Abstract

The direct and indirect impacts of Wildland-Urban Interface fires on infrastructures and communities have become more severe in the last few decades, mainly due to the disproportionate growth of urban areas lacking planning and management, the abandonment of rural areas and activities, and climate changes. Many regions of the southern Mediterranean, the United States, Australia, and South America have been severely affected with catastrophic losses.

Building codes addressing the problem of WUI fires in the vicinity of the built environment are still scarce, but already with a few good examples, namely the Australian Standard AS 3959-2009, Construction of Buildings in Bushfire Prone Areas. But with the increasing risks, nowadays mainly driven by climate change, it is necessary to develop new approaches and codes for existing and new buildings effectively contributing to enhancing the resilience of the built environment and communities in the WUI. Moreover, taking advantage of new and ever-evolving computational tools, the use of a performance-based approach, replacing or complementing prescriptive codes, shows great potential to enable a deeper understanding of the complex fire spread mechanisms from forest fires to urban fires, namely radiant heat, direct flame contact and firebrands.

Physics-based modelling enables a better understanding of such phenomena, bearing in mind that up to date no accurate and reliable models for firebrands can be found. In this investigation, a performance-based approach is considered, exploring the capabilities of computational fluid dynamics and the software Fire Dynamics Simulation (FDS) to investigate and quantify WUI fire exposures. This was achieved by considering available experimental data on vegetation burning and developing and calibrating the numerical models using FDS. A Particle Method, based on Lagrangian particles was selected for this investigation since this model is particularly suitable to simulate surface and raised vegetation fire spread. With this strategy all thermo-physical properties of the fuels must be used as input, ensuring that the fire spread can be computed by the model.

Based on the calibrated models for a single tree, a new case study scenario was created (structure exposed to wildfire) and investigated aiming to assess in detail WUI fire exposures under different conditions by varying several parameters, such as wind speed and direction, distance to the structure and elevation of the terrain. Since a performance-based approach was selected and considering the basic principles associated with Fire Safety Engineering (FSE), 3 basic components must be assessed, namely the fire modelling, the thermal analysis of the structure and finally the structural analysis considering temperature increase and degradation of mechanical properties of materials. From the fire modelling investigated in this paper, some attention was devoted to assessing Adiabatic Surface Temperatures in the structure and consequently defining in a simple way to couple CFD field models to Finite Element Models (FEM) that will enable the understanding and development of ignition resistant structures in the WUI.

1. Introduction

The direct and indirect impacts of Wildland-Urban Interface (WUI) fires on infrastructures and communities have become more severe in the last few decades, mainly due to the disproportionate growth of urban areas lacking planning and management, the abandonment of rural areas and activities, and climate changes. Catastrophic loss of lives, property damage and environmental destruction have been observed on several occasions, such as the 2005 and 2017 wildfires in Portugal (Independent Technical Commission 2022; Chas-Amil et al. 2020; Independent Technical Commission 2018), the 2009 Victorian bushfires (Teague B. et al., 2009), the 2018 Camp Fire in Northern California (P. Eavis et al. 2020; Spearing et al. 2020; Ager et al. 2021), the Australian bushfires (I. Kwai 2020); Mclennan et al. 2015) or the wildfires in Eastern Attica, Greece (Efthimiou et al. 2020). The severity of the problem is relevant and may be intensified in the next few years by climate changes. In the Sixth Assessment Report of the Intergovernmental Panel on Climate Change (IPCC

2021), it is stated that in southern Europe, northern Asia, the USA, and Australia, the weather conditions promoting the occurrence of wildfires, are becoming more likely. The increasing frequency of such events shows the urgent need to understand these phenomena and the existing risks, aiming to predict their consequences and implement adequate mitigation measures, strengthening the resilience of communities and the built environment (Ager et al. 2021; Álvares-Miranda et al. 2018; Syphard et al. 2017). Understanding the fire spread mechanisms from wildfires to the built environment in the vicinity of forest areas is a complex task requiring extensive investigation considering not only the WUI fire exposure (radiant heat, direct flame contact and firebrands) but also the vulnerability of infrastructures (Quarles and Standohar-Alfano 2018) for the development of science-based resilient solutions/methods for retrofitting existing structures and to design new structures in the WUI, that can be incorporated in future codes.

