWIS (Vitolo et al., 2020), developed by the European Centre for Medium-range Weather Forecasts (ECMWF). The data cover spatially the European region from 25^o W to 40^o E and from 34 ^{o}N to 72 ^{o}N (Figure 1) and extend temporally from 1 January 1980 to 31 December 2019 (40 years). Extreme fire danger days were defined based on DSR exceeding the locally (grid cell-specific) defined 95th percentiles (reference period 1981

– 2010). We opted for using percentile-based local thresholds since previous studies have shown that local extremes promote large fire growth (e.g., Abatzoglou et al., 2021).

The statistic used to quantify changes in extreme fire danger occurrence in Europe is the annual count of extreme DSR days. We applied the non-parametric Pettitt test (Pettitt, 1979) to detect abrupt changes in the time series of extreme DSR days, and the non-parametric Mann-Kendall (MK) test (Mann, 1945; Kendall, 1976) to quantify long-term trends. Finally, we supplemented our analysis with observed burnt area data for the 2001 – 2019 period, retrieved from the FireCCI v5.1 dataset (Lizundia-Loiola et al., 2020) of the European Space Agency (ESA) Climate Change Initiative.

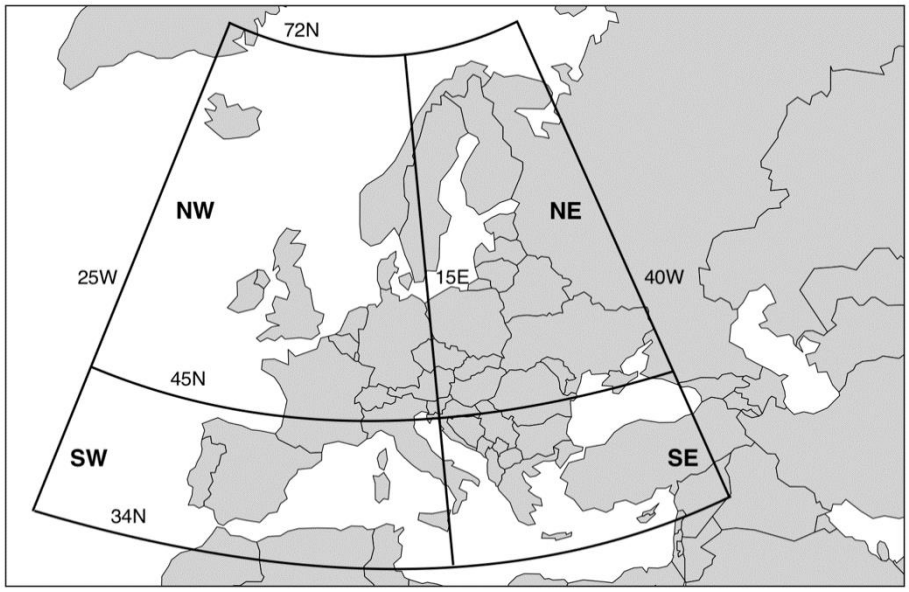

Figure 1 – Study area with identification of the different sub-regions used in the analysis.

3. Results

3.1. Relationship between fire danger and burnt area

Figure 2 summarizes a simple exploratory analysis between the annual count of extreme fire danger days and the annual total burnt area (in non-agricultural vegetation class categories) in the examined sub-regions of Europe (Figure 1). Results indicate a statistically significant ($p < 0.05$) positive relationship between the two variables (Figure 2a), which is stronger in the eastern part of the study area (SE, NE) than in the western part (SW, NW). Further, it can be seen that the most destructive years during the examined period (2001 – 2019) coincide well with peaks in the annual count of extreme fire danger days in all European sub-regions (Figure 2b).

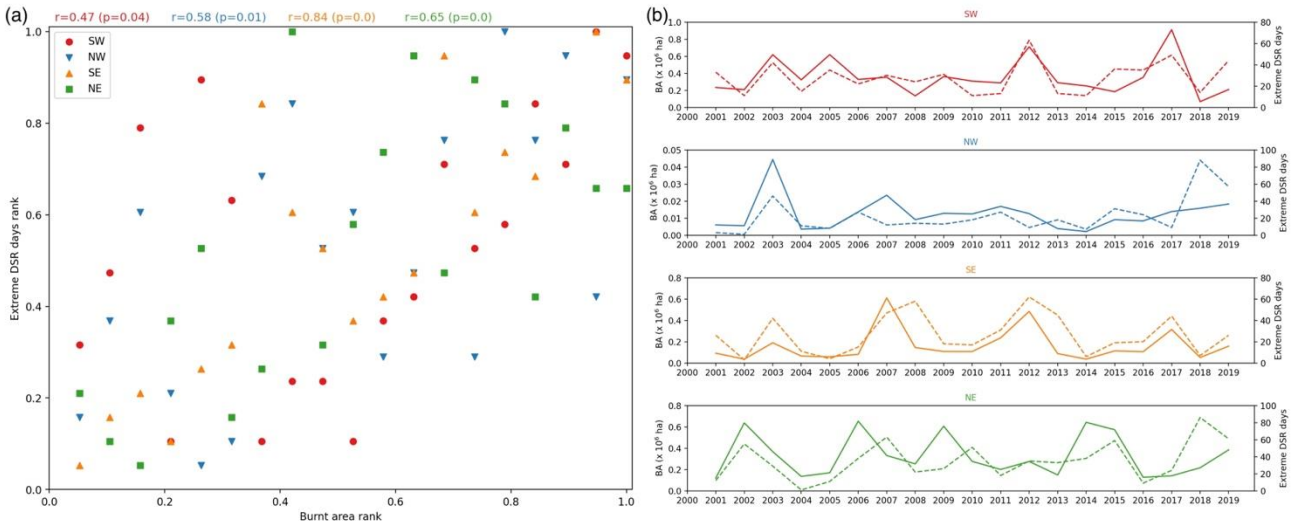

Figure 2 – (a) Scatter plot between the annual total burnt area in the different European sub-regions and the corresponding annual count of extreme DSR days. All data are plotted in their rank order, scaled between 0 and 1. Different colors and symbols are used for the data pooled from the different sub-regions. Spearman correlation coefficients (r) and their associated p-values are shown on top of the plot, with colors corresponding to the different European sub-regions. (b) Time series of the annual total burnt area (solid lines) and the corresponding annual count of extreme DSR days (dashed lines) in the different European sub-regions.

3.2. Seasonality and changes in extreme fire danger occurrence

Extreme fire danger days exhibit a clear seasonal cycle (Figure 3), occurring primarily during the warmest part of the year, from June to September in southern Europe (SW, SE) and from May to September in northern Europe (NW, NE). This suggests that the northern European countries are more prone to experiencing locally extreme fire danger days at the edge of the traditional fire season (May to October) compared to the southern Mediterranean countries, where occurrences of extreme fire danger days peak during the hottest months of July and August.

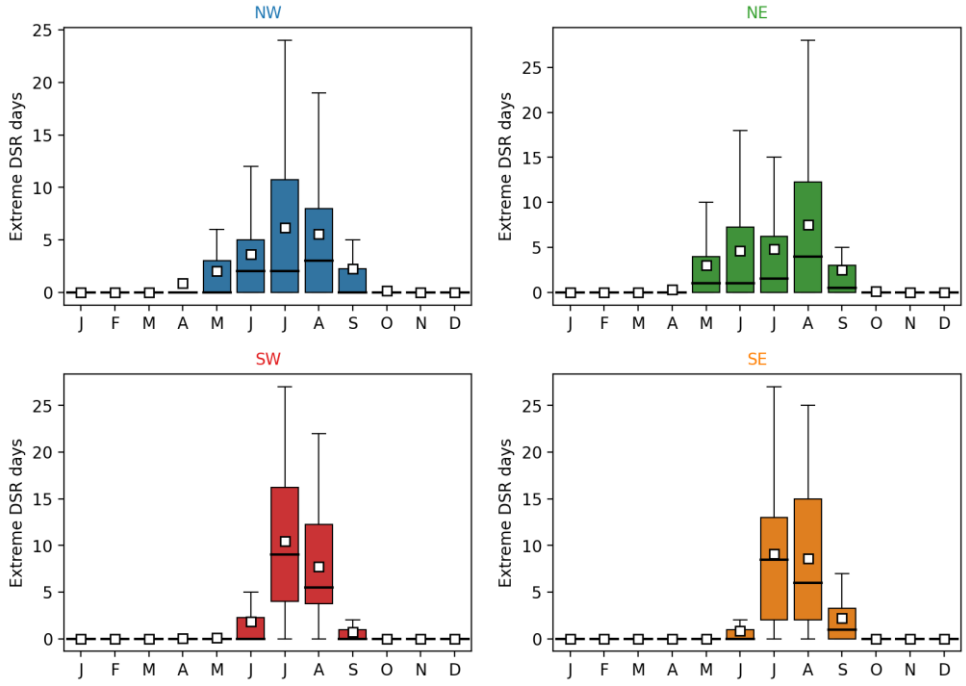

Figure 3 – Monthly distribution of extreme DSR days in the different European sub-regions for the period 1980 – 2019. Solid black lines and white boxes denote median and mean values, respectively. Error bars indicate the interquartile range of the data.

Extreme fire danger days have increased between 1980 and 2019 in all European sub-regions (Table 1). Statistically significant ($p < 0.05$) increases were computed for the SW, SE, and NE sub-regions, whereas a non-significant trend was found in the NW sub-region. The magnitude of the statistically significant increasing trends was found to range from an additional 4 days per decade in the SE sub-region to more than 10 days per decade in the NE sub-region.

Table 1 – Extreme DSR days trends in the different European sub-regions, computed for the 1980 – 2019 period. Show are the decadal trends computed using the MK test and the associated p values.

European sub-region	Trend (days decade^{-1})	p-value
SW	6.3	0.00
NW	3.0	0.23
SE	4.3	0.01
NE	10.9	0.00

Results of the Pettitt test indicate that the increasing occurrences of extreme fire danger days in the SW and NE European sub-regions may be linked to abrupt changes in the means. The change-points for the above two sub-regions occurred in the 1990s (1991 for the NE and 1997 for the SW), marking sharp increases in the mean annual number of extreme fire danger days (Figure 4).

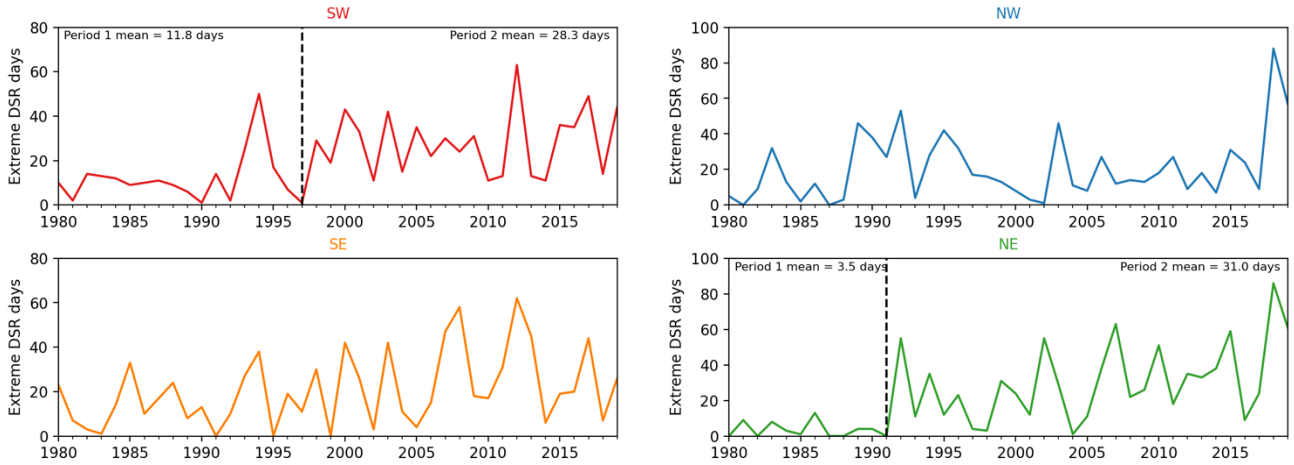

Figure 4 – Time series of the annual count of extreme DSR counts in the different European sub-regions. Vertical dashed lines denote statistically significant potential change-points.

Concerning the spatial variability of changes in extreme fire danger days, Figure 5 reveals widespread, statistically significant potential change-points over a large part of Europe. The largest changes were found in the eastern part of the study area, where many grid cells were found to experience up to more than 30 additional extreme fire danger days per year after the year of the potential change-point (Figure 5b). The related change-points were found to occur mostly in the early 1990s (Figure 5a, green-colored grid cells). Grid cells in south-eastern Spain were also found to experience large increases, up to more than 20 additional extreme fire danger days per year after potential change-points that occurred in the mid-1990s. Finally, grid cells in central Europe (eastern France, southern Germany) were found to exhibit 10 – 15 additional extreme fire danger days per year after potential change-points that occurred in the 2000s.

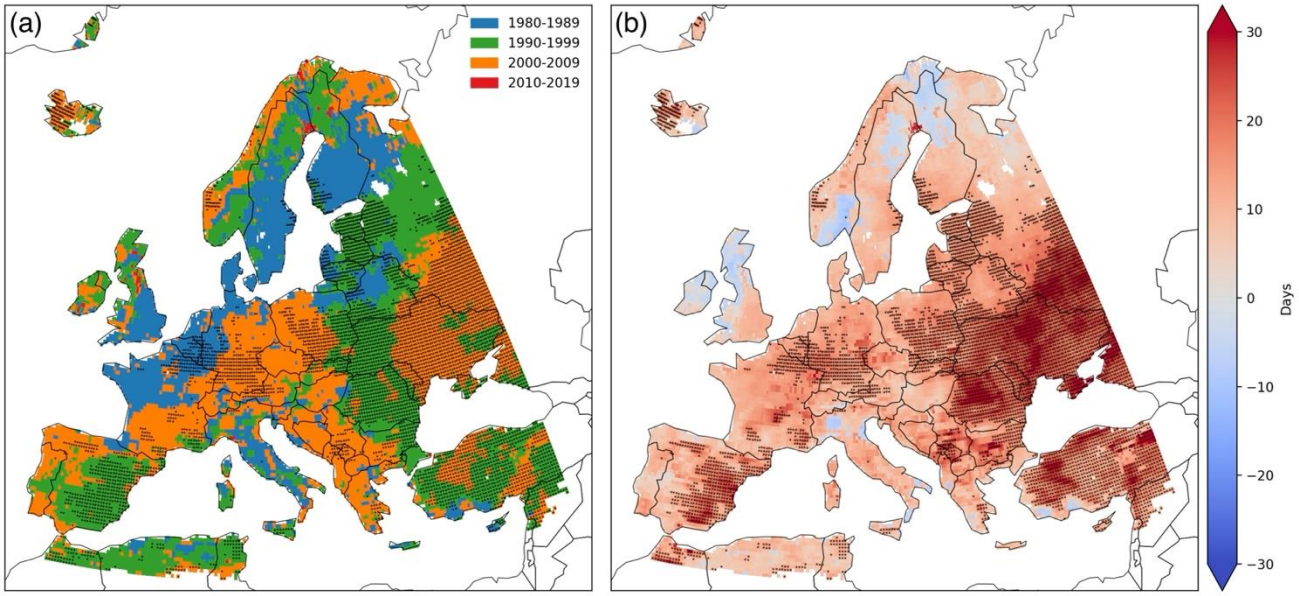

Figure 5 – (a) Years of potential change-points in the time series of the annual count of extreme DSR days. (b) Change in the mean annual count of extreme DSR days before and after the potential change-points. Stippling indicates statistical significance (at the 95 % confidence interval) of the potential change-points. Change points and the associated statistical significance were computed using the non-parametric Pettitt test.

4. Conclusions

The preliminary results of our spatiotemporal analysis indicate that extreme fire danger days have increased in Europe during the period from 1980 to 2019. Within large parts of the SW and NE European sub-regions, but also in central Europe, these increases seem to have taken place abruptly. This conclusion is supported by the statistically significant potential change-points that were identified in the time series of the extreme fire danger days. Abrupt changes appear to have occurred in the mid-1990s in the SW sub-region and over the largest part of the NE sub-region, marking very large changes in the mean annual occurrences of extreme fire danger days before and after the year of change. It can be speculated that these abrupt changes may be associated with changes in large-scale atmospheric circulation and atmospheric teleconnection patterns, which in turn gave rise to increases in temperature and decreases in humidity and precipitation. However, this is an hypothesis that needs to be statistically verified before reaching to robust conclusions.

Wildfire Management, Planning, Suppression Cost, Matching Methods

Abstract

Wildfire suppression expenditures in the United States regularly exceed a billion dollars and are expected to continue rising due to climate change, high fuel loads, and a growing wildland urban interface. Risk management research suggests that pre-fire planning reduces uncertainty and may lead to better wildfire management outcomes including lower suppression costs, less damage to values at risk and improve safety outcomes. One form of pre-fire planning in US National Forests is known as potential operating delineations (PODs) whereby stakeholders collaboratively identify area on the landscape where wildfire can be safely and effectively engaged. Moreover, the area defined by the PODs are classified based on the level of urgency to suppress fire.

The objective of this paper is to test whether fires that have occurred within areas that have undergone the POD process are systematically different from fires that have not undergone PODs. We evaluate the following wildfire outcomes: final fire cost, final fire size, cost per acre, and duration. We employ statistical matching methods to find comparable non-POD fires that serve as "control" units for our POD "treated" fires. Our results suggest that POD fires cost $373 per acre less than non-POD fires, and that the POD fires cost per acre is comparable to prescribed burning cost per acre in the Southwestern US. These results imply that pre-fire planning like the POD process may reduce suppression costs to a level comparable with prescribed burning facilitating the long-standing recommendation from fire ecologists to "restore fire to the landscape."

1. Introduction

Billions of dollars are spent on wildland fire management in the United States each year. These costs are a result of decisions to commit resources to manage and suppress fire. Climate change, a growing wildland urban interface, and the accumulation of fuels are expected to drive increased fire activity necessitating additional resources that will likely increase costs. For decades, the default response had been to suppress all fire as quickly as possible. This strategy has led to an accumulation of fuels that currently contribute to large costly incidents (Thompson et al., 2013). Risk management offers insights that when applied to wildfire management can improve effectiveness, reduce costs, and increase safety (Thompson et al., 2011, 2019). Risk management involves planning in advance of an incident to identify risks and make informed decisions.

The wildfire community has recognized the importance of planning in advance of incidents. The process to identify and characterize potential operational delineations (PODs) is an attempt to plan in advance of the incident (Dunn et al., 2020). PODS summarize wildfire risk before ignitions occur and may guide operations as fires progress. In cases where a fire is burning in a POD with a low risk rating, managers may employ less aggressive suppression strategies that may reduce cost. While less aggressive suppression may result in larger fires, they may provide ecological benefits and reduce the risk of firefighter injury.

Fuel treatments are another tool used to mitigate the impacts of fire. Fuel treatments are an important tool to reduce fuel loads thereby reducing the risk of uncontrollable wildfire. However, fuel treatments can be costly (US Forest Service, 2015). Mechanical treatments involve considerable machinery and labor. Prescribed burns carry political risk and generate smoke that impose additional costs on society (Navaro et al., 2018). Managing wildfire to achieve the benefits of fuel treatment may represent a less costly method for mitigating fuels and the potential for future fire damage.

We investigate the impact of the POD process on economic and operational aspects of fire management. Our approach is to compare fires that occur in forests that have developed PODs to statistically similar fires that

occur in forests that have not developed PODs. After controlling for numerous factors that may influence fire outcomes, we attribute differences in fire outcomes to the POD process. We find that POD fires have a lower cost per acre, which supports the idea that planning prior to the fire event can improve the efficient use of suppression resources. We then compare the average cost per acre of POD and non-POD fires to mechanical and prescribed treatments to see if cost savings are present.