Exploring the versatility of advanced computational tools, it is possible to adopt a Performance-Based Design (PBD) approach to investigate in detail fire spread mechanisms from forest fires to the built environment using similar strategies as the ones presented by Vacca et al. (2020) in the scope of the research project WUIVIEW - Wildland-Urban Interface VIrtual Essays Workbench ((ECHO/2018/826522), considering that serious limitations still exist mainly related to the behaviour of firebrands and their interaction with structures and how external fires impact buildings. In this investigation, physics-based models, using the software Fire Dynamics Simulator (FDS) (McGrattan et al. 2020), were developed to calibrate experimental tests on single burning trees (Douglas-fir experiments conducted at NIST) reported by Mell *et al*. (2009). Then some case study scenarios were designed, incorporating surface vegetation and trees in the vicinity of a building. Additionally, the influence of elevation and wind speed on the fire behaviour was considered to evaluate the possible fire spread mechanisms from wildfires to buildings.

2. Methodology

2.1. Modelling of single-burning trees

To conduct parametric numerical studies, it is necessary to accurately calibrate the developed models using available experimental results. In this study, the experimental tests performed by Mell *et al*. (2009) on single-burning Douglas-fir trees were reproduced using FDS 6.7.7 (McGrattan et al. 2020). The calibration was performed for 2 m and 5 m Douglas-fir trees, with a moisture content of 14% and 26%, respectively. The Particle Method was used to model the vegetation in fire. In this case, the trees are represented by a collection of Lagrangian particles that are heated up by convection and radiation, as explained by Vanella *et al*. (2021). Using the Particle Method, it is necessary to use as input all relevant thermo-physical properties of fuels, allowing the model to compute the fire spread. Physical and thermal properties/parameters used in the simulations are presented in Table 1. It is worth mentioning that different fuel chemical compositions were assumed, namely $C_{3.4}H_{6.2}O_{2.5}$ (Hostikka and McGrattan 2001), $C_6H_{10}O_5$ (Browne 1958) and $CH_{1.7}O_{0.74}N_{0.002}$ (McGrattan et al. 2021). The heat of combustion was 17500 kJ/kg.

Table 1 – Physical and Thermal Parameters used in FDS

Quantity	Value	Quantity	Value
Drag Coefficient [--]	2.8	Heat of Combustion [kJ/kg]	14516|17500
Moisture Vegetation [%]	14|26	Soot Yield [kg/kg]	0.02
Vegetation Density	514	Initial Temperature [º C]	28
Fuel Geometry Tree	Cone	Heat of Reaction [kJ/kg]	418
Crown Width (radius) [m]	0.85|1.45	Specific Heat Capacity [kJ/kg K]	2.0|1.5|4.184
Crown Base Height [m]	0	Thermal Conductivity [1][W/ m K]	0.11
Tree Height [m]	1.9|4.3	Density [2] [kg/m^3]	300|67
N_PARTICLES_PER_CELL	1	Reference Temperature [º C]	300 [3], 100 [4]
PACKING_RATIO (s, m, l) [5]	68, 48, 44| E-5	Shape	Cylindrical

[1] Vegetation; Char and Ash.; [2] Moisture, Char Veg and Dirt.; [3] Vegetation Grass. [4] Moisture. (small, medium, large) [5]

Mesh sensitivity tests were also performed, considering two mesh sizes, namely 10 and 25 cm. It was observed that mesh size played a very relevant role in the accuracy of the developed model. Overall, it was observed that the FDS can accurately reproduce the observed experimental behaviour in terms of Mass Loss Rate for both

single Douglas-fir burning trees using a mesh size of 10 cm and a fuel chemical composition of $C_{3.4}H_{6.2}O_{2.5}$ (S. Hostikka and K. MacGrattan, 2001). As in the experimental test, a circular shape burner was prescribed with a heat release rate of 30 kW.