2. Data and Methods

Our objective is to empirically analyze the impact of the POD process on suppression operations and to compare the cost of POD fires to alternative methods of fuel treatment. The POD process is relatively new and has only been administered on a few forests. In particular, the Tonto National Forest (Southwestern US) developed PODs in 2017. As of 2021, the Southwest Region has 40+ landscapes in national forests that have undergone the PODs process. We compare a set of fires that burned in the Southwest region in 2019 (POD fires) to statistically similar fires that were not in a forest with developed PODS (non-POD fires). We compare POD fires to non-POD fires across multiple outcome variables through regression analysis. We then compare the costs of wildfires managed under these strategies to fuel treatment costs in the same areas. Our methods are straightforward and contribute to the novel research around POD fires. Prior research on the benefits of PODs is qualitative in nature using mechanisms like interviews and surveys. Our econometric-driven approach is a useful lens to support other PODs research.

2.1. Data

We assemble a dataset from several disparate sources to investigate the impact of PODs on suppression operations. We begin with 20 fires from 2019 that occurred in US National Forests that underwent the POD planning process. We extract the ignition location point, start and end dates of suppression or management operations, and final fire size from USFS records. We cross-reference this list of fires with US Forest Service suppression billing records to estimate the cost of the fires. We also extract preparedness level from the National Interagency Fire Center to account for the level of strain on the wildfire response system during a fire.

In addition to location and dates, we use weather and topographical data to incorporate pre-fire conditions into our matching approach. Weather variables, including temperature, energy release component, precipitation, humidity, and wind speed were averaged for the 10 days leading up to the first reporting date from Gridmet data. Topographical features such as elevation, slope, aspect, and ruggedness are generated from a digital elevation model using the elevatr package in R.

2.2. Matching Methods

We employ several empirical strategies to analyze the impact of the POD process on suppression operations. Our primary empirical strategy is to match fires that ignite in forests that have undergone the PODs process, so called POD fires, with fires that ignite in forests that have not undergone the PODs process, non-POD fires. The intuition behind matching is that we are able to identify non-POD fires that are similar to POD fires along several observable dimensions to serve as the "control" group in our experimental design. Ideally, the occurrence of the fire in a POD forest is the only meaningful difference between the POD fire and its non-POD (control) counterparts.

To accurately investigate the cost savings and other benefits of POD fires, similar non-POD fires are needed for comparison. Using the data described above, we develop a propensity score matching model to find suitable non-POD matches for the set of POD fires. Specifically, fires are matched based on: region of the US (GACC), national preparedness level, fire cause, topographic and weather in the 10 days preceding ignition. Topographic data include elevation, slope, aspect, and ruggedness within 2km of the point of ignition. Weather data include energy release component, precipitation, minimum near-surface relative humidity, maximum near-surface air temperature, wind speed. We use the 10 days before fire ignition to avoid the effects of the fire progression and suppression operations that may confound our estimate of the effect of the POD process on wildfire outcomes.

POD fires were matched to non-POD fires at a ratio of 1 to 3. In total, we matched 17 POD fires to 51 non-POD fires. We requested management cost data for non-POD fires and received data for 24 fires where at least one of the 51 matched fires corresponded to a POD fire. Our end sample size included 16 POD fires and 24 non-POD fires. The locations of these fires are shown in Figure 1.

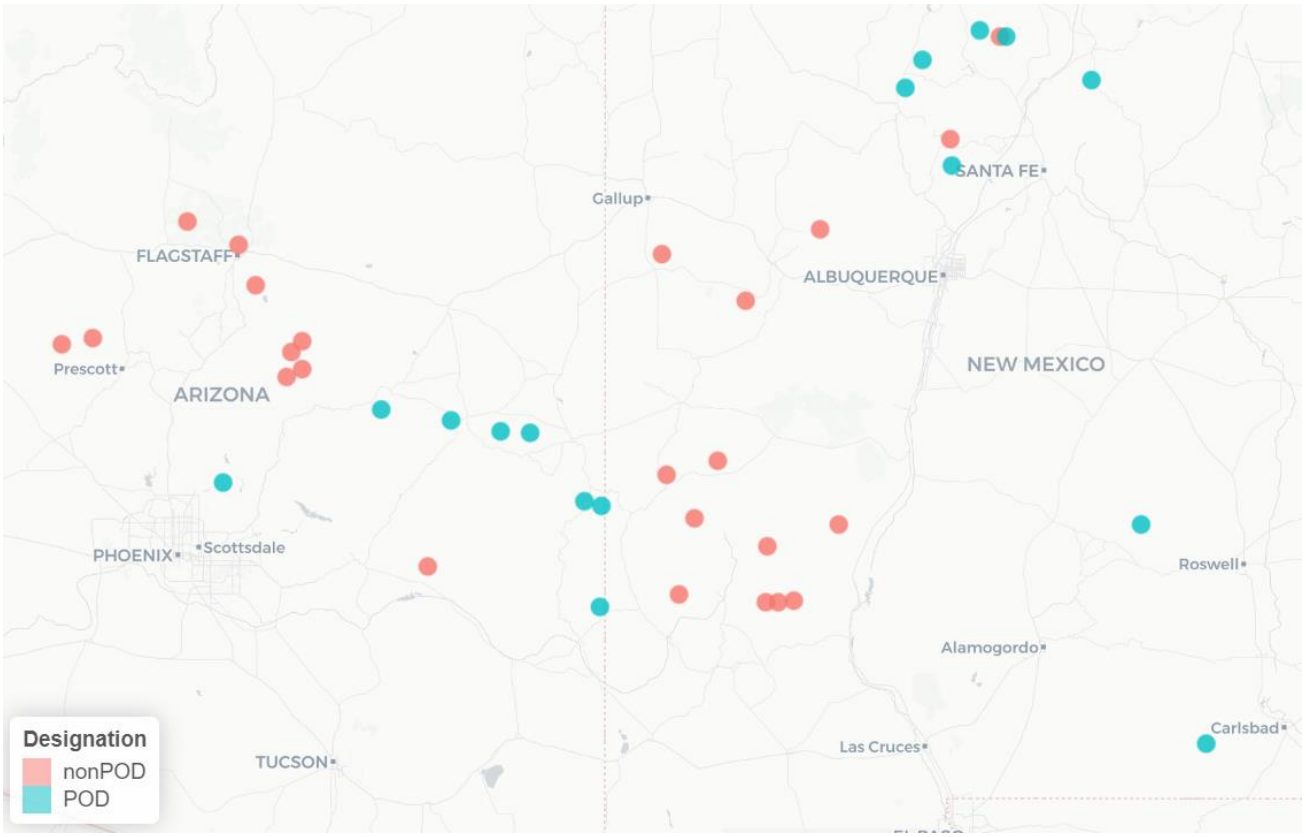

Figure 1: Map of Arizona and New Mexico (USA) showing location of POD and non-POD fires used in the sample.

Table 1 contains summary statistics for the set of POD and non-POD fires used in the matching analysis. Suppression costs are lower on POD fires than their non-POD counterparts both in total cost and cost per day. POD fires, on average, have a larger start size in acres than non-POD fire counterparts but also have a smaller ending size. This could indicate effective planning of POD fires before ignition. Interestingly, POD fires have shorter durations than non-POD fires, possibly suggesting a more efficient use of daily resources. POD fires are also shorter in duration and less expensive per acre when compared to fires managed under direct, modified, and limited suppression strategies from 2006-2008 (Gebert and Black, 2012).

Table 1. Summary statistics comparing POD and non-POD fires

Variable	N	Mean	SD
Fire Size first day (acres)			
POD	16	901	1,572
non-POD	24	265	243
Fire size last day (acres)			
POD	16	3,536	3,966
non-POD	24	4,041	5,466
Fire Cost			
POD	16	720,419	1,313,024
non-POD	24	1,011,137	1,783,758
Duration			
POD	16	13.69	8.52
non-POD	24	18.33	14.29
Fire Cost ($USD/Day)			
POD	16	57,287	84,080
non-POD	24	57,643	95,458
Fire Cost ($USD/Acre)			
POD	16	206	182
non-POD	24	591	971

3. Results and Discussion

Table 2 contains the results of the matching analysis. POD and non-POD fires are matched on characteristics and conditions that exist before ignition to mitigate the effect of matching on factors affected by management decisions over the course of the fire. We compare the POD and non-POD fires along four dimensions: Final Cost, Final Fire Size, Cost/Acre, Duration. We run regressions using only the POD indicator and then again with the variables the POD and non-POD fires are matched on.

Table 2. Regression results based on matched dataset

	Final Fire Cost	Final Fire Size	Cost/Acre	Duration
(Intercept)	30,577	308,778*	-33,864	419
	[-68,048, 129,202]	[-4,226, 621,782]	[-76,144, 8,414]	[-548, 1,388]
POD Fires	-222	603	-373*	-3.40
	[-1225, 779]	[-2,577, 3,784]	[-802, 56]	[-13.25, 6.44]
R2 Adj.	0.279	0.217	0.440	-0.158

Notes: N=40 in all regressions. All regressions include the following controls, but are omitted from the table for brevity: region of the US (GACC), national preparedness level, fire cause, topographic and weather

We find little statistical evidence that there are differences between POD and non-POD fires with the exception of Cost/Acre. Specifically, the cost per acre on POD fires is $373 less than comparable non-POD fires (statistically significant at 10% level. This result supports the hypothesis that less costly suppression effort is expended on POD fires. Suppression resources may be monitoring fire growth in areas with few values at risk or focusing containment effort on the operating delineations identified in the planning process rather than responding to fire growth as an emergency. The lack of statistical significance in the other regression models is likely the result of small sample sizes given the relatively recent implementation of the POD process.

3.1. Comparison to Mechanical and Prescribed Treatments

While we observe some evidence that POD fires are cost effective compared to non-POD fires, we also compare the average cost per acre to the costs of prescribed and mechanical treatments. We estimate per-acre prescribed burning and mechanical treatment costs in the Southwestern US (USFS Region 3) using data from the Hazardous Fuel Treatment Reduction dataset. We remove all prescribed and mechanical projects that fall outside of three standard deviations of the mean cost per acre. We find that POD fires average suppression expenditures of $206/ac and are less expensive per acre than mechanical treatments ($408) and non-POD fires ($591, Table 3). While not all POD fires are necessarily managed for resource benefits, our results suggest that the pre-fire planning during the POD process does curtail suppression expenditures making them comparable to prescribed burning treatments. This result suggests a potential role for managing POD fires for resource benefit.

Table 3: Cost per acre ($USD) of POD and non-POD fires and Southwestern US fuel treatments

Fire Treatment	**N**	**Mean**	**SD**
POD Fire	16	$206	$182
Non-POD Fire	24	$591	$971
Prescribed	982	$189	$1,268
Mechanical	3,356	$408	$612

Extreme wildfire events; fire regimes; fuels management; climate change; stochastic fire simulations; transboundary wildfire exposure

Abstract

Greece has an ever-increasing appeal for establishment of new and/or expansion of existing human settlements in the wildland-urban interface that in turn cause pressures on the natural environment, increasing the fire risk and decreasing resilience at a landscape level. A multitude of Mediterranean-type of ecosystems exist in the country, ranging from low shrubs and coniferous woodlands on coastal sites to high-elevation conifer and broadleaf forests. Fire plays a critical role on how these ecosystems were formed and function. Due to the topography, land uses, numerous islands, extensive coastlines and local microclimates, we find either broad zones with similar fire-related characteristics or enclaves where unique interactions with landscape fires prevail. We described the fuel and fire schemes in Greece as formed by different combinations of topography, weather, vegetation and human activity. A geographical context for this analysis was provided by examples of recent wildfires occurred in Greece during the 21st century, which re-shaped the landscape and affected in multiple ways the natural environment and human settlements from severe fire effects. In addition, we showed how these wildfires created crises that drove fire management policies; and we illustrated how fuels and wildfires should be managed based on their respective fire regimes and expected fire effects. Finally, we briefly reviewed future implications for wildfire management from the cumulative effects of climate change, urban sprawl and unmanaged forest growth.

1. Fire environment and regimes

The problem of forest fires in Greece is intensified when extreme events occur that cannot be suppressed immediately due to the inherent weaknesses of firefighting, the widespread wildland-urban interface (WUI) and the lack of forest management in the midst of climate change. Apart from the high and increasing risk of forest fires, a large number of deaths from wildfires in residential areas in Greece has shown that the problem cannot be solved by suppression alone. Extreme behavior of the recent catastrophic fires with human losses in Greece can be attributed to many explanatory factors, such as the ever-expanding urban footprint in forested areas, increasing human-caused fires, mountainous topography, fuel accumulations, intensifying drought and stronger winds from unexpected directions due to climate anomalies.

In Greece, the low elevation pine forests of the moderate-sized serotinous-cone species of Aleppo pine (*Pinus halepensis*) west of the 25th meridian, and Calabrian pine (*Pinus brutia*) at the east of the 25th meridian, have frequent crown fire regimes and transmit most of the catastrophic wildfires; trees can reach a height of up to 30 m, if left undisturbed, but usually they are between 10-20 m in frequently burned forests (Keeley *et al.* 2012). Other important conifers that burn less often and under surface fire regimes are the serotinous Mediterranean cypress (*Cupressus sempervirens*) and maritime pine (*Pinus pinaster*), and the non-serotinous stone pine (*Pinus pinea*), Scots pine (*Pinus sylvestris*) and black pine (*Pinus nigra*). Except Scots pine, all these pines have thick bark and large-sized buds to tolerate relatively high fire intensities and heating. The needle drape (suspended live and detached dead needles) of all these conifers is usually mixed with conifer saplings, broadleaf evergreen shrublands (referred as maquis or phrygana) and cured annual plants (Kalabokidis and Palaiologou 2019).

The shrub fuel types consist of non-tree, woody and foliage vegetation biomass (live with hard leaves or dead twigs) from the dominant shrub species. When assorted with conifers, the shrub fuelbed is mixed with conifer

needles and branches, and saplings in canopy openings. Maquis form high canopy density shrublands with heights between 2-8 m and foliar cover >30%, when they are dominant in open landscapes (scrub), forming woodlands with tree heights of more than 8 m if left undisturbed for several decades. When found on the understory of conifers, they can be either sparse and suppressed in closed canopy stands (low shrubs, 0-2 m tall) or dense and tall in open canopy or sparsely forested stands. These shrublands regenerate vigorously after fire through resprouting with high success rates or seedling recruitment, forming a densely covered post-fire fuelbed mixed with dead conifer biomass, fallen logs and annuals. The most typical maquis evergreen shrub is Kermes oak (*Quercus coccifera*), forming vast and severely burned shrublands (and sometimes low woodlands on moister sites), which has a strong post-fire resprouting capacity from rhizomes. In phrygana and/or garrigue shrublands, *Sarcopoterium spinosum* is a thorny dwarf shrub colonizer that accumulates high proportions of standing fine and dead fuel in over-burned and overgrazed areas with land degradation and desertification problems (Moreira *et al.* 2012). Oaks (*Quercus* spp.) have important contribution in the formation of fuelbeds forming woodlands on a transitional zone to temperate forests, including winter-deciduous species. Oaks epicormically resprout from dormant buds (buried in bark) after moderate-severity wildfires, but they may fail following high-intensity fires. Fuelbeds in oak-dominated landscapes consist of dead leaves and branches, mixed with annual vegetation (usually geophytes that resprout by means of underground buds) and short shrubs or maquis, and rarely support active crown fires. When mixed with conifers or tall maquis, oaks can be scorched or completely consumed by passive crown fires (Kalabokidis and Palaiologou 2019).

2. Fire activity during the 21st century

While the annually burned area in Greece has been around 40 thousand hectares on the average in the last 40 years from approximately 1,500 fires per year, certain years stand out as exceptionally catastrophic such as indicated from the European Union's wildfire history statistics (EFFIS 2020). These are the years of 2000 with 145,033 ha and 2007 with 225,734 ha burned in the 21st century. More than 2,500 ignitions occurred during the years 2000 and 2001. The largest fire events of history for the prefectures of Greece took place in the record year of 2007 in the region of Peloponnese, namely in Achaea (30,000 ha), Messenia (11,000 ha), Laconia (22,000 ha) and Ilia with four wildfires (40,000, 32,000, 30,000 and 12,000 ha). In 2000 the fire of Samos Island in the north-eastern Aegean burned 14,500 ha, summing up to a total of 18,000 ha burned during that year in the region. Evia also experienced a large-scale event during 2007 with 18,000 ha burned. During 2012, a large fire on Chios Island burned 15,000 ha including a significant area occupied by the precious and unique mastic producing tree (*Pistacia lentiscus* var. *chia*). Forest fires of 2021 in Greece amounted to 140,000 ha burned, from six large-scale events (more than 5,000 ha each) and one mega-fire in Evia (46,000 ha).

Attica experienced the largest fire event during 2009 with 20,500 ha burned and repeated catastrophic wildfire years in the vicinity of certain highly populated suburbs of Athens. On July 23, 2018, at the eastern foothills of Penteli Mountain in eastern Attica, a lethal forest fire burned through the urban settlements of Neos Voutzas and Mati where houses intermingled with pine stands, killing 102 people, destroying more than 1,500 homes and burning 1,450 ha. These wildfires caused a lot of pain, had a huge impact on society and demonstrated dramatically the urgent need for better fire prevention planning and coordination of fire control resources, including a major reform to obsolete wildfire management policies and tactics in Greece.

3. Fire management implications

Wildfire management of the various forest types needs to take into consideration the fire regime group to which they belong, that as a rule is linked to the adaptation of the particular species to fire effects (damage severity, capacity for post-fire regeneration), and the fuel hazard they represent (characteristics as fuel accumulation rate, fuel loading and arrangement, and ultimately fire behavior). Locally, of course, management needs to also consider non-forest values-at-risk, and the possibility for fire regime alterations due to the increased presence of humans as source of deliberate or accidental ignitions.

In response to the growing scale of fire risk in Greece, it is proposed to implement new forest management principles with landscape-scale fuel management activities and a more representative geography of risk in terms of setting goals and priorities. Effective fire risk management strategies and comprehensive preventive planning are required, rather than investing solely or mainly in forest firefighting and aerial firefighting. Without the

management of fuels and forests to mitigate the intensity and spread of fires before they occur, the effectiveness of firefighting is dramatically reduced. Preventing, suppressing and reducing the risk of wildfires follow interconnected paths, and require alternative practices of vegetation management, mitigation of accumulated fuel and clearing of forest areas with timely and valid scientific interventions to reduce fire risks (Palaiologou *et al.* 2020), in relation to the global climate change we are experiencing today.

The management of forest fuels has proven to be an effective method for stopping the continuity and reducing their quantity, reducing the rate of spread and the intensity of fires. Using stochastic forest fire simulations (Kalabokidis *et al.* 2014) and alternative scenario planning and evaluation tools, different fuel management priorities can be located in forest areas to: 1) block the main fire flows to protected areas; 2) decrease the possibility of high-intensity fires, 3) reduce the likelihood of fires spreading within residential areas, 4) protect areas of increased economic value, and 5) optimize the production of commercial forest products. Results show how investing and implementing one management priority can offer trade-offs to other priorities (Palaiologou *et al.* 2021), and where there are opportunities (spatial coincidence) for achieving multiple management objectives at the same time (e.g. Figure 1).

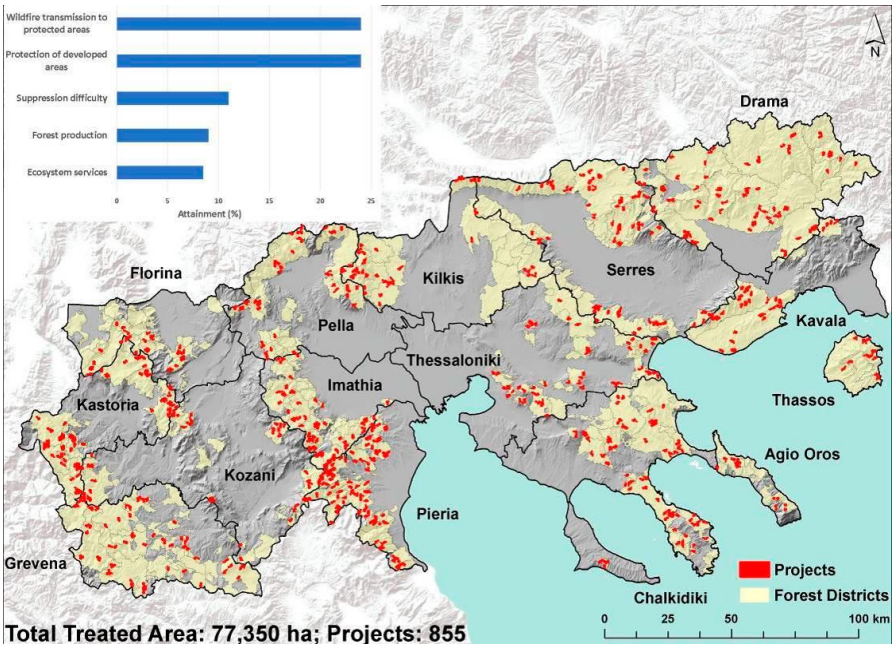

Figure 1: The best 100-ha projects in Macedonia, northern Greece, for each priority with a four-year fuel treatment plan. Attainment for each priority, if all stands that appear on the map are treated, is shown at the upper left corner (Palaiologou et al. 2021).