2.2. WUI case study

The selected case study comprised a small industrial warehouse (15 × 10 m^2) facing a set of trees. The maximum height of the building is 12 m. Two doors (3.5 x 8 m^2) are located on the eastern and western sides. Two square gates (8 × 8 m^2) are placed on the northern and southern wall perimeters. The trees are on a slope, as depicted in Figure 1. The dimensions of the computational domain are the following: X = 57 m, Y = 36 m and Z = 40 m. Four meshes were created to optimize the computation time. Three meshes, with a cubic cell of 25 cm were created (Z direction ranging from 0 to 24 m). The fourth mesh with cubic cells of 50 cm was created in the Z direction from 24 to 40 m. A total of 3.414.528 cells are generated. The cladding of the walls is made of a concrete panel with a thickness of 25 cm. The glass surfaces are 15 mm thick. The terrain has two flat planes with an 8 m difference in altitude. The warehouse is located on the higher ground (west side), where there is no vegetation. The flat ground has an extension of 37 x 36 m^2 and an elevation of 8 m above the bottom level (east side). The ground area covered with grass is 20 x 36 m^2. A slope of 46 º (*i.e.*, 80 %) is considered. Grass and nine trees, having a height of 15 m and a girth of 1.5 m, are positioned on the slope. The wind is a critical parameter and was considered in the model, using different wind speeds aiming to assess its influence on the fire behaviour. The wind was modelled using the Monin-Obukhov (Vanella et al. 2021) similarity theory, considering neutral stability with an Obukhov length of 1000000 m and a Davenport-Wieringa roughness length classification of 0.03 (classification: open; grass prairie, farm fields, tundra, airports, heather) (McGrattan et al. 2021). For the detailed case study, the following wind speeds were assessed: 4.15 m/s, 5.80 m/s and 6.7 m/s.

To assess the impact of the forest fire in the structure, aiming to easily transfer data from the fire model to the heat transfer model and mechanical model and understand heat transfer to solids, several Adiabatic Surface Temperature (AST) devices were used. The AST concept is useful to calculate temperatures in fire-exposed structures (expressing the thermal exposure of a surface).

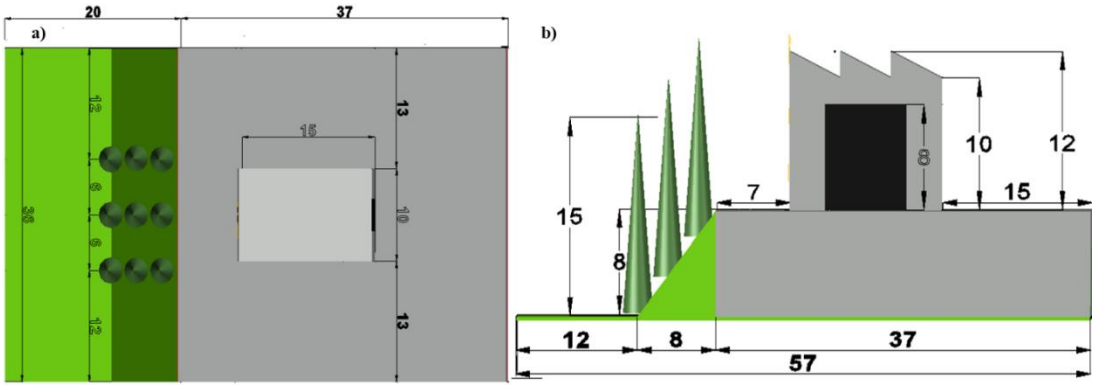

Figure 1 – Schematic representation of the selected case study. a) Top view. b) Lateral view.

3. Results

3.1. Calibration of single-burning trees

The previously described modelling strategies and assumptions provided accurate estimations using a more refined mesh size of 10 cm, but with significantly higher needs in terms of computational resources. The comparison between experimental and numerical results is depicted in Figure 2. The peak mass loss monitored in the experimental test of the Douglas-fir tree with 2 m (moisture of 14%) was 0.417 kg/s, whereas the numerical model provided an estimation of 0.409 kg/s. The results show an excellent agreement, hence enabling additional parametric studies. Regarding the case of a tree with 5 m (moisture of 26%), as depicted in Figure 2b), the peak mass loss rate was 1.90 kg/s in the experimental test and 2.03 kg/s in the numerical simulation considering a mesh size of 10 cm (showing a difference of less than 7%).