Post-management changes in forest structure and fuel loads can change the spread and intensity of wildfires and increase the resilience of forest ecosystems. Recent studies have examined the performance of appropriate spatial (composition and density) and temporal (seasonality, efficiency over time) strategies, as well as the effects of different institutional constraints (e.g. protected area management legislation, permitted land uses per property) in reducing the fire risk. In addition, the role and importance of forest management in the protection of settlements is highlighted, with emphasis on the strategic planning of projects and the consideration of the future fire occurrence and behavior (Palaiologou *et al.* 2018). Emphasis should be placed on a combination of thinning, mechanical treatments for managing or arranging the fuel and understory burning to reduce surface and canopy fuels (Omi 2015), while the appropriate planning of fire protection and other socio-economic values that are endangered will be needed, in combination with the fire size and fire regimes (Keane 2015).

4. Concluding remarks

Regions with Mediterranean-type of ecosystems have an ever-increasing appeal for establishment of new and/or expansion of existing human settlements in WUI, which in turn cause pressure on the natural environment (e.g. introduction of alien species, deforestation, human activities in formerly natural areas) that increase the fire risk. This complicated intermix of natural and human systems (Liu *et al.* 2007), aided by the catalyst role of wildfires,

leads to new risk governance systems and policies that aim to manage these ecosystems to reduce the loads, change the arrangement and alter the composition of forest fuels on the landscape. Communities can neither eliminate forest fuels (only manage them at a high economic cost on a limited extent), nor totally control the increasing frequency and intensity of wildfires that are influenced by the climate change (Kalabokidis *et al.* 2015), fire suppression policies, land abandonment and reforestation. Human adaptation requires a deep understanding of the role of forest fuels and their effective management, at scales that will prevent future wildfire loses and re-introduce the fire ecosystem resilience (Moritz *et al.* 2014).

Forest Fire, Numerical Simulation, Pine Trunk, Thermal Response, Wind Speed

Abstract

This article presents a numerical study on a two-dimensional model of heat transfers verified in a pine trunk under the effect of a forest fire. The thermal response model of the pine trunk was developed from a geometric model of complex topology of the trunk obtained using mesh generation. The thermal response model of the pine trunk is founded on energy energy balance integral and differential equations. Heat exchanges are considered by conduction inside the pine trunk, by convection between the outer surface of the pine trunk and the surrounding environment, and by radiation between the outer surface of the pine trunk and the and the surroundings, including the fire front. The radiative heat exchanges between the pine trunk and the fire front are calculated from the view factors obtained taking into account the meshing in the pine trunk and in the fire front. In this numerical study, it is considered that the fire front evolves with a spread rate with random and oscillatory characteristics, depending on wind speed, whose flame temperature has an average value of 500ºC. The evolution of the temperature distribution inside the pine trunk as well as in its outer surface was obtained for a variable and random wind speed. Temperature fluctuations on the outer surface of the trunk are affected by fluctuations in wind speed decreasing with time and with increasing distance from the fire front. Inside the trunk, temperature fluctuations occur mainly in the two outermost rings.

1. Introduction

The main influences on how fire spreads in forests are humidity, topography, wind and temperature (Tošić et al., 2019). The higher the temperature, the lower the humidity, and the lower the humidity, the drier the air, therefore dry fuel ignites and burns more easily. The slope of the landscape is also important: fires burn much faster uphill than downhill (Eftekharian et al., 2019). A fire creates radiation and convection phenomena that preheat the unburned fuel ahead of the fire front more effectively upslope than down. Fire spread is significantly affected by wind speed (Beer, 1991; Cruz and Alexander, 2019). Wind can bias fire behavior by moving moist air away from fuels, causing them to dry quickly. It transports burning embers that have been lifted aloft by convection air and starting spot fires ahead of the perimeter. It bends the convection column, which promotes preheating of unburned fuels in front of the fire. It brings a continuous supply of oxygen to the fire. Strong winds have a pressing dominant effect on the spread rate of wildfires when fuels are dry (Cruz et al., 2020). The environmental wind fluctuates in both direction and speed, with increased air instability implying greater fluctuations (Beer, 1991). Works on wildfire spread models (Nelson, 2002), simulations of spread and behavior of real fires (Jahdi et al., 2014), and fire spreads with variable wind strengths (Song and Li, 2017) present relevant aspects about the behavior of forest fires when under the effect of fluctuations in wind speed.

The numerical model used to simulate the pine trunk thermal response was founded on a numerical model used to simulate the human body thermal response (Conceição et al., 2010a; Conceição and Lúcio, 2016), because both models consider the use of energy equations in the boundary conditions in a similar way. These equations represent the following heat transfer processes: by conduction inside the pine trunk; by convection between the outer surface of the pine trunk and the surrounding environment; and by radiation between the outer surface of

the pine trunk and the surroundings (fire front included). In the assessment of the radiative exchanges between the outer surface of the pine trunk and the surroundings is utilized view factors. The sub-model used in the calculation of the view factors was established in the same way as the sub-models used in the calculation of the view factors in buildings (Conceição and Lúcio, 2010; Conceição et al., 2010b) and in passenger compartments (Conceição et al., 2000).

The purpose of this numerical study is to present a model that simulates the transient thermal response of a pine trunk under the influence of a forest fire, considering the variable wind speed. The forest fire is represented by a front fire with a variable spread rate. The transient thermal response will be assessed by the temperature distribution evolution inside and on the outer surface of the pine trunk.

2. Numerical Model

The differential energy equations and the generated mesh are utilized by the numerical model to evaluate the thermal response of the pine trunk, which consists of bark and cambium. This numerical model takes into account energy balance equations at the boundary between the pine trunk and the surrounds assuming the following thermal phenomena: heat conduction inside the pine trunk, heat convection (natural, forced and mixed) between the outer surface (bark) and the environment air and heat exchange by radiation between the outer surface (bark) and the surrounding body surfaces (fire front, fuel bed and sky).

These energy balance equations are established considering the following hypotheses:

- The heat flux is defined in two dimensions;
- The air temperature around the pine trunk, uniform and equal to the ambient temperature, will increase as the fire front approaches its vicinity;
- Use of heat transfer coefficients by convection developed for isothermal surfaces;
- The effects of fire around the pine trunk are neglected.

In the generation of the mesh of the pine trunk and fire front, the finite differences method is used. The numerical mesh generation considers a physical space and a computational space. The model transforms the physical domain into the computational plan, using two elliptic partial differential equations, of Poisson's type.

3. Methodology

The results of the numerical simulation will be the evolution of the temperature distribution inside and on the outer surface (bark) of the pine trunk obtained in a transient regime. In the numerical simulation carried out, it was considered that the wind speed is variable according to the profile represented in Figure 1, with an average value of 5.04 m/s.

The fire front progresses with a variable fire spread rate, according to the profile shown in Figure 2, with an average value of 0.0116 m/s, from a distance of 10 m upstream of the pine trunk. The pine trunk has a height of 2.0 m and an external diameter of 0.4 m. The fire front has a tilt angle of 70º relative to the ground plane, 2 m wide, 4 m high and an average flame temperature of 500ºC. The representation of fire propagation towards the pine trunk is shown in Figure 3. As environmental conditions, there is an air temperature of 20ºC and a relative humidity of 50% near the trunk. The temperature distribution was obtained at 33 points (P) equidistant distributed along the outer surface (bark) of the pine trunk in a plane located at a height of 2.0 m and at 20 points (Q) distributed along the radius of the pine trunk, as shown in Figure 4.

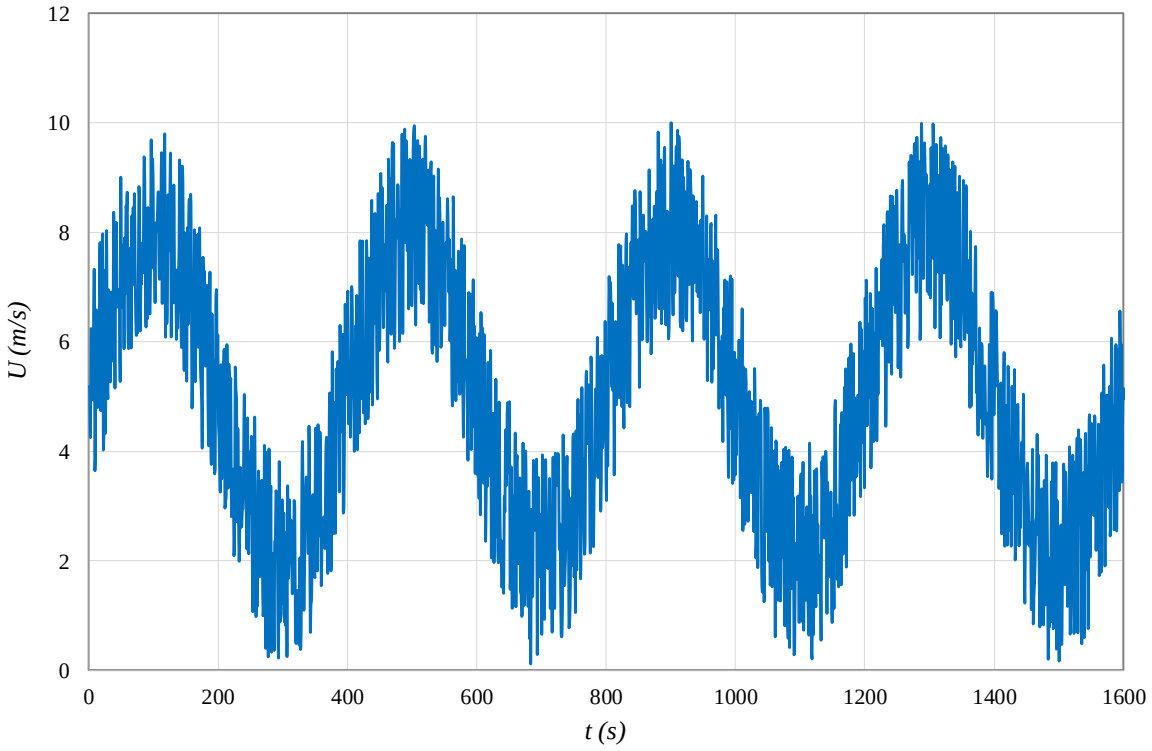

Figure 1 – Profile of wind speed.

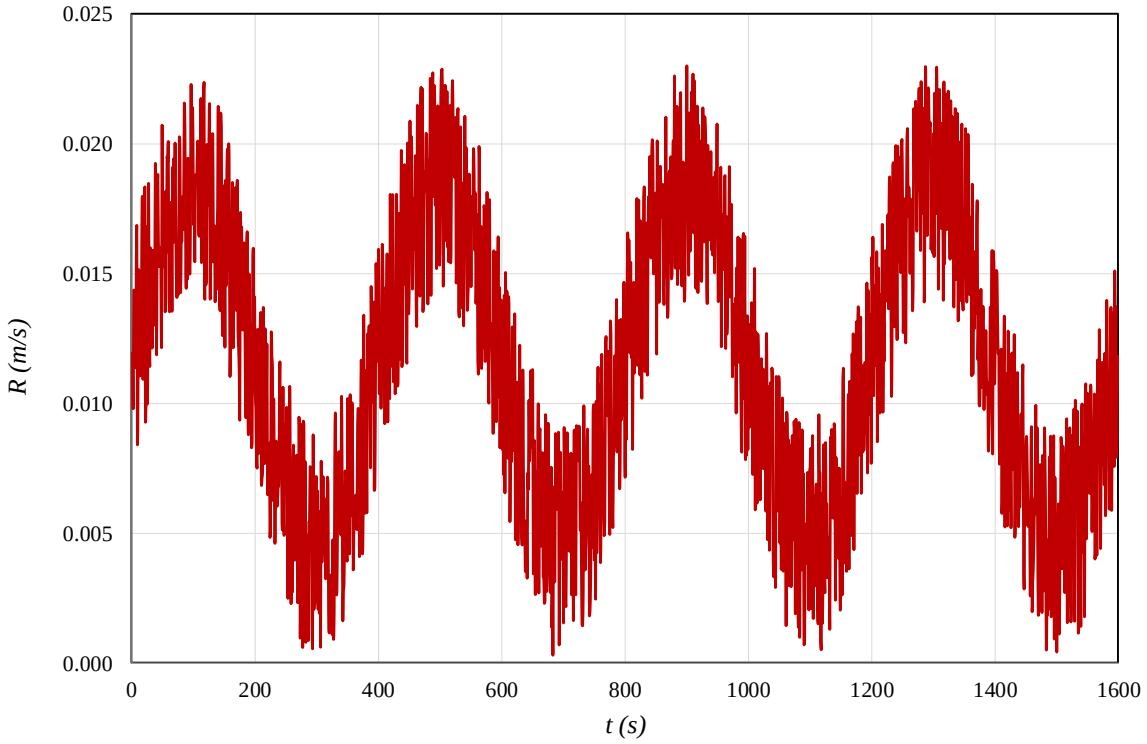

Figure 2 – Profile of fire spread rate.

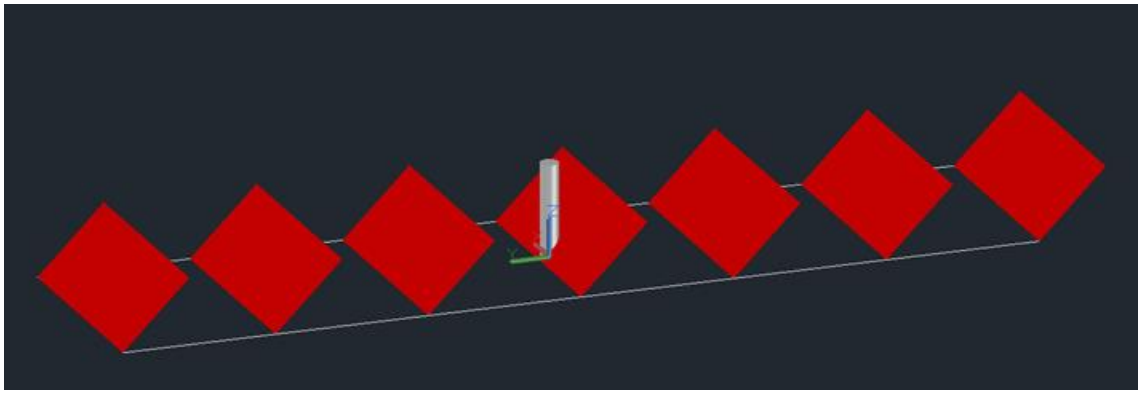

Figure 3 – Representation of the movement of the fire front towards the pine trunk.

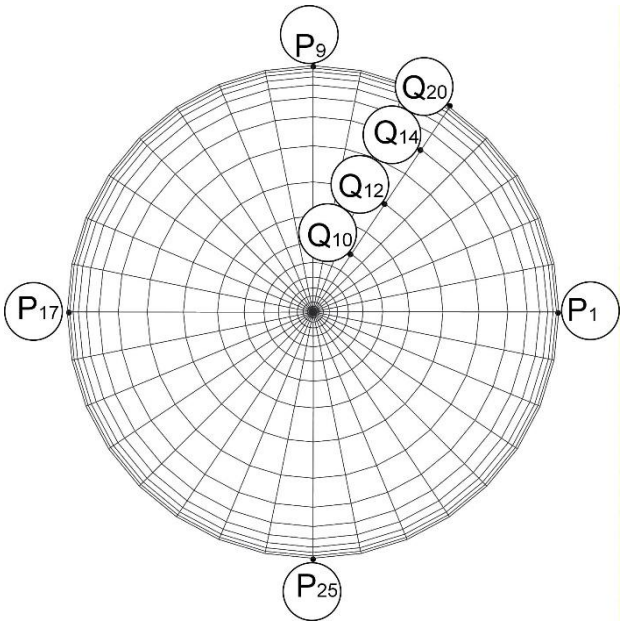

Figure 4 – Cross-section of the pine trunk with the location of the 33 P-points on its outer surface (bark) and the 20 Q-points on its interior.

4. Results and Discussion

The evolution of the temperature distribution on the outer surface (bark, points P1 to P33) of the pine trunk is shown in Figure 5. The results show that during the movement of the fire front, the upstream side of the pine trunk is the first to be affected by the increase in temperature on its outer surface. Fluctuations in wind speed and, consequently, in the fire spread rate, cause fluctuations in the temperature obtained at the marked points on the outer surface of the trunk. The maximum values of temperature fluctuations, as well as the amplitudes of these fluctuations, decrease with time and with the distance of the fire from the pine trunk. Temperatures are higher on the upstream side of the tree trunk than on the downstream side due to the slope of the flame caused by the spread of fire.

The evolution of the temperature distribution in the points Q1-Q20 located on the interior of the pine trunk, containing the point P1 on the side, on the upstream side, the point P9 on the upstream side and the point P25 on the downstream side (see Figure 4), is shown, respectively, in Figure 6, Figure 7 and Figure 8.

As can be seen from the temperature variation in relation to the ambient temperature of 20ºC, fire influences the four outermost rings, mainly the two rings represented by points Q18 and Q19. In these two rings, fluctuations in wind speed and fire spread rate have a noticeable impact on the fluctuations obtained in the evolution of temperature. Therefore, it can be seen that the passage of a forest fire with the characteristics presented here can cause the interior areas of the trunk to heat up to values around 60ºC on its upstream side.

Temperatures of 60ºC can cause the death of tree tissues (Kelsey and Westlind, 2017). Inside the trunk, temperatures are generally higher at points located on the upstream side of the trunk than on the downstream side. Again, this is due to the way the flame leans in the downstream direction of the fire's movement.

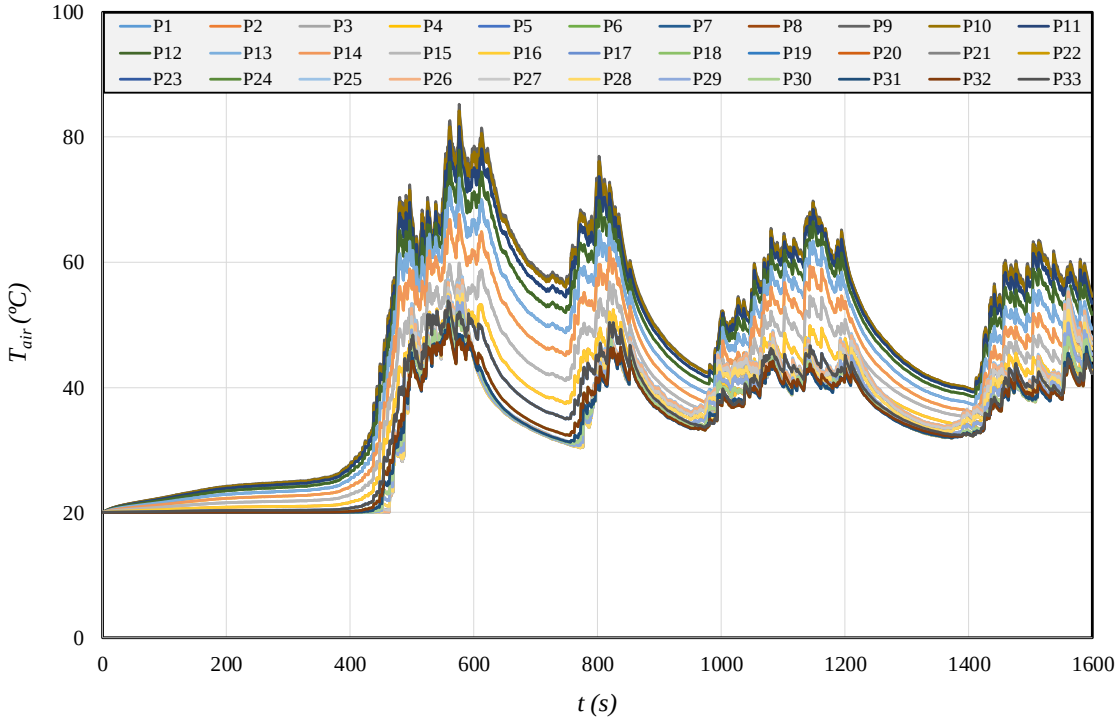

Figure 5 – Evolution of the temperature distribution on the outer surface (points P1 to P33) of the trunk according to the environmental conditions in which the fire propagates.