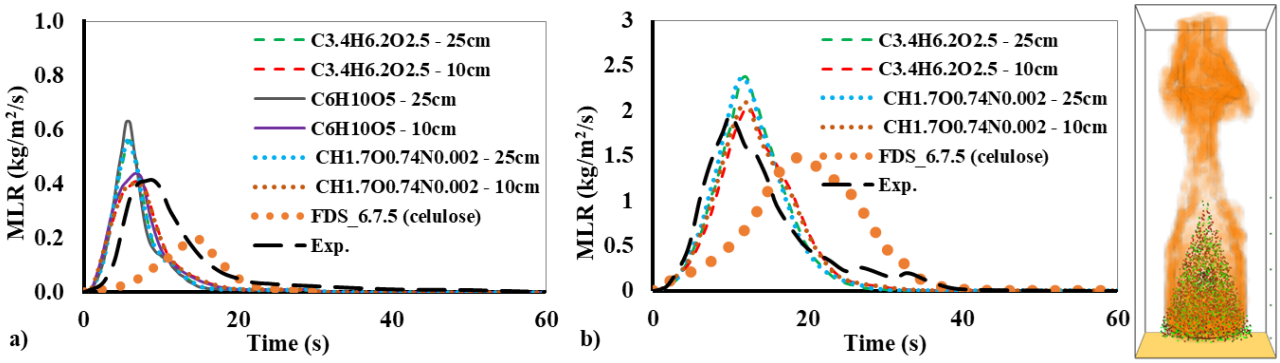

Figure 2 - Calibration of the numerical models against single burning Douglas-fir trees. Mass loss rate comparison. a) Tree with 2 m with a moisture content of 14%. b) Tree with 5 m with a moisture content of 26%.

3.2. Case study

Figure 3 shows values referring to Radiative Heat Flux obtained in the investigated scenario. Two quantities are displayed, F and R, respectively from the façade and the roof, considering three different wind speeds expressed in m/s (4.15, 5.85 and 6.70). Figure 4 depicts the obtained Adiabatic Surface Temperatures (AST) at different locations.

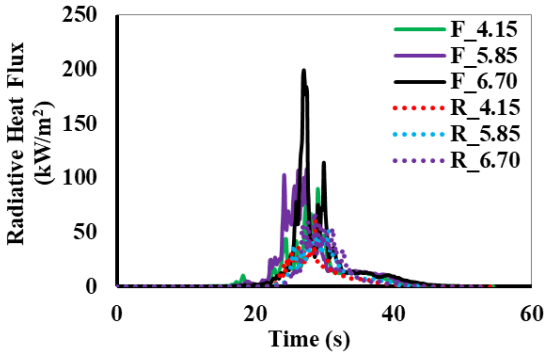

Figure 3 – Radiative Heat Flux as a function of the adopted wind speed.

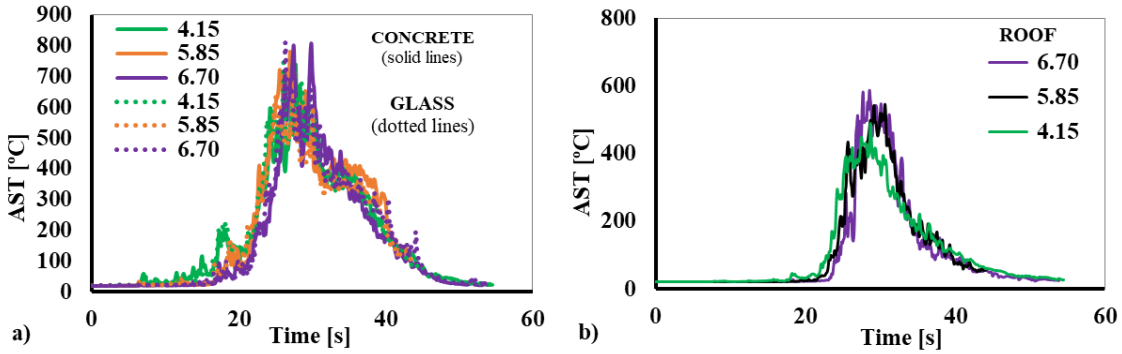

Figure 4 – Adiabatic Surface Temperatures at different locations of the building as a function of wind speed. a) AST in concrete and glass. b) AST in the roof.

The highest values are obtained on the façade (around 200, 108, and 90 kW/m^2 respectively, for 6.70, 5.85 and 4.15 m/s). The higher values were obtained when the higher wind speeds were considered, which caused a greater deflection of the flames. The average maximum value of the radiative flux measured on the roof was about 60 kW/m^2.

AST temperatures on concrete and glass (placed on the façade) and on the roof are depicted in Figure 4 a) and b), respectively. All the curves in Figure 4 a) are very close. For concrete, the peak value was 806ºC, and for glass, it was 813ºC. Both values were reached for a wind velocity equal to 6.70 m/s. Figure 4 b) shows that the difference between the maximum peak values is 100ºC, with the highest value of 587ºC with the wind blowing

at 6.70m/s. The obtained information allows coupling CFD results with finite element software, enabling the mechanical analysis of buildings in the WUI and consequently the analysis and design of fire-resistant and resilient buildings.

4. Conclusions

Fire spread mechanisms from wildfires to the built environment are complex phenomena that still require extensive research, especially when related to the behaviour of firebrands and their interaction with structures (different levels of vulnerability of structures may lead to new secondary fires). However, existing tools already show the potential for further developments for a better understanding and more accurate quantification of fire exposures in the WUI. This will lead to relevant developments in terms of new design methodologies for buildings in the vicinity of forest areas incorporating Performance-based principles.

In this study, numerical models were developed and calibrated against experimental results, enabling new parametric studies focusing on the relevant heat transfer phenomena from wildfires to the built environment. Wind speed was one of the key parameters investigated. Its impact on the radiative heat flux and AST was assessed and reported. For the selected case study, the higher the wind speed the higher the incident radiative heat flux and AST in the structure.

Further studies on firebrands and new mathematical models must be developed to better simulate their behaviour and interaction with surrounding infrastructures.

Abstract

Wildland fires are frequent events worldwide, particularly in the European-Mediterranean region, USA, and Australia. These fires have been more frequent and intense in recent years due to climate changes and may cause significant damage, especially when reaching theWildland-Urban Interface (WUI) areas. The presence of liquefied petroleum gas (LPG) cylinders may cause severe events in WUI areas, as occurred in Portugal during the large wildfires of 2017, which could have been avoided if the cylinders were protected. Devices for protecting the parts of houses under WUI fire were previously presented, but a protective device for cylinders was not. In this work, a protective device for LPG cylinders made with a thin fabric with an aluminum coating on the external face was tested in laboratory and field conditions. The cylinder and the fabric were equipped with thermocouples and heat flux sensors attached to their surfaces. The tests showed that the device gave effective protection to the cylinder, decreasing the radiative heat flux that reaches it and keeping it in a safe condition when exposed to a fire; consequently preventing extreme behavior such as an explosion.

1. Introduction

Wildfires cause huge socio-economic damages, particularly when they occur in Wildland-Urban Interface (WUI) areas. These fires are becoming more frequent and severe in recent years due to climate change (Barbosa et al., 2022; Oliveira et al., 2020; Pastor et al., 2020; D. X. Viegas et al., 2021). Liquefied petroleum gas (LPG) cylinders are widely used in many countries for different domestic purposes, such as cooking, heating water, and keeping homes warm (Heymes et al., 2013; Scarponi et al., 2020) . Given the fact that the majority of rural WUI areas do not have a gas distribution network, the presence of mobile gas cylinders near each house is common. When a wildfire occurs nearby, the cylinders become a relevant hazard for the people and structures because of the enormous amount of energy stored.