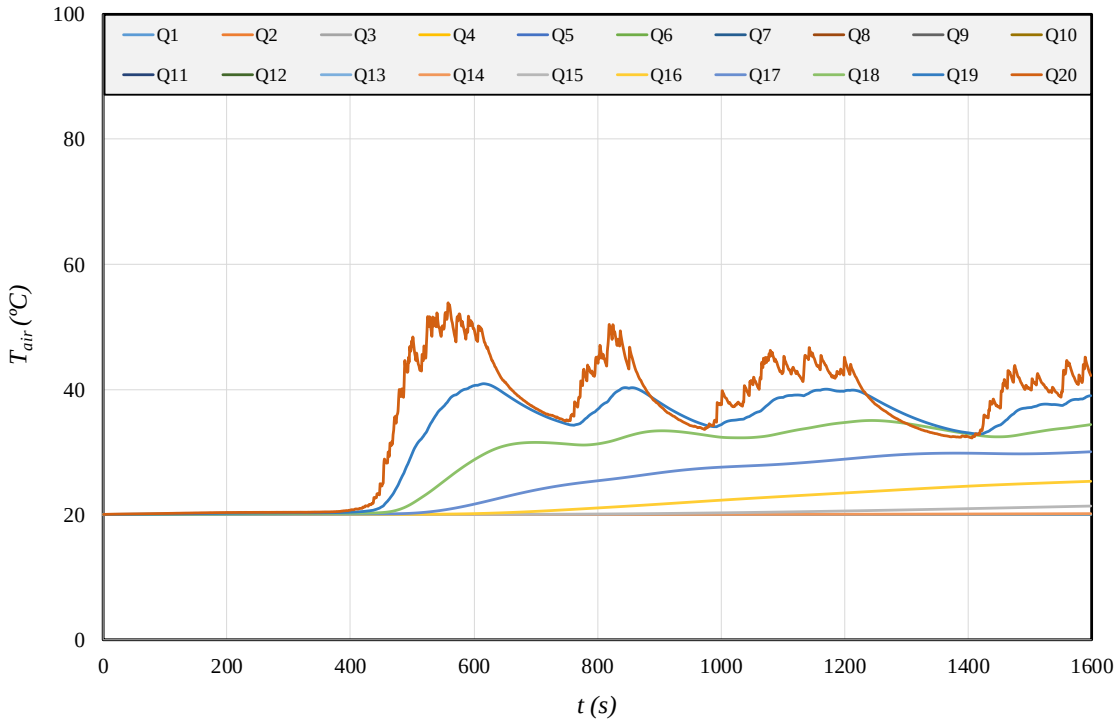

Figure 6 – Evolution of the temperature distribution in the points Q1-Q20 located inside the pine trunk containing the point P1 (coincident with point Q20) on the outer surface.

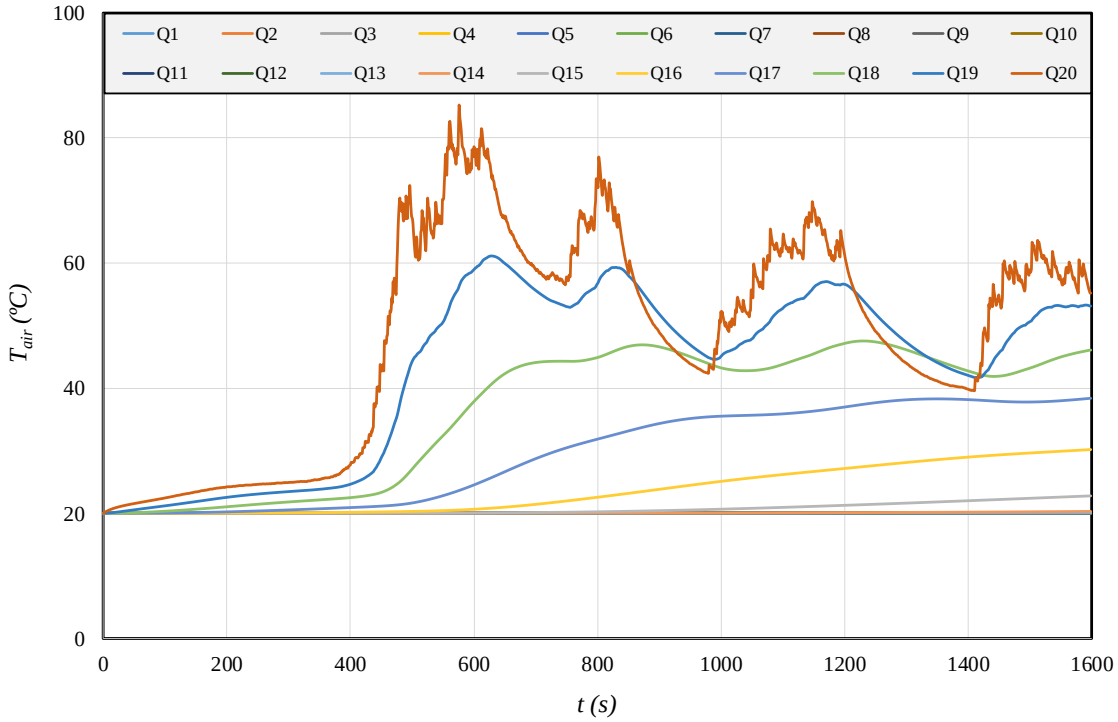

Figure 7 – Evolution of the temperature distribution in the points Q1-Q20 located inside the pine trunk containing the point P9 (coincident with point Q20) on the outer surface.

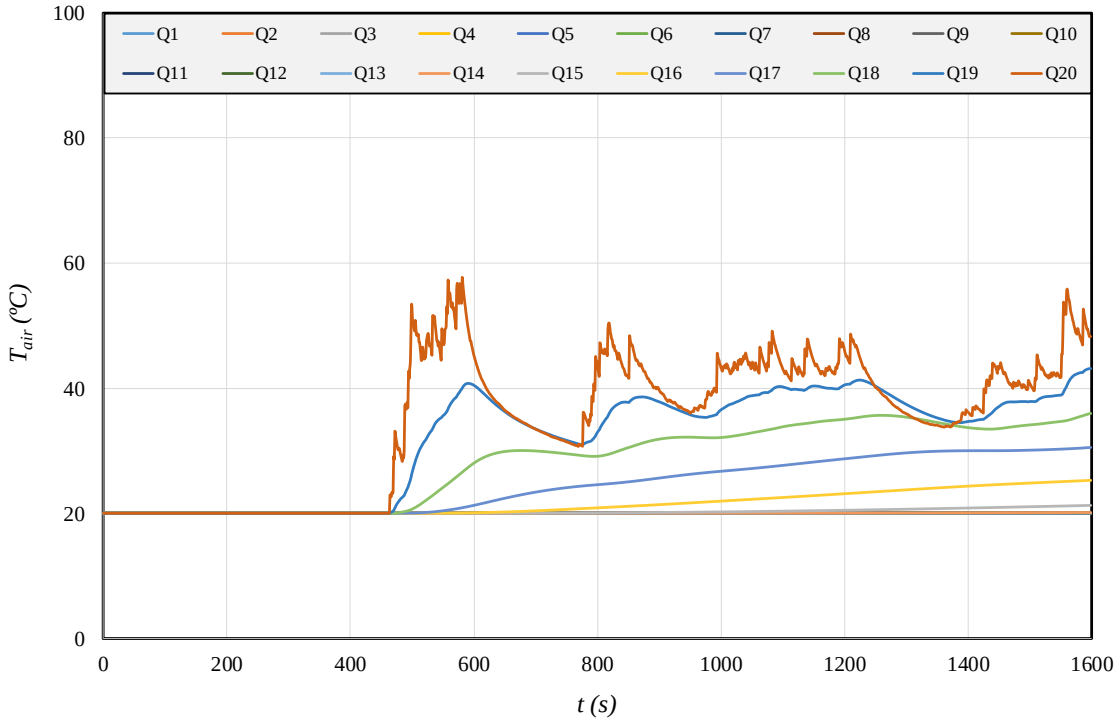

Figure 8 – Evolution of the temperature distribution in the points Q1-Q20 located inside the pine trunk containing the point P25 (coincident with point Q20) on the outer surface.

5. Conclusions

The thermal response of a pine trunk under the influence of a forest fire was numerically evaluated in this article. Forest fire is represented by a moving fire front. The temperature distributions inside and on the outer surface

of the pine trunk were obtained in a transitory regime. The numerical study was carried out assuming that the wind speed and the fire spread rate have a random evolution.

The results show that fluctuations in wind speed and fire spread rate also cause fluctuations in temperature calculated at points on the outer surface and in the four outermost rings of the pine trunk. At points on the outer surface, the maximum temperature values and the amplitudes of temperature variations decrease with time and with increasing distance from the fire to the pine trunk. Inside the trunk, on the upstream side, there are points on its outermost ring that reach 60ºC, which can cause tissue death there. Points on the upstream side of the pine trunk have higher temperatures than those on its downstream side due to the inclination of the flame in the direction of fire movement downstream of the pine trunk.

Science-Policy Interfaces, Bibliometrie, Wildfire Risk Management, Altmetrics

Abstract

The impact of research is increasingly gaining importance as science is understood as a means to solve the challenges of humanity. Therefore, processes of interaction between science and policy makers are needed, these processes are named Science-Policy Interface (SPI). But who is actually participating in SPIs? This question is relevant since scientific findings can be subject to interpretation, might contradict each other or can be driven by normative frameworks. Additionally, complex challenges require the involvement of all relevant disciplines and if certain disciplines are not heard, policies might as well only address parts of the problem. To unpack respective processes, this paper explores the opportunities of bibliometrics to trace and track science-policy interactions applying it to the field of wildfire risk management (WFRM).

An analysis of bibliometric data provided by Dimensions (https://app.dimensions.ai) was carried out. Therefore, the development of the numbers of publications and policy documents over time as well as the numbers of publications and policy documents in different fields of research (FoR) are considered. Furthermore, the Altmetrics of publications which are cited in policy documents are compared to the total of publications with reference to WFRM.

It can be stated that the number of publications with reference to WFRM follows the general trend of an increasing publication rate. Individual deviations from the general trend can be attributed to extraordinary wildfire events. The number of policy documents with reference to WFRM seems to correlate more strongly with the number of scientific publications with reference to WFRM than to the general trend in the number of policy documents. In addition, indicators for delay of 6 to 7 years in knowledge uptake from science to policy were found. Regarding the FoRs, three clusters of were identified. While two of these clusters indicate a positive correlation between the number of publications in a FoR and the number of citations, one cluster of FoR has low numbers of citations in policy documents while the number of publications is high. That leads to the conclusion, that there are bias respective unknown impacting factors which affect whether or not a policy maker considers a particular FoR. One impacting factor seems to be the attention a publication receives in scientific but also non-scientific communities. The Altmetric Scores of publications with citations in policy documents are double as high as the Altmetric Scores of the total of publications with reference to WFRM. By analysing the composition of the Altmetric Scores of cited publications respective the Altmetric Donuts, it could be found that the vast majority of publications that are cited in policy documents did receive attention in social media, especially twitter.

Another result of the analysis is, that the data quality concerning the links between policy documents and publications is insufficient. However, the bias found in the SPI demonstrate the usefulness of this bibliometric approach. With increasing reliability of bibliometric databases, the methodology presented in this paper can be applied broadly as a tool to analyse SPIs and help to create transparency on the integration of scientific findings into policy processes.

1. Introduction: The Science-Policy Interface in WFRM

The impact of research is increasingly gaining importance as science is understood as a means to solve the challenges of humanity. Therefore, processes of interaction between science and policy makers are needed, these processes are named Science-Policy Interfaces (SPI). But who is actually participating in such SPIs? This question is relevant since scientific findings are often subject to interpretation, might contradict each other or can be based on normative frameworks. Additionally, complex challenges require the involvement and consideration of all relevant and related disciplines and if certain disciplines are not heard, policies only address parts of the problem.

However, SPI processes sometimes seem to be black-boxes that are hard to reconstruct or understand from an outside perspective. It is not necessarily clear who contributed to certain papers or who was involved in committees and fora. To unpack respective processes, the review of policy papers and their scientific input, this paper explores the opportunities of bibliometrics to trace and track science-policy interactions applying it to the field of wildfire risk management.

1.1. Research Questions

In many cases, it is not always comprehensible why scientific findings are considered in policies or why they have not been considered. This raises the question of potential biases that influence the transfer of knowledge. *In order to divide and specify this overarching question, the following subsequent research questions (RQs) have been devised:*

1. *Is there a time lag between the publication of scientific publications and the publication of the policy document? (RQ1)*
2. *Do more publications in a field of research lead to more citations in policy documents? (RQ2)*
3. *Are publications that are frequently mentioned online cited more often in policy documents? (RQ3)*
    a. Are there similarities or differences between the Altmetric Scores of the publications cited in policy documents and those of the publications as a whole?
    b. How are the Altmetric Scores of the publications cited in policy documents composed?

2. Methodology: bibliometric analysis

In this chapter Altmetrics are introduced, the development of the hypothesis and the used statistical tools are described.

2.1. Hypotheses and statistical tools

In order to answer the research questions by the use of statistical tool, hypothesis derived from the research questions are necessary.

To answer the RQ1 the hypothesis

"There is no time lag between the publication of scientific publications and the publication of the policy document."

is examined by comparing the timelines of publications with reference to WFRM and the timeline of all scientific publications. In addition to this descriptive approach, the hypothesis is also examined with multiple regression of the publication numbers.

The RQ2 is examined by testing the hypothesis

"The number of publications per field of research does not corelate with the number of citations in policy documents"

Therefore, histograms and scatter plots of the numbers of publications within the fields of research (FoR) are analysed and rank correlation test according to Spearman is applied (Handl und Kuhlenkasper 2018, pp. 169-173)

The hypothesis to answer the RQ3 is:

"The number of online citations does not correlate to the number of citations in policy documents."

This hypothesis is examined by analysing the key figures of the Altmetric Scores of the publications cited in policy documents compared to the total number of publications with reference to WFRM.

2.2. Altmetrics

Altmetrics were developed in response to the expansion of opportunities to publish and disseminate scientific results. They offer an insight into how often publications are used or discussed by others already after a short amount of time and are applicable on big numbers of publications. Furthermore, by including attention outside

of the scientific community can decrease the influence of bias which exist within the scientific community and affect scientific processes. (Priem et al. 2010; Howard 2012; Galligan und Dyas-Correia 2013, p. 56).

2.3. Data Collection

The Dimensions database is used to collect the bibliometric data. The database is characterised by the fact that different types of data are made available and shows linkages between different publications. (Dimensions n. a; Hook et al. 2018; Singh et al. 2021, p. 5).

3. Findings of the bibliometric analysis

The following chapter presents the results of the analysis of the bibliometric data of publications and policy documents with reference to WFRM. In addition, first findings with regard to data quality are presented.

3.1. Publications over time

The number of publications with refence to WFRM as well as the total of scientific publications has increased significantly over the 50 years (Figure 1, bottom graph). This trend, however, is not exclusive to WFRM publications, but number of publications in general (Figure 1, top graph).

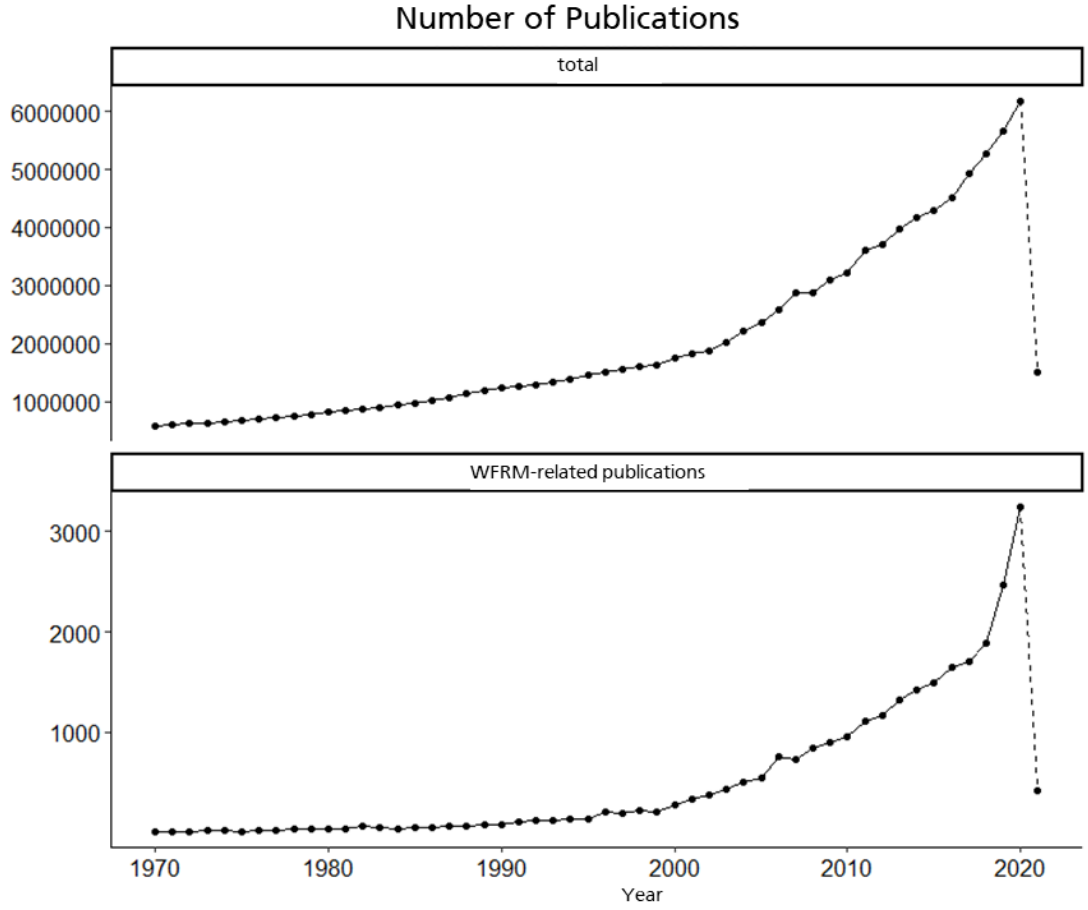

Figure 1 – Annual numbers of publication, total and with reference to WFRM

The numbers of publications with reference to wildfire follows the trend of exponentially increasing numbers of publications (Parthey und Biedermann 2002, p. 113) Exceptional effects can be attributed to outstanding wildfire events, e.g. wildfires as a consequence of a heatwave in Europe in 2003 can be associated with the exceptionally high number of publications in 2006 Spain (Lyamani et al. 2006, pp. 6456-6460). The average delay between these events and effects in the publication numbers is three years.

During the time period in question from 1970 to 2021, 476.548 policy documents were published. Out of those, 69 make reference to WFRM. Regarding the annual numbers of policy documents, a strong growth from 2010

to 2015 can be identified. From 2015 on, the numbers of policy documents declined (Figure 2). The numbers of publications with reference to WFRM fluctuate strongly during this time, still displaying a tendency of growing numbers of policy documents with reference to WFRM. That leads to the assumption that the number of policy documents with reference to WFRM possesses a stronger correlation to the number of publications with reference to WFRM than to the number of policy documents in general.