Accidents related to LPG cylinders have been registered in Portugal during at least five large fires and in other countries (Table 1). Regarding the effects caused by an LPG cylinder's explosion, experimental tests with an LPG cylinder were carried out by other authors (Stawczyk, 2003; Tschirschwitz et al., 2017): the flying projectiles could reach up to 300 meters from the initial position; the overpressure presented high values at distances shorter than 10 meters from the explosion. These effects may jeopardize the safety of persons and structures in the surroundings.

Table 1: Summary of events related to LPG stored at WUI

id	Place	Type	Year	Event	Reference
1	Quinta do Colaço, Portugal	Cylinder	2015	BLEVE	(Almeida, 2015)
2	Funchal, Madeira, Portugal (2 cases)	Cylinder	2016	BLEVE	(Barbosa et al., 2022; Caballero et al., 2019; Scarponi et al., 2020)
3	Calabassas, California, USA	Domestic tank	2016	Jet fire	(Scarponi et al., 2020;Bartholomew, 2016)
4	Benitatxell, Spain (2 cases)	Domestic tank	2016	Jet fire	(Scarponi et al., 2020; Caballero et al., 2019)
5	Louriceira, Portugal	Cylinder	2017	BLEVE	(Viegas et al., 2017)

6	Oliveira do Hospital, Portugal (2 cases)	Cylinder	2017	BLEVE	(Barbosa et al., 2022; Viegas et al., 2019)
7	Vale do Laço, Portugal	Cylinder	2017	BLEVE	(Viegas et al., 2019)
8	Balsa, Portugal	Cylinder	2017	BLEVE	(Viegas et al., 2017)
9	Mati, Greece (2 cases)	Domestic tank	2018	Jet fire	(Scarponi et al., 2020)
10	Llutxent, Spain	Cylinder	2018	Jet Fire	(Caballero et al., 2019)

Protective devices were presented to protect house walls and roofs in a WUI fire case (Barbosa et al., 2022; Takahashi, 2019; C. Viegas et al., 2021) . However, the LPG cylinders are commonly placed outside of the houses as a safety recommendation. Thus, cylinders should also be protected to avoid accidents.

To fill the gap related to the LPG cylinder's protection, this study presents a light and cheap protection for LPG cylinders capable of keeping them in a safe condition when exposed to WUI fires (Barbosa et al., 2022; Takahashi, 2019; C. Viegas et al., 2021).

2. Materials and Methods

2.1. The protective device

The protective device (PD1) was manufactured with two main parts. The first and most external one is made with a fabric manufactured with fiberglass with an aluminum coating on the external face to decrease the radiative heat flux. The fabric is classified "A" (non-combustible) according to the European fire classification for construction products (EN 13501). The second one is a structure made with a square metal tube, with geometry the same as a cube, with opened faces and a handle on top used for moving. On one face, near the bottom, there is a small vent square of 15 x 15 cm to pass the gas tube. This tube was wrapped in the fabric. The goal of the protection device is to reduce the heat flux that reaches the cylinder and prevent the LPG stored in the cylinder from getting warm. It is an alternative system for people living in rural areas without access to an industrialized or commercial protection system; it is easy to be built, cheap, light, mobile, and ergonomic. The protective device was built for cylinders of 11 kg of propane or 13 kg of butane and manufactured in accordance with European codes (EN 12245:2009+A1; EN 1442). It has the following dimensions: 65 cm in height and 45 cm in length and width. The cost of the protection was 56 Euros, and the total system weight was 6.4 kg.

2.2. Laboratory tests

Seventeen tests were carried out (Table 2), sixteen at the laboratory and one in the field. The laboratory tests were performed in the Forest Fire Research Laboratory (LEIF) in Lousã, Portugal, at four different flame distances, to evaluate the protection efficiency related to the heat flux at flame distances similar to those found in fires near rural houses. The field test was aimed at evaluating the cylinder protection in a real fire scenario and validating the laboratory tests.