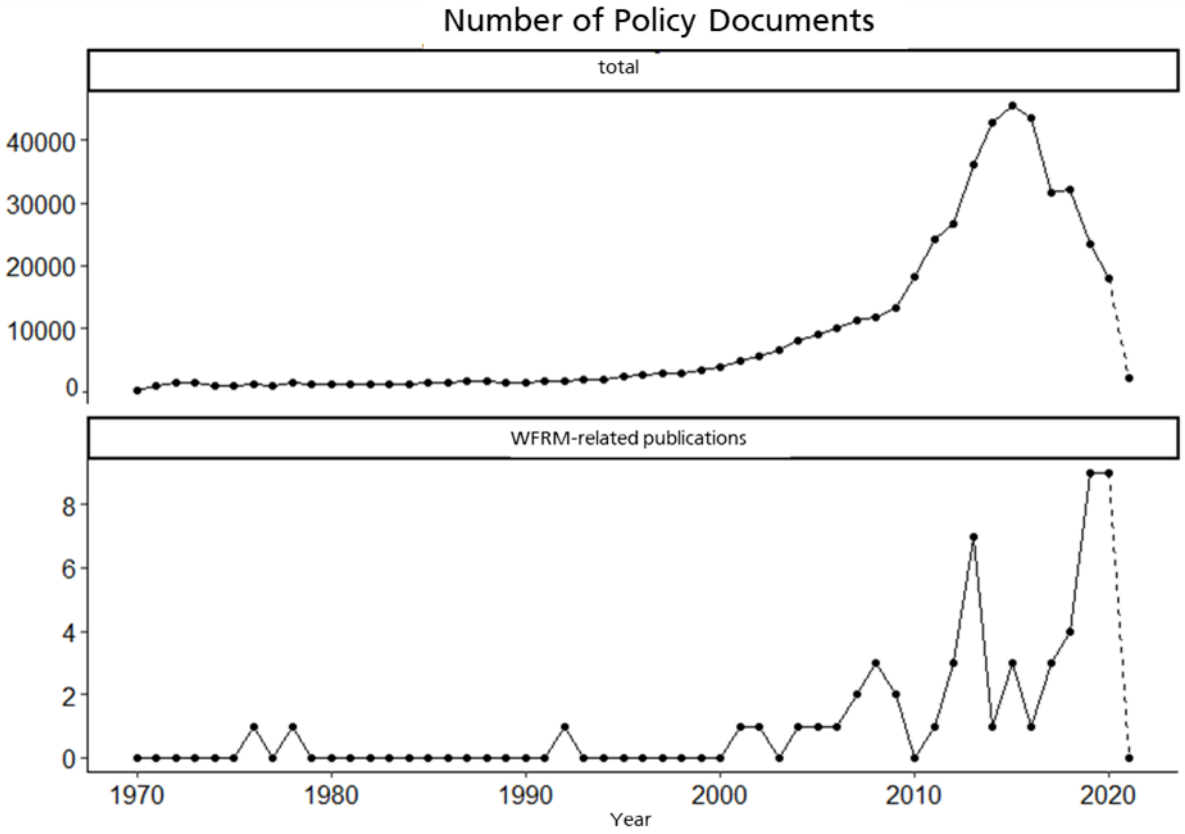

Figure 2- Annual numbers of policy documents, total and with reference to WFRM

To examine this assumption multiple regression analysis is carried out. The regression model considers the number of annual publications with reference to WFRM for the past 14 years as an impact number for the annual number of policy documents. Thus, a regression model was developed which contains the numbers of publication for the past 14 years as variables, 14 coefficients and one constant:

$$n_{PD}(t) = b_{t-1} * n_{pub}(t-1) + b_{t-2} * n_{pub}(t-2) + b_{t-3} * n_{pub}(t-3) + b_{t-4} * n_{pub}(t-4) + b_{t-5} * n_{pub}(t-5) + b_{t-6} * n_{pub}(t-6) + b_{t-7} * n_{pub}(t-7) + b_{t-8} * n_{pub}(t-8) + b_{t-9} * n_{pub}(t-9) + b_{t-10} * n_{pub}(t-10) + b_{t-11} * n_{pub}(t-11) + b_{t-12} * n_{pub}(t-12) + b_{t-13} * n_{pub}(t-13) + b_{t-14} * n_{pub}(t-14) + \epsilon$$

The result of the regression analysis is significant with values of $p=2{,}919*10^{-10}$ and $R^2=0{,}77$.

Table 1 – results of the multiple regression analysis

Ranking	*Coefficient*	*Value*	*Ranking*	*Coefficient*	*Value*
1.	b_{t-7}	0.0285282	8.	b_{t-12}	-0.0014705
2.	b_{t-13}	0.0197481	9.	b_{t-5}	-0.0036211
3.	b_{t-6}	0.0178220	10.	b_{t-1}	-0.0039888
4.	b_{t-14}	0.0068295	11.	b_{t-2}	-0.0057053
5.	b_{t-3}	0.0037625	12.	b_{t-10}	-0.0127954
6.	b_{t-11}	0.0026201	13.	b_{t-9}	-0.0142249
7.	b_{t-4}	0.0005291	14.	b_{t-8}	-0.0250294

Half of the coefficients is positive; the others are negative. While there is no factual explanation for the negative values of the coefficients, positive values might be an indicator for a certain delay of time. The coefficients b_{t-7}, b_{t-13} and b_{t-6} have the highest values, b_{t-10}, b_{t-9} and b_{t-8} have the lowest values (Table 1).

In the analysis of the publications over time it can be shown, that wildfire incidents lead to more publications with a delay of 3 years. Furthermore, a delay of 6 to 7 years from science to policies is indicated by the results of the multiple regression analysis.

3.2. Fields of Research

The scatter plot in Figure 3 shows a correlation between all publications with reference to WFRM and those which are cited in policy documents. Each dot represents a FoR. For the cited publications all values are increased by one (TC+1). Three cluster can be identified in the scatter plot.

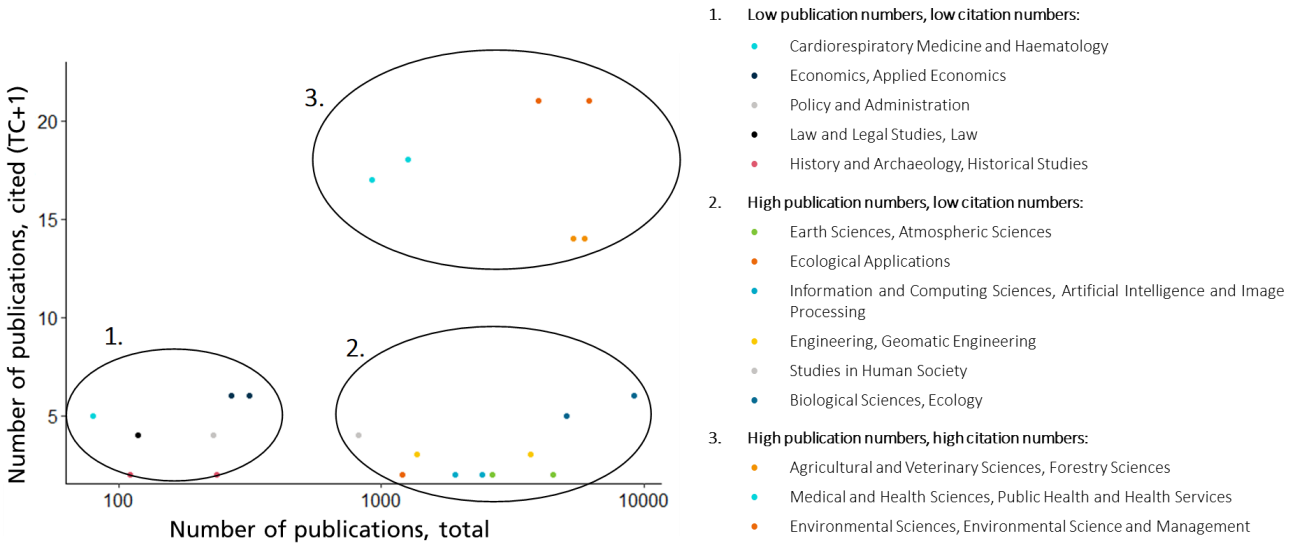

Figure 3-Number of publications per FoR, total and cited in policy documents

The rank correlation test by Spearman shows that the number of publications in the superordinate FoR corelates significantly (p=0,0022) with the number of publications cited in policy documents. With correlation coefficient ϱ= 0,62, which is a strong effect according to Cohen (1988). For the super- and subordinate FoR cumulated the correlation is also significant ($p=6{,}784*10^{-13}$) and with a strong effect (ϱ=0,52).

These results correspond with first and the third cluster which indicate that the numbers of publications in a FoR correlate to the number of citations in policy documents. The second cluster, where the number of publications is high and the number of citations is low contradicts this correlation which leads to the conclusion, that there are further impacting factors involved.

3.3. Altmetrics of the publications

For those publications which are cited in policy documents with reference to WFRM the Altmetric Scores and Donuts are analysed.

The arithmetic mean of Altmetric Scores of the cited publications is 50 and double the Altmetric Score of all publications, which is 25. The median is also double with a value of 6 for the cited publications and 3 for all publications. With a standard deviation of 124 the distribution of the Altmetric Scores of all publications is more homogeneous than the distribution of the Altmetric Scores of the cited publications with 213.

Table 2 – Comparison, key figures of the Altmetric Scores

Value	*Total of publication with reference to WFRM*	*Cited publication with reference to WFRM*
Arithmetic mean	25	50
Median	3	6
Standard deviation	124	213
Range	5289 (x_{min}=1; x_{max}=5290)	3089 (x_{min}= 3; x_{max}= 3092)

As the Altmetric Score is only an indicator for the amount of attention a publication receives, the Altmetric Donuts are analysed to get an insight of the platforms on which the publications are mentioned. All cited publications with a minimum score of 8 for the Altmetric Score are considered. These are 84 publications of which:

- 78 are cited on Twitter
- 41 are cited in Blogs
- 42 are cited on Facebook
- 15 are cited on Google+
- 5 are cited on Reddit
- 3 are cited on YouTube
- 1 is cited in the Stack Overflow Q&A

The Altmetric Scores of the cited publications have a higher arithmetic mean than the total of publications with reference to WFRM. Furthermore, it can be shown, that publications which were cited in policy documents were also often cited on Social Media as well.

3.4. Limitations of the results

The findings of this study of bibliometric data are limited by several factors. The results are only valid for the sector of WFRM. As the number of policy documents is generally low and most policy documents were published after the year 2000, which is a short observation timeframe when considering the observation that knowledge transfer from science to policies takes 6 to 7 years, this delay needs to be confirmed by further research.

Another limitation is given by the quality of data. To evaluate the quality of the data provided by Dimensions an exemplary manual analysis of citations in a policy document was carried out. The policy document "Advances in remote sensing and GIS applications in forest fire management - EU Law and Publications" includes 203 citations according to Dimensions. In a manual analysis, 445 citations were found. One reason for these 242 citations which are not regarded in Dimensions is that not all kinds of publications are considered by Dimensions, but 112 of the 242 missing citations are articles which should be included in Dimensions. Of these 112 articles only 18 are not listed in Dimensions. One reason might be inconsistencies in the references in the policy paper. At least in the exemplary policy paper, different styles of citation were used and several citations were incomplete. On the other hand it might be the case, that the AI which identifies the citations in Dimensions is not sufficientlytrained in analysing policy documents, because these are not the main focus of Dimensions. Another problem which was identified in the evaluation of the data is that Dimensions does not include all crucial policy documents, e.g. the policy document "Forest Fires: Sparking firesmart policies in the EU" which is a key publication of the EU is not listed in Dimensions.

4. Conclusion

The use of bibliometric data and analyses has great potential to understand and reconstruct SPIs on a larger scale. As a direct effect, this would allow to compare and complement the consideration of certain disciplines in policy processes. Particularly for complex settings such as WFRM, this could lead to an enhancement of a holistic perspective by integrating (potentially so far disregarded yet important inputs. From an indirect perspective, it would contribute to enhancing transparency and thus democratic principles. Specifically, in times of "fake news" and science scepticism, the suggested approach could provide important contributions to not only reconstructing science-policy relations but to enhance the overall credibility in science and policy making through transparency.

Nevertheless, the generated insights for the WFRM domain have to be assessed against the fact that the list of policy papers is incomplete, as do the listed citations. Assuming however that these systematic errors affect all fields of research evenly, we can for example assume that policy makers do not regard all FoR evenly. There are fields like Earth Sciences, Engineering or Ecology that publish articles with reference to WFRM and are not properly regarded by policy makers. This clustering can be used by policy makers to identify blind spots. At the same time, it might be the case, that scientists in these fields do not communicate and spread their findings as

efficient as scientists in other fields. For further research, it might be useful to analyse the communication and dissemination in Cluster 1 of the FoRs (Figure 3) to identify best practises.

Finally, this paper results in additional research questions and aspects that require for further analysis. First of all, the mentioned data base shortfalls have not yet been understood in their entirety and they seem to be related to systematic errors, most likely caused by artificial intelligence and the applied machine learning approaches. More detailed insights can only be provided by the operators and experts. Since the access to the policy paper database is a service that needs to be paid, it can be assumed that this challenge will be addressed in the near future.

In a second stage, the use of national (or even local) level language policy papers should be considered since the presented approach seems also useful for analysing SPIs at the national level. However, respective papers are currently not covered by any database and can hence not be subject to analysis.

Abstract

Fire spread can be characterized as a continuous sequence of ignitions. Ignition is a local phenomenon, governed by complex interactions between temporal and spatial variations in fuel and environment. Seemingly insignificant changes in vegetation orientation or spacing can significantly affect the ignition process and result in fire either bridging a gap in fuels or extinguishing at the gap boundary. This study seeks to improve understanding of ignition by exploring the physics underlying fire's response to gaps in vegetation under the influence of wind, fuel conditions and microtopography. A series of 70 experiments were conducted at the US Forest Service Missoula Fire Science Laboratory (MFSL) and the Insurance Institute of Business & Home Safety (IBHS) wind tunnel facilities to test fire's response to fuel discontinuities under varying wind conditions and fuel moistures. Winds speeds ranged between 0.5 to 9 m/s over 4 different levels. Fuel moistures varied between dry (2-6%) and wet (8-17%) by weight gravimetrically. Fuel discontinuity gap sizes varied from 10 to 160cm. Fuels consisted of long leaf (Pinus palustris) pine straw. Fuel loading was 0.56 kg/m^2 and packing ratio was 0.02. Six replicates were performed at each gap bridging threshold, three at the minimum gap and three at the minimum plus one for statistical significance and probability. Under all wind speeds and moisture conditions the gap threshold between fire bridging and fire extinction was 10cm.

1. Introduction

Fire professionals within land management agencies in the United States recognize that vegetation and environmental heterogeneity collectively drive fire behaviour and fire effects on soil and plants (SERDP, 2014). The interactions between energy transport in wildland fires and the spatial distribution of fuels and wind are complex. While intuition and anecdotal observations provide some guidance, the current state of wildland fire science lacks full understanding of the dependency between fire and the spatial distribution of wind and fuels (Arno, 1997). Improved understanding of how fire responds to changes in vegetation type and density combined with wind and topography would improve the ability of the fire science community to effectively model fire behaviour and the capability of operational fire managers to use fire as a land management tool (Finney, 2013).

Experienced fire practitioners recognize that seemingly insignificant changes in wind, topography (slope or aspect) or vegetation orientation can influence fire intensity and spread (Hessburg, 2005; Camp, 1995; Ottmar, 1996). The sensitivity of fire to variations in fuel element geometry, location, and orientation as well as local air flow complicates effective fire-based land management. The dependence of fire intensity on local winds is readily recognized, but we do not yet know which scales are most relevant. Knowledge gaps pertinent to this effort include: 1) dependence of ignition on wind; 2) relative contribution of radiant and convective heating across fuel gaps as a function of burning conditions; 3) probability of ignition success as a function of fuel moisture; 4) ignition critical scales for fuel composition, load, and distribution; 5) dependence of fuel

consumption as a function of arrangement of spatial discontinuities within the fuel matrix (Anderson, 1969; Anderson, 2010; Butler, 2004).

2. Methods

The underlying hypothesis for this work is that ignition is a dose verses response mechanism. The dose is total energy absorbed by fuel particles and the response is ignition or extinction. This study seeks to identify the minimum energy dose to affect ignition through study of fire's interaction to gaps in the fuel array. To address these knowledge gaps, a series of laboratory burn experiments were completed at two different wind tunnel facilities, the US Forest Service Missoula Fire Science Laboratory (MFSL) located in Missoula, MT and the Insurance Institute for Business & Home Safety (IBHS) located in Rock Hill, SC. The lower wind speed experiments were conducted at MFSL wind tunnel while the upper wind speed experiments were conducted at the IBHS test facility. Windspeed was digitally controlled at each test facility and ranged from 0.5 to 9 m/s at 4 different levels. Fuel beds of long leaf (Pinus palustris) pine straw (nominally 2.5-3.5 m wide by 5-12 m long) were constructed with artificially imposed gaps (10 to 160 cm wide) in the fuel bed (Figure 1). Pine straw fuels were conditioned in an environmental chamber to achieve desired dry (2-6%) and wet (8-17%) fuels moisture levels.

Figure 1 – Fuel bed with pine straw fuels and discontinuous fuel gap layout at IHBS wind tunnel

Fuels were evenly distributed on the burn bed once they were weighed and measured. Light detection and ranging (LiDAR) was used to characterize the 3-dimensional distribution of fuels for each test bed. Local microscale (<1 m) winds were measured at the fuel gap using mechanical 2-dimensional (horizontal and vertical) anemometers combined with fine scale wind simulations. Local energy transport within and above fuel gaps were characterized using established *in-situ* heat flux sensors and methods (Butler, 2004). Infrared and visible imagery of flames and fuels from both horizontal and nadir orientations characterized flame presence and geometry, and kinetic and radiometric fuel surface temperature at the fuel gap. For each wind speed and fuel moisture level, the fuel bed was burned with decreasing gap width until the fire bridged the gap. Once this gap width is identified four replicates, two at the threshold and two at the threshold plus one, were burned under the same environmental conditions to verify the results and aid in the statistical analysis. Measurements for each burn experiment included whether the fire successfully bridged the gap (Yes or No), fire front progression (rate of spread, ROS) using in-situ thermocouples and overhead infrared imagery, radiative and convective energy release from the flames, wind speed, fuel moisture, gap size, relative humidity, ambient air temperature. From these data a statistical dose verses response relation will be developed and analysed to identify critical spatial scales in fuels that affect ignition and subsequent fire spread. Lab and field-scale data will be used to evaluate a new heat transfer based coupled fire/atmosphere model.

3. Experimental Design

We hypothesize that fire can be characterized as a continuous sequence of ignitions and the physical processes governing fire are directly linked. We intend to differentiate ignitions across gaps based on incident energy transport and not from ember transport. This fundamental approach seeks to improve understanding of physical fire scales, identify critical fuel spatial and temporal scales in three dimensions and improve understanding of fuel consumption and fire effects. In order to differentiate ignitions across the gap a series and visual and infrared cameras were deployed from multiple positions.

A series of 70 experiments were conducted at the US Forest Service Missoula Fire Science Laboratory (MFSL) and the Insurance Institute of Business & Home Safety (IBHS) wind tunnel facilities to test fire's response to fuel discontinuities under varying wind conditions and fuel moistures. MFSL is a research facility owned and operated by a US Forest Service and is located in Missoula, MT. The facility encompasses several buildings, including the main test chamber that is equipped with a low-speed wind tunnel capable of generating wind speeds from 0.5-3.0 m/s. This low-speed wind tunnel has a 3x3m cross section and is 26.2m long. IHBS is a $40M research facility owned and operated by a consortium of insurance companies and is located in Richburg, SC. The facility encompasses several buildings, including the main test chamber that is equipped with a vertical wall comprised of 105 interlinked, process-controlled fans. The fan bank is capable of generating hurricane force winds in excess of 54 m/s.

Variables to be tested include wind speed (0.5-9 m/s), fuel moisture (dry and wet) and gap size (10 to 160 cm). Test order was chosen at random to eliminate bias. For each test, fuels were weighed and measured for moisture content to achieve a consistent fuel load (0.56 kg/m2) and a packing ratio (0.02). Fuels were conditioned in an environmental chamber to achieve dry (2-6%) and wet (8-17%) moisture levels. Fuels were evenly distributed on the burn bed once they were weighed and measured. The pre-determined gap size was left void of fuel. Fuel was place at the downwind edge of the gap at the same pre-determined loading and packing ratio.

Each fuel bed at the IHBS test facility was measured using light detection and ranging (LiDAR) prior to ignition. Four separate scans were performed on each burn bed in order the characterize the 3D nature of the fuels. The LiDAR unit used was a Leica BLK360. The laser scans at 830nm wavelength, has a range of 0.6 - 60m, scans up to 360,000 pts/sec and a 3D point accuracy of 6mm at 10m and 8mm at 10m. Most of the points within the fuel bed scans were within 20m. Fuel beds were not scanned at the MFSL due to the complexity and space limitations associated with the wind tunnel design.

Each burn was instrumented with a vast array of sensors. A fire behaviour sensor array was placed at the leading edge of the receiving bed to measure incident heat flux, 2-dimensional wind flow and air temperature. The sensor array contained a total of three Medtherm® heat flux sensors to measure total, radiant and convection incident energy on the receiving bed. The sensor array contained five 2-dimensional Keil static wind probes to measure horizontal and vertical wind velocity at the receiving bed. Finally, the sensor array contained five type K thermocouples to measure air temperature at the receiving bed. All sensors on the fire behaviour array scanned at 180 Hz. The sensor array was constructed of a 5.1 x 15.2 cm metal stud on wooden supports to provide a flush surface between the fuel bed and receiving bed. The gap was filled with 5.1 x 10.2 cm metal studs on wooden supports that were each instrumented with three type K thermocouples to measure air temperature in the gap. The list of imaging sensors used can be seen in Table 1.

Table 1: Visual and infrared sensors used during IBHS test burns.

Sensor	Resolution	Frame Rate	Orientation	Range	Field of View
GoPro	2.7k	24 fps	end, side, nadir	N/A	infinite
Sony	4k	30 fps	side	N/A	infinite
FLIR Duo IR	640 x 512	30 Hz	side	-300C - 1035C	45º
& Visible	4k	24 fpm	side	N/A	56º x 45º
FLIR A655sc	640 x 482	25 Hz	nadir	300C - 2000C	45º
Optris PI 400	382 x 288	27 Hz	nadir	-20C - 900C	13º

These imagers were deployed in several configurations to monitor fire rate of spread, flame geometry, flame impingement across the fuel gap, ember transport across the fuel gap, fuel particle temperature and radiant energy release. The GoPro cameras were placed in three separate configurations: end view, side view and nadir view (Figure 2). This imagery will be used to quantify flame geometry and fire rate of spread. The Sony camera was oriented side view at the gap to measure flame geometry as well as flame impingement on the receiving bed.

Figure 2: In order; GoPro screen capture of end view, side view at the gap and nadir view of burns.

Two infrared cameras were deployed during the MFSL experiments, and three infrared cameras were deployed during the IBHS experiments for each of the test burns. Ground control points were established for each infrared camera for image rectification. The Optris PI400 was oriented nadir to the fuel bed. The narrow field of view (FOV) on the Optris made it ideal for determining fuel particle temperature, whether fire crossed the gap and if ignition was derived from ember transport or flame impingement. The FLIR A655sc was oriented nadir to the fuel bed for the IBHS experiments. The wide angle on the A655sc allowed for full view of the fuel bed and was used primarily for fire rate of spread and radiate energy release. The FLIR Duo is a dual infrared and visible high-resolution imager. This camera was oriented to the side and above the gap and was primarily used to determine fuel particle temperature, whether fire crossed the gap and if ignition was derived from ember transport or flame impingement. (Figure 3).

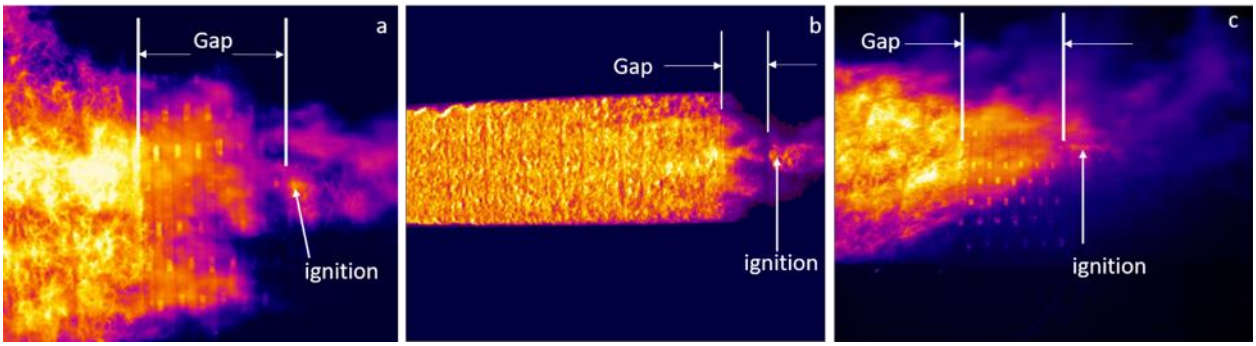

Figure 3: (a) imagine from the Optris PI400, (b) image from the FLIR A655sc, (c) image from the FLIR Duo.

4. Results

Four test scenarios were designed for the both the MFLS and IBHS test facilities. These include, 1) low wind speed/dry fuels, 2) low wind speed/wet fuels, 3) high wind speed/dry fuels and 4) high wind/speed wet fuels. The test scenarios were chosen at random to eliminate bias. All tests in a series were completed before changing to the next set of parameters to maintain consistent weather conditions. For each wind speed and fuel moisture level, the fuel beds were burned with decreasing gap width until the fire bridges the gap. Once the gap width was identified, four replicates were burned under the same environmental conditions to verify the results and aid in the statistical analysis. Two replicates were burned at the gap size where fire crossed the gap to identify probability of a false positive and two replicates were burned at the increased gap size where fire did not cross to identify probability of a false negative result. Table 2 outlines the results from the four test scenarios.

Table 2: Summary of test results showing wind speed, fuel moisture, gap size and whether the fire crossed the gap.

Test Series	Wind Speed (m/s)	Fuel Moisture	Gap Size (cm)	Crossed Gap (Y/N)	Replicate Crossed (Y/N)
MSFL					
Low Wind/Dry Fuel	0.5	Dry	10 17	Yes No	Yes/Yes No/No
Low Wind/Wet Fuel	0.5	Wet	15 23	Yes No	Yes No/No
High Wind/Dry Fuel	1.0	Dry	39 46	Yes No	Yes/Yes No/No
High Wind/Wet Fuel	1.0	Wet	23 39	Yes No	Yes/Yes No/No
IBHS					
Low Wind/Dry Fuel	6	Dry	100 110	Yes No/No	Yes/No No/No
Low Wind/Wet Fuel	6	Wet	90 100	Yes No	No/No No/No
High Wind/Dry Fuel	9	Dry	150 160	Yes No	Yes/Yes No/No
High Wind/Wet Fuel	9	Wet	120 130	Yes No	Yes/Yes No/No

The data suggests that the incident energy threshold required to cross the fuel gap is extremely narrow, in each case the separation distance was equal to or less than 10 cm. The low wind speed wet fuels scenario initially crossed a gap of 90 cm, but neither replicate crossed suggesting a false positive at this setting. This test scenario will be repeated at a future date. Comparing data between the two test facilities shows linear alignment, but mid-range wind speeds are lacking (Figure 4).

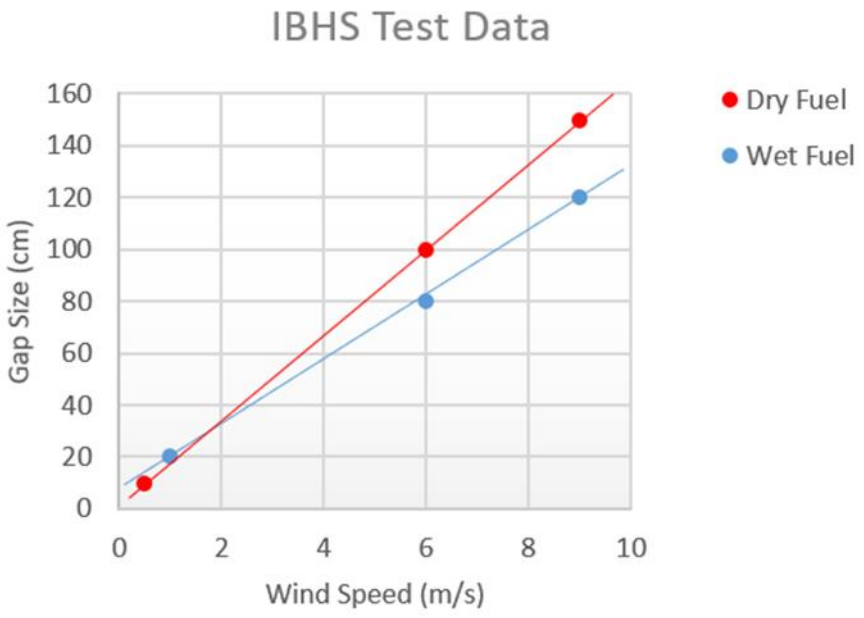

Figure 4: Test results comparing low wind speed data collect at FiSL and high wind speed data collected IBHS.

This poster will outline the methods, experimental design, and initial results from the data collected to date.

Abstract

In recent years, the growth in size and duration of wildland fires and the increasing demand for high-performance protective clothing have led Thermal Protective Clothing (TPC) research and development to seek solutions to minimise firefighter thermal load and skin burns. In this context, the present work was developed under the framework of the DIF-Jacket project (https://difjacketproject.fe.up.pt), where the main goal is to develop a new multilayer system with phase change materials (PCMs) to be used in a jacket of wildland firefighters and the subsequent development of an experimental procedure to evaluate its transient behaviour. For that purpose, a small-scale multilayer system was developed, which consisted of three layers: an outer textile layer, a pouch with PCMs (intermediate layer) and an inner textile layer. The pouch with PCMs was incorporated into the multilayer system to absorb the incoming heat from the environment, increasing the time a firefighter can be exposed to it. Subsequently, an experimental set-up was developed to evaluate the transient behaviour of the solution with PCMs, simulating the different phases to which a firefighter is exposed to (i.e., direct exposure to a radiative heat flux followed by a post-fire period). Therefore, the effect of some pouch-related parameters on the multilayer system thermal behaviour was studied, namely different geometries of the pouches (square and rectangular) and two types of PCMs. As main conclusions, similar tendencies were obtained with the square and rectangular pouches. The best temperature homogeneity of the PCM pouches was obtained with the macro encapsulated PCM. The incorporation of PCMs in the multilayer system significantly delays its heating. Further research must be conducted to delay even more the increase of temperature during the exposure time. Nevertheless, the described set-up can be used to analyse several opposing requirements of a multilayer system with PCM pouches integrated, allowing the correlation of geometrical features and properties of the system components (either textiles or PCM pouches) with the system transient temperature behaviour.

1. Introduction

The intense demands of Thermal Protective Clothing (TPC) market and the technological development in the textile industry encourage the development of protective clothing with high thermal protection while maintaining high comfort performance (G. Song and F. Wang, 2019; R. Paul, 2019). Emerging technologies have come into sight to minimize the heat stress felt by users exposed to a hot environment, such as cooling vests either with water perfused tubes (L.P.J. Teunissen *et al*., 2014) or incorporating Phase Change Materials (PCMs) (C. Gao *et al*., 2012). Recently, A. Fonseca et al. (2020) obtained promising numerical results showing the potential of phase change materials (PCMs) to increase the thermal protection of firefighters' bodies.

Phase change materials (PCMs) are materials that can be used to absorb/release energy in the form of latent heat through a phase transition (L. F. Cabeza *et al*., 2015; A. Fonseca *et al*., 2018). The incorporation of PCMs into firefighter's protective clothing can target absorption of metabolic heat produced by the human body (enhancing comfort) or absorption of heat from the environment (enhancing protection). R. Paul, (2019) stated that when PCMs are incorporated into the firefighter's protective clothing, they can absorb the heat metabolically produced by the human body during its melting process, giving the wearer a cooling effect. However, A. Fonseca *et al*. (2018) found that the optimum position for the PCM layer is the closest to the external heat source, since it favours a higher use of the PCM storage capacity and takes advantage of its high thermal inertia in a more efficient way. As this work targets protection enhancement, PCMs were incorporated into the firefighter's protective jacket to absorb the heat from the fire, thus increasing the time that the firefighter can be safely exposed to it. However, it is also crucial to release the energy accumulated during fire exposure, as excessive heat accumulation promotes the occurrence of third-degree burns, limiting the time the firefighter has to remove the garment. For that reason, the next step is to develop an innovative solution following the multilayer system of a convectional jacket structure with the addition of PCMs incorporated through pouches. Additionally, it is necessary to consider the transient behaviour of PCMs and, consequently, a new methodology for evaluating the protective clothing under transient conditions was developed.

2. Materials and methods

2.1. PCMs and its incorporation in the multilayer system

To incorporate the multilayer system of the firefighter jacket, two different PCMs were studied and their main thermophysical properties are presented in Table 1.

Table 1 - PCMs and their thermophysical properties; T_m, ΔH_m, C_p, k, and T_{max} stand for melting temperature, latent heat of fusion, specific heat, thermal conductivity and maximum operation temperature, respectively.

PCM	Form (at 25 ºC)	T_m / ºC	ΔH_m / kJ·kg^{-1}	c_p / kJ·kg^{-1}·ºC^{-1}	k / W·m^{-1}·ºC^{-1}	T_{max} / ºC
A	Solid (pure state)	69-73	120	2	0.6	90
B	Solid (powder)	77-85	75	2	0.1	110

In the PCMs pouches construction, a low thickness polymeric film was chosen due to its high thermal resistance and ability to maintain its excellent mechanical properties under hot severe environmental conditions. Square 7 cm x 7 cm pouches and rectangular 7.0 cm x 3.5 cm pouches were constructed in order to evaluate the effect of the pouch geometry. PCM A was melted before being incorporated into the pouches to have a more homogeneous distribution across the pouch. It was not necessary to melt PCM B since it was already a uniform powder (macro encapsulated in silica).

2.2. Experimental set-up for the evaluation of transient behaviour

The experimental procedure developed to evaluate the transient behaviour consisted of two different phases:

1) Heating phase – the sample is placed between the installation table and the IR lamp and therefore exposed to a constant radiant heat flux;
2) Cooling phase – the sample is removed from the installation (i.e., not exposed to a heat flux) and is left to cool down to room temperature.

The installation shown in Figure 1 was used to evaluate the sample transient behaviour. It consisted of a table and an IR lamp at the height of 30 cm from the table top, corresponding to a heat flux of 3.07 kW·m^{-2}. Additionally, a thermal camera was used to monitor the surface temperature of the sample and three data loggers to monitor the temperature on the sample's inner layer. The samples were placed in the laboratory 24 hours before testing to ensure they were in equilibrium with ambient conditions at the start of the test. As test stopping criteria of the heating phase, the maximum operating temperature of the PCM was used, i.e., 90 °C and 110 °C, respectively, for the tests with PCM A and PCM B (maximum obtained in, at least, one of the data loggers).

Figure 1 – Installation for the evaluation of samples transient behavior.

The tests were performed with the PCMs pouches and the assembly (outer layer + PCM pouch + inner layer), both insulated with extruded polystyrene (XPS) to maximize a unidirectional heat transfer. Also, XPS surface reflectivity was increased by applying a white coating to reduce temperature increase and prevent it from melting. The PCM pouches' mass to surface area ratio was also considered since the mass influences the amount of energy that the PCM will accumulate. Thus, a mass to surface area ratio of 0.38 $g \cdot cm^{-2}$ (maximum achievable ratio) was used to make a comparative analysis of the efficiency of the PCMs. The experimental set-up for the transient behaviour evaluation tests is shown in Figure 2.

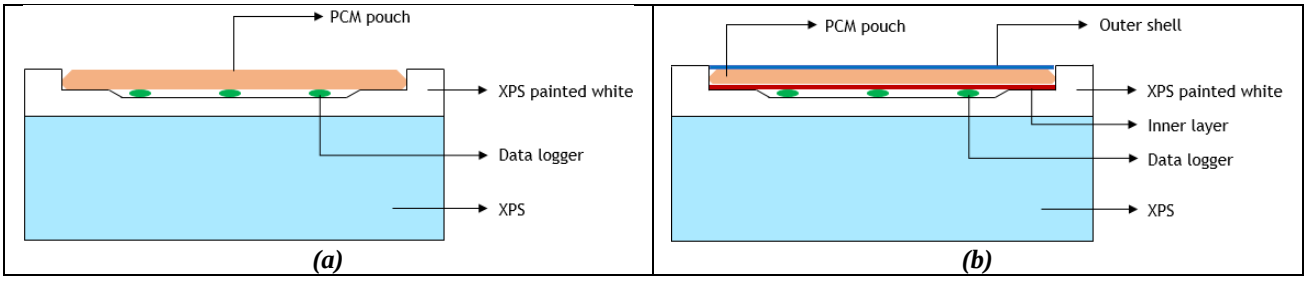

Figure 2 - Schematic representation of the experimental set-up for the transient behavior evaluation tests considering: (a) only the PCM pouch and (b) the assembly outer layer + PCM pouch + inner layer.

3. Results

This work focused mainly on evaluating the effects of the pouch geometry and the type of PCM introduced into it and, in addition, the influence of the incorporation of PCMs pouches into a firefighter jacket. Thus, the test described in section 2.2 was performed on square and rectangular pouches to study the transient behaviour of PCM pouches. Similar tendencies were obtained, so only the results obtained with the square pouches were included in this article. The comparison of the temperature profiles obtained during heating/cooling test of PCM pouches with PCM A or PCM B is shown in Figure 3. This figure contains the mean value (solid lines) of the temperatures of the three data loggers of three tests and the respective standard deviations (areas around the solid lines with the same colour).

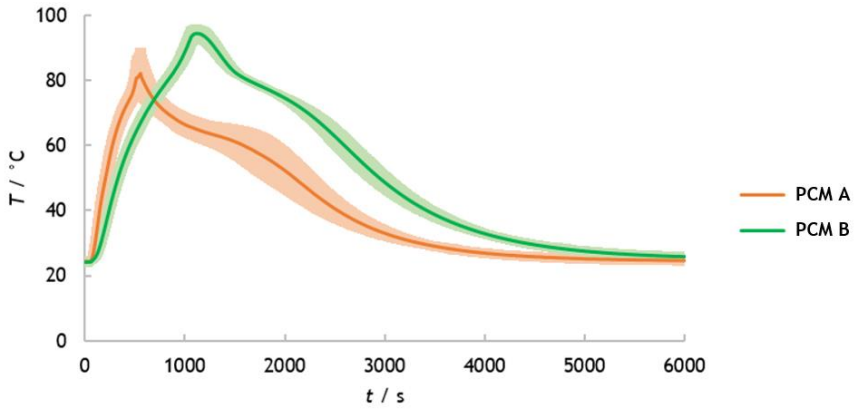

Figure 3 - Temperature profiles obtained in the PCM pouch during the heating/cooling test, considering PCM A and PCM B (three independent measurements per sample; standard deviation).

In Figure 3, it is shown that PCM B exhibits slower heating and cooling than PCM A, which can be explained by the fact that PCM B has a thermal conductivity six times lower than PCM A and equal specific heat (Table 1). The density of PCMs can also influence their heating and cooling rates. However, the supplier did not provide this information and, therefore, the density effect on the heating and cooling rates of the PCMs could not be analysed. In addition, PCM B is more homogeneous in the way it spreads across the pouch and it is easier to incorporate into pouches as it is already a uniform powder. As it is necessary to melt the PCM A before introducing it into the pouches, this PCM has the drawback of the appearance of air bubbles during the construction of the pouch. This air bubble is visible in the thermal camera image shown in Figure 4 and leads to a higher standard deviation in the results.

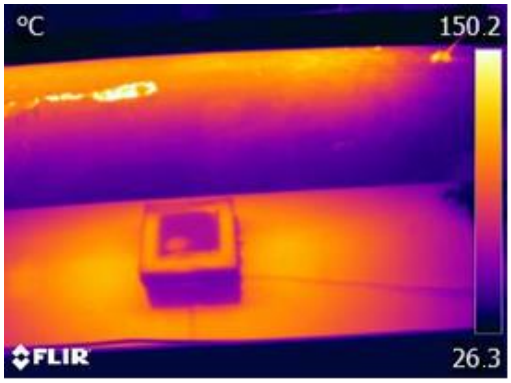

Figure 4 - Thermal camera image of the square pouch with PCM A after 4 min of exposure to IR radiation.

Lastly, the impact of the incorporation of PCM pouches on the thermal performance of the multilayer system was studied. PCM B was chosen for this study since it showed greater homogeneity (without bubbles) and was easier to incorporate into the pouches. The effect of the incorporation of PCM B on the sample's inner layer measured by the data loggers is presented in Figure 5, where the solid line is the mean value of the temperatures of the three data loggers of three tests and the area around the solid line with the same colour is the respective standard deviation.

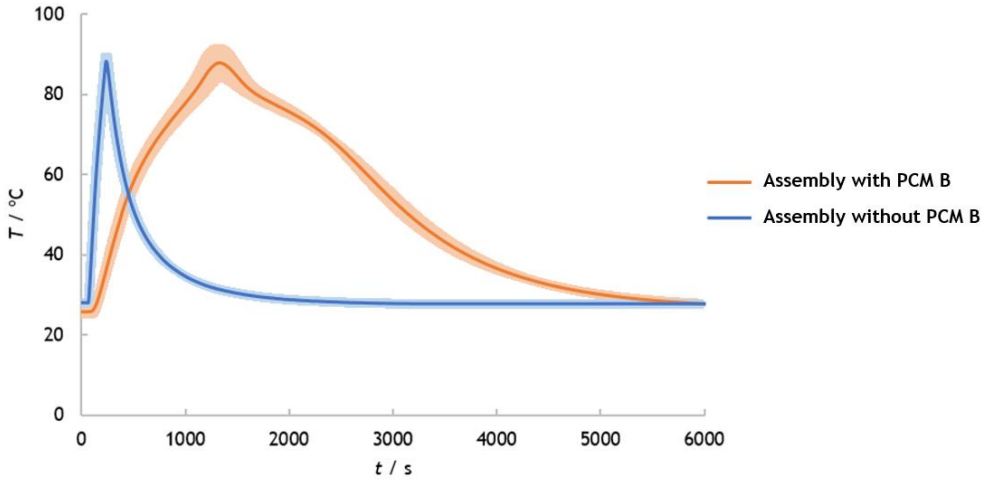

Figure 5 - Effect of the incorporation of PCM B on the multilayer system temperature (three independent measurements per sample; standard deviation).

Figure 5 shows that the assembly's behaviour without PCMs is different from the assembly with PCMs. During the exposure to the radiant heat flux, the assembly without PCM pouch (i.e., consists only of an outer shell and an inner layer) shows an increase in heating rate significantly sharper than the increase rate obtained for the assembly with PCM pouch, with an initial heating rate of 0.44 ± 0.01 ºC·s^{-1}. As the initial heating rate of the assembly with the incorporated PCMs is 0.09 ± 0.01 ºC·s^{-1}, it corresponds to a decrease of 79.5 %. This decrease is due to the fact that the assembly with PCM pouch has an additional layer, which provides higher thermal insulation (due to the addition of PCM and pouch material). Nevertheless, the effect of PCM latent heat on the pouch temperature is slightly evident at approximately 1600 s (beginning of the cooling phase); it is observed a slight change in the decline of the temperature profile. Further studies considering a large amount of PCM should be interesting to study. Although the incorporation of PCMs is beneficial since it decreases the heating rate of the assembly, it also dramatically delays its cooling by almost 4500 seconds.

As future considerations, to avoid the increase in the cooling time, further research must be conducted to delay even more the increase of temperature during the exposure time. Furthermore, it is important to study the impact of incorporating PCMs on the weight and on the evaporative resistance in the firefighter jacket. Also, since one of the most important considerations to be taken in the development of protective clothing is mass transfer, it is still necessary to optimise the performance of the developed multilayer system, considering relevant aspects related to mass transfer (e.g., the effect of the distribution/quantity of water inside the jacket on the occurrence of burns).

4. Conclusions

A multilayer system with integrated PCMs was studied at a small scale. The developed multilayer system consists of three layers: an outer shell, a PCM pouch, and an inner layer. An experimental procedure was also developed to evaluate the transient behaviour of PCMs pouches and the multilayer system, simulating different phases that a firefighter is exposed to in firefighting. As a result, the following conclusions were obtained:

- The pouch geometry does not significantly influence the thermal performance of the multilayer system;
- Powder rather than pure state PCMs must be selected to fill in the pouches to avoid operational problems. For instance, the macro encapsulated PCM showed the most promising results since it presented a greater homogeneity in its spread across the pouch and a more straightforward incorporation method into the pouches;
- The incorporation of PCMs is beneficial since it decreases the initial heating rate of the assembly, but it also dramatically delays its cooling.

Furthermore, the developed set-up can be used to analyse several opposing requirements of a multilayer system with PCM pouches integrated, allowing the correlation of geometrical features and properties of the system components (either textiles or PCM pouches) with the system transient temperature behaviour.

Fire weather, extreme fire behavior, ERA5, validation, Greece

Abstract

Accurate simulations of fire weather conditions for both the past and future are of great importance for fire management and preparedness. With the advancement of numerical weather prediction models and data assimilation techniques, more accurate reanalysis products have been developed the recent years. Here we validate fire weather conditions in Greece which are computed based on ERA5 reanalysis data against surface observations from the automatic weather station network of the National Observatory of Athens (NOA). We assess the fire weather conditions in an application of the Canadian Forest Fire Weather Index (FWI) System in both datasets. Although, ERA5 FWI archive is available since 1979 here we limit our analysis during the period from 2007 to 2019, due to the limited data availability from the NOA network. The validation of FWI in ERA5 data shows good agreement with the NOA observations with a mean correlation of 0.87. Furthermore, FWI in ERA5 data is overall slightly underestimated compared to NOA observations, which is driven by an underestimation of the three moisture components of FWI, namely the Fine Fuel Moisture Code (FFMC), the Drought Code (DC) and the Duff Moisture Code (DMC). Preliminary results also indicate that the largest errors are found over the eastern and southern parts of Greece, which is the area that experiences the highest FWI values during the summer.

1. Introduction

The evaluation of the atmospheric conditions which are prone to extreme fire behavior is very critical for both the ecosystems and human life. Furthermore, accurate knowledge of fire weather conditions is also critical for civil protection preparedness and management. Fire weather conditions are determined by the meteorological conditions across weather and climate scales (Abatzoglou and Kolden, 2013; Flannigan and Wotton, 2001). Across longer time scales, such as sub-seasonal to seasonal and climate scales, changes in atmospheric state expressed via changes in basic meteorological variables (e.g. precipitation and temperature) influence the state of the fuels. On the other hand, across shorter time scales, changes in synoptic to mesoscale atmospheric conditions can modulate fire weather primarily via changes in temperature, wind speed and humidity.

These changes in fire weather conditions can be monitored by using fire weather indices. One of the mostly used fire weather indices is the Canadian Forest Fire Weather Index (FWI) System (Van Wagner, 1987). FWI is used by many agencies and national weather services to assess fire weather. Thus, its evaluation for both past conditions as well as for forecasting fire weather conditions is of great importance. Here we present preliminary results of an evaluation of ERA5 FWI and its components in Greece using observations from the network of automatic weather stations that is operated by the National Observatory of Athens (NOA).

2. Data and methods

For the purpose of this analysis we use the recently developed by the European Centre for Medium-range Weather Forecasts (ECMWF) daily gridded dataset of FWI based on ERA5 reanalysis. The ERA5 FWI dataset is based on an application of the Global ECMWF Fire Forecast (GEFF) model in ERA5 reanalysis data (Vitolo

et al., 2020). The ERA5-based FWI data extends from 1979 till present and has a spatial resolution of 0.25˚ x 0.25˚. However, for the validation analysis here we limit our analysis in the period of 2007—2019, when the NOA automatic weather station (AWS) observations are available. For the comparison we use the nearest land ERA5 grid point to the each AWS location. The locations of the 76 AWS that we use in this analysis are shown in Fig. 1. AWS-based FWI components are calculated in the same way as in Vitolo et al. (2020).

For the validation, following previous work of McElhinny et al. (2020), we consider four simple metrics: (1) mean bias error (MBE), (2) mean absolute error (MAE), (3) Spearman rank correlation and (4) root mean square error (RMSE) applied in the ERA5-based FWI and the AWS-based FWI time series.

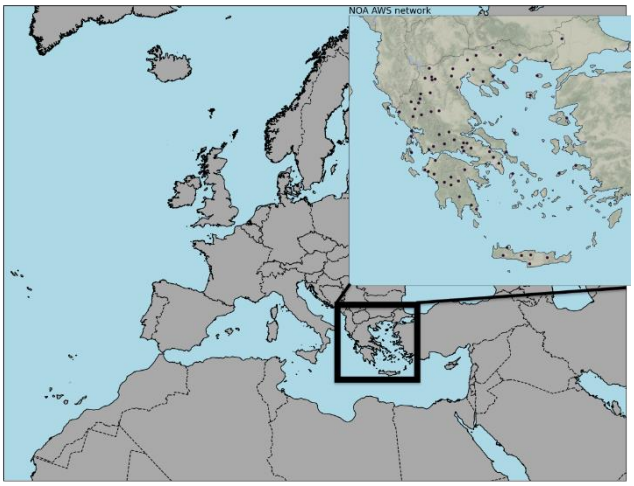

Figure 1- Study area (black box) and the locations (white dotes) of the automatic weather stations operated by the National Observatory of Athens (NOA) during the period of 2007—2019 that we use in this analysis.

3. Results

3.1. Climatology of fire weather in Greece

In Figure 2 we present the monthly climatological mean FWI values for four selected months based on ERA5 data during the period of 1981 to 2010 in Greece. This analysis illustrates, not surprisingly, the substantial spatiotemporal variability of FWI in Greece suggesting that a dense observational network is necessary for monitoring fire weather conditions. Results show that FWI is lower across the entire country during winter (Fig. 2a) and peaks during the summer particularly over the eastern and southern parts of the country (Fig. 2c). During spring and mostly during autumn FWI exhibits a NW-SE gradient with higher values over the southeastern parts and lower values over the northwestern parts of the country (Fig. 2b, d).

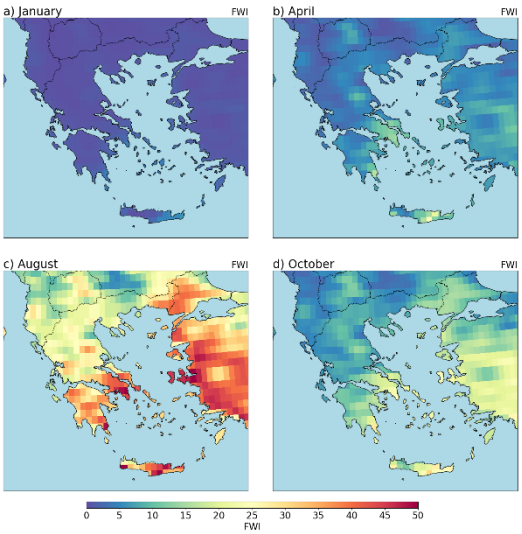

Figure 2- Monthly climatologies of mean FWI for (a) January, (b) April, (c) August and (d) October based on 1981-2010 ERA5 reanalysis data.

Similar spatiotemporal variability to the FWI exhibits the daily severity rating (DSR), which is a component of the FWI and it is a good indicator of fire suppression effort that is required (Fig. 3).

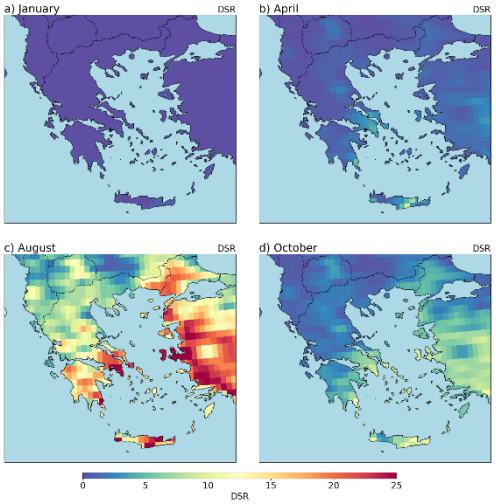

Figure 3- Monthly climatologies of mean DSR for (a) January, (b) April, (c) August and (d) October based on 1981-2010 ERA5 reanalysis data.

3.2. Validation of ERA5 fire weather

A validation analysis of ERA5-based FWI over the 76 NOA AWS locations in Figure 4 reveals that overall ERA5 is in good agreement with the AWS data exhibiting a mean Spearman rank correlation of 0.9, mean MAE of 5.19 and a slightly mean negative bias of -0.6 (Fig. 4). These findings are in line with previous analysis performed in Canada by McElhinny et al. (2020). The spatial distribution of MAE (Fig. 4b) and MBE (Fig. 4a) reveals that a negative bias is mainly evident in AWS near coastal areas and islands suggesting a model bias primarily in wind speed as it has also been discussed in previous studies (Betts et al., 2019; McElhinny et al., 2020). However, the source of this bias is beyond the scope of this study but users should be aware of these potential limitations (Vitolo et al., 2020).

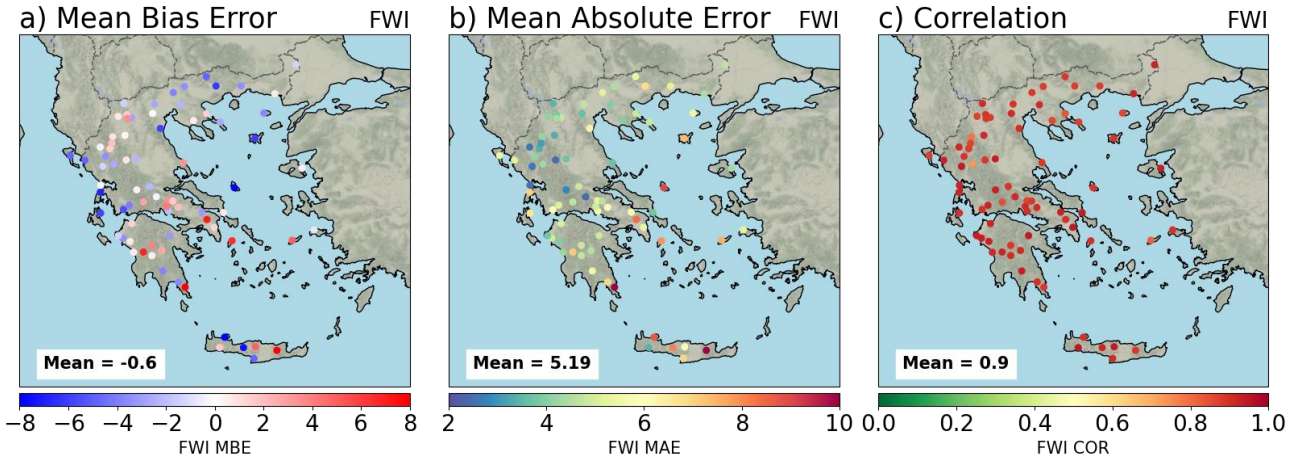

Figure 4- FWI (a) mean bias error, (b) mean absolute error and (c) Spearman rank correlation of ERA5 data against NOA AWS observations.

Validating ERA5 DSR data yields even greater agreement between ERA5 and NOA AWS with a mean Spearman correlation of 0.9, mean MAE of 2.54 and mean bias of -0.02. The mean biases in DSR are substantially smaller compared to FWI (near 50%) and are mainly identified in the southern parts of the country. These findings suggest that DSR might be a more useful indicator of fire behavior and fire weather conditions across broader regions in ERA5 data compared to FWI. Furthermore, DSR mean bias errors exhibit smaller variance suggesting an overall better agreement with the AWS data compared to FWI (Fig. 6).

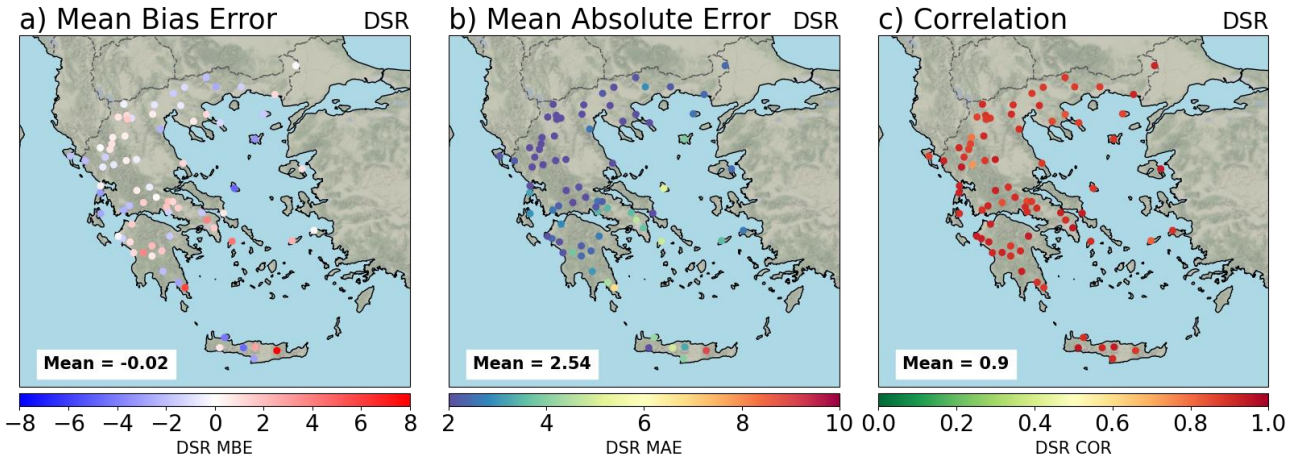

Figure 5- DSR (a) mean bias error, (b) mean absolute error and (c) Spearman rank correlation of ERA5 data against NOA AWS observations.

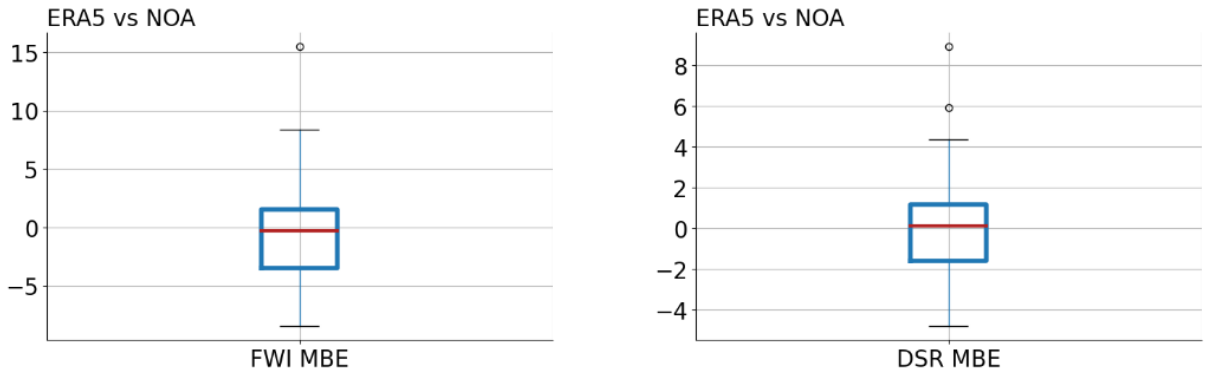
We further validate all the components of the CFFWIS and we provide a summary of the statistical metrics that use here in Table 1. Overall, we find that the largest biases are evident for the three moisture components of FWI, namely the Fine Fuel Moisture Code (FFMC), the Drought Code (DC) and the Duff Moisture Code (DMC) and therefore by construction the Build Up Index (BUI). The smallest mean biases are evident for DSR, Initial Spread Index (ISI) and FWI. Furthermore, the largest MAE are evident for DC, BUI, DMC, FFMC, while the smallest occur for ISI, DSR and FWI. It is notable that even though some moisture components exhibit high correlation, they are also accompanied by the largest MBE, MAE and RMSE.



a) ***b)***

Figure 6- Distribution of ERA5 (a) FWI and (b) DSR mean bias errors across all 76 NOA AWS locations.

Our findings are in line with previous results from McElhinny et al. (2020), where similar magnitudes of MBE and MAE are shown, however here we find stronger Spearman rank correlation between ERA5-based and NOA AWS-based FWI suggesting an overall good performance of ERA5 despite the dataset limitations. As mentioned above, these limitations arise from ERA5 biases mainly in precipitation and wind, which then influences the computations of the CFFWIS components.

Table 1- Statistics of fire weather indices based on ERA5 data against NOA AWS observations.

	Mean Bias Error	Mean Absolute Error	Root Mean Square Error	Correlation
FWI	-0.6	5.19	8.05	0.9
ISI	0.24	1.2	3.03	0.81
FFMC	-4.43	7.42	11.5	0.86
DMC	-9.5	26.1	50.4	0.93
DC	-161.3	187.25	252.9	0.85
BUI	-18.7	31.23	54.9	0.93
DSR	-0.02	2.54	4.8	0.9

4. Conclusions

In this study we present preliminary results of the validation of ERA5 fire weather conditions in Greece using automatic weather station observations during the period from 2007 to 2019. Our results show that ERA5 overall perform well mostly in the continental parts of the country, while some biases are evident over the eastern and southern parts of the country. A detailed validation of each component of the Canadian Forest Fire Weather Index System suggests that the daily severity rating component performs better than any other component and could be a more reliable indicator of fire weather and fire behavior for future studies that focus over broader areas compared to other components.

Pinus Halepensis needles, prescribed burning, slope effect, Small World Model, vegetation fire.

Abstract

This work aims to validate the Small World Network Model by comparing the numerical predicted rate of spread results to those obtained from a prescribed burning in the city of Oran in Algeria using Pinus Halepensis needles. In the first part of the experimental tests pine needles partially dried using microwave oven and climatic chamber were used. Fire propagation tests were then realized at different fuel moisture contents. In the second part of the tests, dead Pinus Halepensis needles were used in order to evaluate the effect of the terrain slope on fire spread. This model may be used to simulate the fire patterns both in homogeneous and heterogeneous landscapes. This model takes into account both the deterministic effects induced by the flame, and the probabilistic long range effects due to the spotting process of firebrands. Therefore, it combines as well the advantages of network models and those of macroscopic semi-physical models.

1. Introduction

Forest fires are very complex to model because of the number of intricate factors that can influence their propagation, and their multi-scale nature. Indeed, the characterization of their behavior depends on several parameters such as the fuel moisture content and the inclination of the terrain.

The small world model was proposed for the first time in 1998 by Watts and Strogatz in order to describe social behavior (Watts D. J. and Strogatz S. H., 1998). It is characterized by a high clustering coefficient and its ability to include randomly generated long-range connections. It was applied to model various phenomena such as epidemics, propagation of rumors (Zanette., 2002), the synchronization networks of cortical neurons (Yu Shan et al., 2008) etc.

On 2005, this model was successfully applied for the first time to forest fires within a collaboration between the two laboratories IUSTI (Polytech Marseille, France) and LEPM (USTO, Oran, Algeria) (Zekri et al., 2005). This variant of the small world model is based on two important requirements : it takes into account the flame radiation and the convection induced by the flame. In fact, the flame is modeled as having a cylindrical shape that emits a thermal radiation from its surface. Indeed, from each m² of the flame surface, N quanta of energy q are randomly generated using the statistical Monte Carlo method. In the other side, it considers the physics of combustion and the ignition and combustion properties of fine fuel elements which lead to the energy balance. The Small World Model was previously validated for three cases studies: fire experiments conducted in South Africa in 1992 (Savanna fires), historical fires that occurred in Lançon (France) in 2005 (Adou et al., 2010), and the historical fire of Suartone in Corsica 2003 (Hamamousse et al., 2021). In this work, the most recent version of this model is used to compare the real and the numerical rate of spread at different fuel moisture contents (for partially dried samples) and different terrain slopes (for naturally fead fuel).

2. Small World Network Model overview

In this model, the fuel medium is preheated to ignition by wind-driven convective and radiative heat emitted by the fire front and loses, in turn, a fraction of this energy by radiation to its influence area.

Each fuel element has a cylindrical shape with a height *H* and a diameter *D*, and only a top layer of thickness δ corresponding to the mean free path of radiation through the considered combustible that can be related to its surface-to-volume ratio, $\boldsymbol{\sigma_k = \frac{S_k}{V_k}}$, and to the volume fraction of the solid phase, $\boldsymbol{\alpha_k = \frac{V_k}{V}}$, as $\boldsymbol{\delta = 4/\sigma_k \alpha_k}$ (De Mestre et al., 1989), and volume $\boldsymbol{V = \pi D^2 \delta}$ of this combustible is affected in the pre-heating process. Above this penetration length $\boldsymbol{\delta}$, it is supposed that the radiation do not interact with fuel elements. These latter are considered as having the same geometric and thermo-physical properties. We assume also that the wet and dry fine fuel elements absorptivities are equal ($\boldsymbol{a_{WFF} = a_{DFF}}$), and that their volume fraction $\boldsymbol{\alpha}$ and surface-to-volume ratio $\boldsymbol{\sigma}$ are not affected during the thermal degradation process, which implies that $\boldsymbol{\alpha_{WFF} = \alpha_{DFF}}$ and $\boldsymbol{\sigma_{WFF} = \sigma_{DFF}}$.

Following the Koo et al. model (Koo et al., 2005), the receptive vegetation cell is heated in three steps: First, its temperature is raised by the absorbed heat up to the boiling temperature of water, namely 373 K. Then, it stagnates until the moisture content of this combustible is evaporated. Hence, in this desiccation phase, the wet fine fuel (WFF) is dried by the evaporation process turning into a dried fine fuel (DFF). Finally, the temperature of the dried vegetation restarts to increase steadily until it attains the pyrolysis temperature. If the emitted quantity of VOC is sufficient, the ignition process occurs, marking the end of the endothermic phase of this cell. The energy conservation in a receptive cell $\boldsymbol{j}$ exposed to a fire ($\boldsymbol{N_{bc}}$ burning cells) yields to the following equations.

For a temperature below the boiling temperature of water ($\boldsymbol{T(j) < 373K}$), we have:

$$\sum_{i=1}^{N_{bc}}\left[q^{+}_{rad,fl}(i) + q^{+}_{rad,e}(i) + q^{+}_{conv}(i)\right] - q^{-}_{rad}(j) = \rho_{WFF}\, c_{p_{WFF}}\, \alpha_k \frac{dT(j)}{dt} \qquad (1)$$

$\boldsymbol{q^{+}_{rad,fl}}$, $\boldsymbol{q^{+}_{rad,e}}$, $\boldsymbol{q^{+}_{conv}}$ and $\boldsymbol{q^{-}_{rad}}$ correspond respectively to the radiation of the flame, the radiation of embers, the convective preheating of the site located in the influence zone of the burning cell by the emitted hot gases and the radiative losses due to the heat transfer from the cell *j* to the ambient. $\boldsymbol{\rho_{WFF}}$ is the volumetric mass density of the wet fine fuel element and $\boldsymbol{c_{p_{WFF}}}$is its heat capacity.

When the temperature of the receptive cell is equal to $\boldsymbol{373K}$, the equation becomes:

$$\sum_{i=1}^{N_{bc}}\left[q^{+}_{rad,fl}(i) + q^{+}_{rad,e}(i) + q^{+}_{conv}(i)\right] - q^{-}_{rad}(j) = -\rho_{DFF}\, L_{vap}\, \alpha_k \frac{dm_c(j)}{dt} \qquad (3)$$

The latent heat of water vaporization $\boldsymbol{L_{vap}}$ is equal to $\boldsymbol{.25 \times 10^6\ J/Kg}$.

Once the site temperature exceeds that of water evaporation ($\boldsymbol{373K < T(j) < T_{pyr}}$), we have:

$$\sum_{i=1}^{N_{bc}}\left[q^{+}_{rad,fl}(i) + q^{+}_{rad,e}(i) + q^{+}_{conv}(i)\right] - q^{-}_{rad}(j) = \rho_{DFF}\, \alpha_k \frac{dT(j)}{dt} \qquad (4)$$

When it attains the pyrolysis temperature $\boldsymbol{T(j) = T_{pyr}}$, the conservation of energy implies:

$$\sum_{i=1}^{N_{bc}}\left[q^{+}_{rad,fl}(i) + q^{+}_{rad,e}(i) + q^{+}_{conv}(i)\right] - q^{-}_{rad}(j) = -\rho_{DFF}\ L_{pyr}\, \alpha_k \frac{dFPC}{dt} \qquad (5)$$

FPC is the pyrolysis product content of the dry fuel and $\boldsymbol{L_{pyr}}$ is the latent heat of pyrolysis.

The figure bellow schematizes the flame spread, the energy transfer mechanisms and the control volume of the cell involved in preheating.

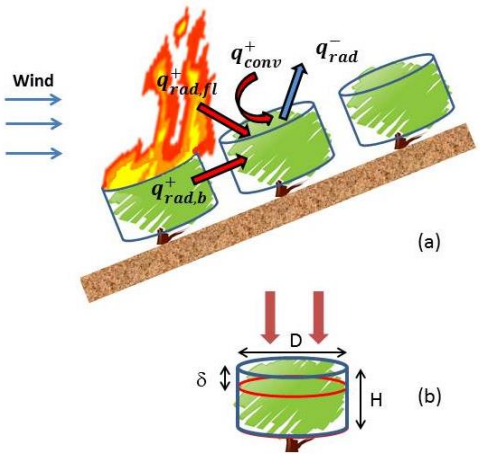

Figure 1: Flame spread schematic, with energy-transfer mechanisms indicated, and control volume of the cell involved in preheating.

We use a Monte Carlo method in order to estimate roughly the number of photons (quanta of energy) received by a healthy cell from the flame. This latter is modeled as a cylindrical solid body emitting radiation energy solely from its surface (solid flame model), this means that the properties of the flame such as its height, length, base diameter, angle and its emissive power are required. It is worth noting that the amount of energy received by a given cell depends on these flame properties, and may be affected by the air layer separating the flame and the cell, and the type of the vegetation cell. Moreover, some of these emitted quanta of energy may be absorbed by another burning cell situated between the emissive and the receptive sites. This screening effect that causes a loss of energy which does not contribute to the preheating of the healthy fuel is also taken into account by this MC method.

The radiated power is given by:

$$\boldsymbol{q^+_{rad,e}(i) = -a_{fm}\sigma\varepsilon_b T_b^4 \frac{d\tau}{dy} = a_{fm}\sigma\varepsilon_b T_b^4 \frac{1}{D_j}(exp(-d_1/\delta) - exp(-d_2/\delta))} \qquad (7)$$

Where $\boldsymbol{\sigma}$ is the Stefan-Boltzman constant (equal to $\boldsymbol{5.67 \times 10^{-8} Kg.s^{-3}.Kg^{-4}}$), $\boldsymbol{\varepsilon_b}$ is the embers emissivity (it is assumed to be equal to one) and $\boldsymbol{T_b}$ is the temperature of the radiating embers. $\boldsymbol{D_j}$ corresponds to the diameter of the preheating site whose center is located at a distance $\boldsymbol{d_{ij} = d_1 + \frac{D_i+D_j}{2} = d_2 - \frac{D_i+D_j}{2}}$ from the burning site.

The fuel cells situated in its influence area may be affected also by a wind-driven convective heat transfer mechanism which contributes to the heating of the receptive cell. If we suppose that the temperature difference decreases exponentially with the distance $\boldsymbol{y}$ as in (Pagni and Peterson., 1973). We can express this convective power as follows:

$$\boldsymbol{q^+_{conv}(i) = \frac{h}{\delta}(T_f - T_j)e^{-0.3d_{ij}/L_f}} \qquad (8)$$

We consider here that the length flame is approximately equal to one third of the characteristic length.
$\boldsymbol{L_f}$ is the flame length and $\boldsymbol{T_f}$ its temperature. $\boldsymbol{h}$ is an average heat transfer coefficient and is determined by the equation hereunder (Pagni and Peterson., 1973):

$$\boldsymbol{h = \frac{k_f}{d_{ij}} 0.037\, Re_{d_{ij}}^{0.8}\, Pr^{1/3}} \qquad (9)$$

$\boldsymbol{k_f}$ and $\boldsymbol{Pr}$ are the thermal conductivity and the dimensionless Prandtl number

Hence, the combustible cell exposed to the flame gains energy by radiative (flame and embers radiations) and convective (heat transported by hot gases) processes. However, it loses also a part of this stored heat by radiating it to the surrounding environment. These radiative losses can be expressed as:

$$q_{rad}^{-}(j) = \frac{1}{\delta}\varepsilon_{fm}\sigma\left(T_j{}^4 - T_\infty{}^4\right) \quad (10)$$

$\boldsymbol{\varepsilon_{fm}}$ is the fuel medium emissivity and $\boldsymbol{T_\infty}$ is the ambient temperature.

3. Validation of the Small world Network Model

In this work, the numerical rate of spread is compared to the experimental one :

- At different fuel moisture contents (for partially dried samples)
- At different terrain slopes (for naturally fead fuel).

The prescribed burning experiences were realized at the laboratory LEPM situated at the University of Sciences and Technology of Oran during spring 2021. 150 g masses of Pinus halepensis needles were homogeneously distributed on a metallic burning table of dimensions 88.5cm x 37.5cm. The fuel bed thickness and charge were about 1cm and 0.5kg/m², respectively. The fuel bed was divided into seven different positions (Figure 2); fire spread was then calculated by recording the time taken by the flame to pass between two successive positions.

Figure 2- Fire propagation table.

The first series of tests was realized on flat ground using pine needles dried partially using a microwave oven and a climatic chamber. The second series of tests was carried out according to different inclination angles (0, 5,9,13 and 17°) using naturally dried pine needles (dead needles) (figure 3).

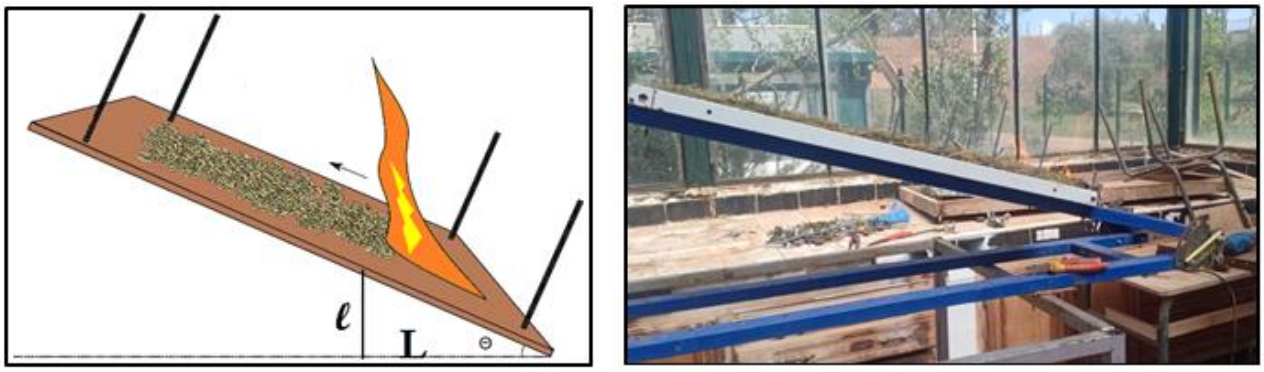

Figure 3- Inclined fire propagation table.

The study was divided into two main parts :

- Part 1 : The Network

2-dimentions network that contains homogeneous and uniform vegetation was constructed on a square based structure. The input data are occupancy, site radius, inclination, ignition type (punctual or linear).

- Part 2 : Fire propagation

The second part consists on the simulation of the fire propagation using the Small World Network Model. The network created in the previous section is integrated as an input of the Small World Network Model to simulate the fire propagation.

4. Results and discussions

In this section, we are going to present the experimental and the numerical results.

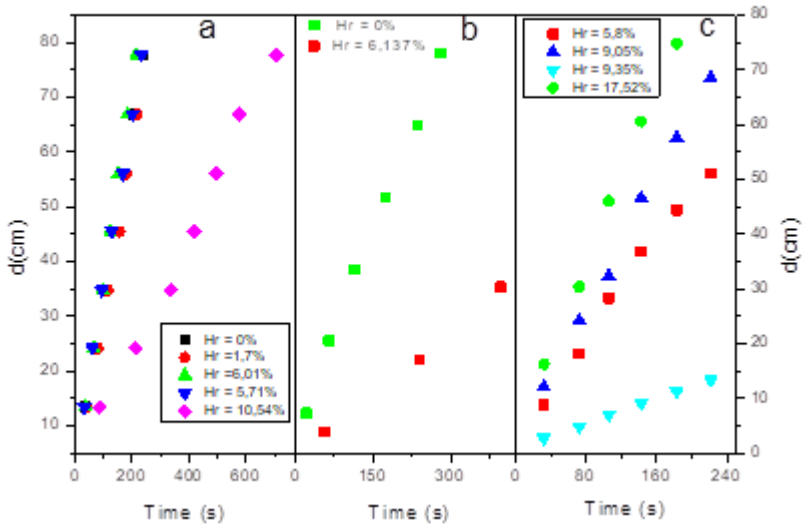

Figure 4- Fire spread evolution at different fuel moisture contents: Microwave oven , b) climatic chamber and c) naturally dead fuel.

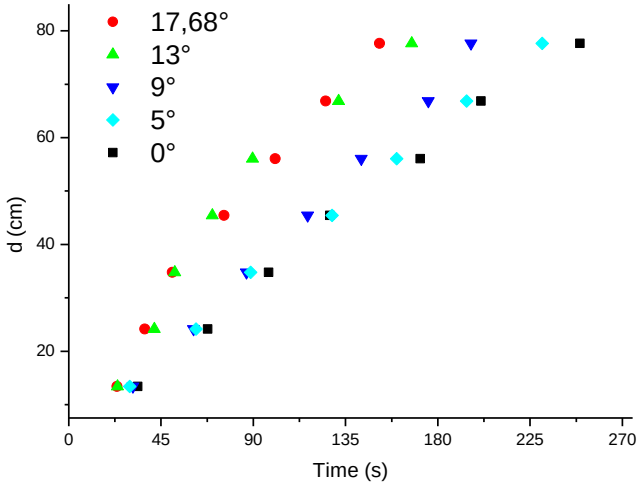

Figure 5- Fire spread at different table inclinations.

The comparison between the experimental and numerical results showed that the numerical simulations underestimate the fire rate of spread. This difference may be due to several reasons :

The intrinsic fuel parameters are not exactly estimated, some parameters differ from a region to another and from a season to another. Thus, it is important to characterize them experimentally.

The flame temperature captured by the thermocouples during the fire propagation indicates that the temperature decreases. This behavior is the same for low fuel moisture content.

5. Conclusion

The Small World Network model of fire propagation which combines the stochastic method of Monte Carlo and the semi-physicalapproach based on the resolution of the energy equation was validated on a prescribed burning realized at the laboratory LEPM situated at the University of Sciences and Technology of Oran during spring 2021. The comparison between the experimental and numerical results showed that the numerical simulations underestimate the fire rate of spread.