Table 2: Summary of the tests

Test	Reference	Distance (m)	Content Moisture (%)	Room Temperature (ºC)
1	F25-1	0.25	16	24.3
2	F25-2	0.25	11.5	19.7
3	F25-3	0.25	11.5	19.5
4	F50-1	0.5	14.3	15.1
5	F50-2	0.5	11.5	19.7
6	F50-3	0.5	11.5	19.7
7	F75-1	0.75	16	25.6
8	F75-2	0.75	11.5	19.7
9	F75-3	0.75	11.5	19.7
10	F100-1	1	16	22.5
11	F100-2	1	10	20
12	F100-3	1	10	19.8
13	Ref25	0.25	16	11.9
14	Ref50	0.5	16	12

15	Ref75	0.75	16	11.6
16	Ref100	1	16	11.8
17	PSS	surrounded	40	21

The cylinders were placed at four different distances ”D”. These distances from the flames used were 0.25, 0.5, 0.75, and 1 meter. For each test were used 10 kg of shrubs. Shrubs were used according to previous studies placed (Pinto et al., 2017; Rodrigues et al., 2019; D. X. Vegas et al., 2021; Viegas et al., 2006), and it is the same fuel present in the field test. This fuel was in a basket with a volume of 1 m^3. Reference tests with the cylinder and without protection were performed to obtain the heat flux and temperature on the cylinder’s surface.

The cylinders were equipped with the temperature and heat flux sensor IHF01 Hukseflux attached to the external surface (FI 1, TI 1) halfway up the cylinder’s height; the same was attached to the external surface of the fabric (FI 2, TI 2) (Figure 1). Two thermocouple type K were used; the first thermocouple was attached to the floor at 10 cm from the fuel basket (TI 3); and the second was attached to a wall surface, far from the influence of the flame (TI 4). The flux sensors were connected to the model 9211 (±80 mV) from National Instruments (NI), and it was plugged into the chassis 9174, also from NI. These instruments allow for the continuous measurement of the signal from the sensor with a frequency of 1 Hz, being able to load and process the data directly to a computer. The thermocouples were connected to a model 9213 from NI.

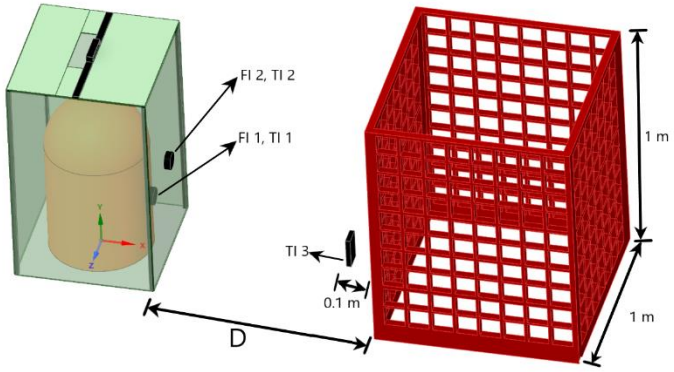

Figure 1- Schematic drawing of laboratory test: protective device at the four distances “D” from the fuel basket, and the instrument’s position on the cylinder’s surface (FI 1, TI 1), fabric’s surface (FI 2,TI 2), and thermocouple 3 – credit Barbosa et al. (2022).

2.3. Field Test

In the field test, the instrumental apparatus used was the same as in the laboratory tests. The field test was performed on a slope of 30% covered by shrubs with less than 50 cm in height and an average moisture content of 40%. The LPG cylinder was covered by the protective device and surrounded by shrubs. The ignition was made on the bottom of the hill (Figure 2 b).

(a) (b)

Figure 2- (a) Laboratory teste, and (b) field test

3. Results and discussion

3.1. Laboratory tests

A significant difference was found (Figure 3) related to the heat flux that reached the cylinder´s surface and the fabric´s surface, showing that the high level of heat flux decreased, and this factor is decisive in keeping the conditions safe in a fire scenario. If there is no high heat flux reaching the vessel, the fluid pressure and temperature will not be high enough to produce an explosion.

The flux sensor attached to the surface cylinder showed values with no significant changes. For the test at 0.25 m from the flames, the difference related to the heat flux that reaches the cylinder´s surface and the fabric´s surface was up to 10 kW· m^{-2} (87%), which shows that the protection device works even at a short distance from the flames. The heat flux registered in the reference tests (Ref) without protection, and the flux on the cylinder´s surface under protection (Cylinder), show a significant difference in the flux that reaches the cylinder.

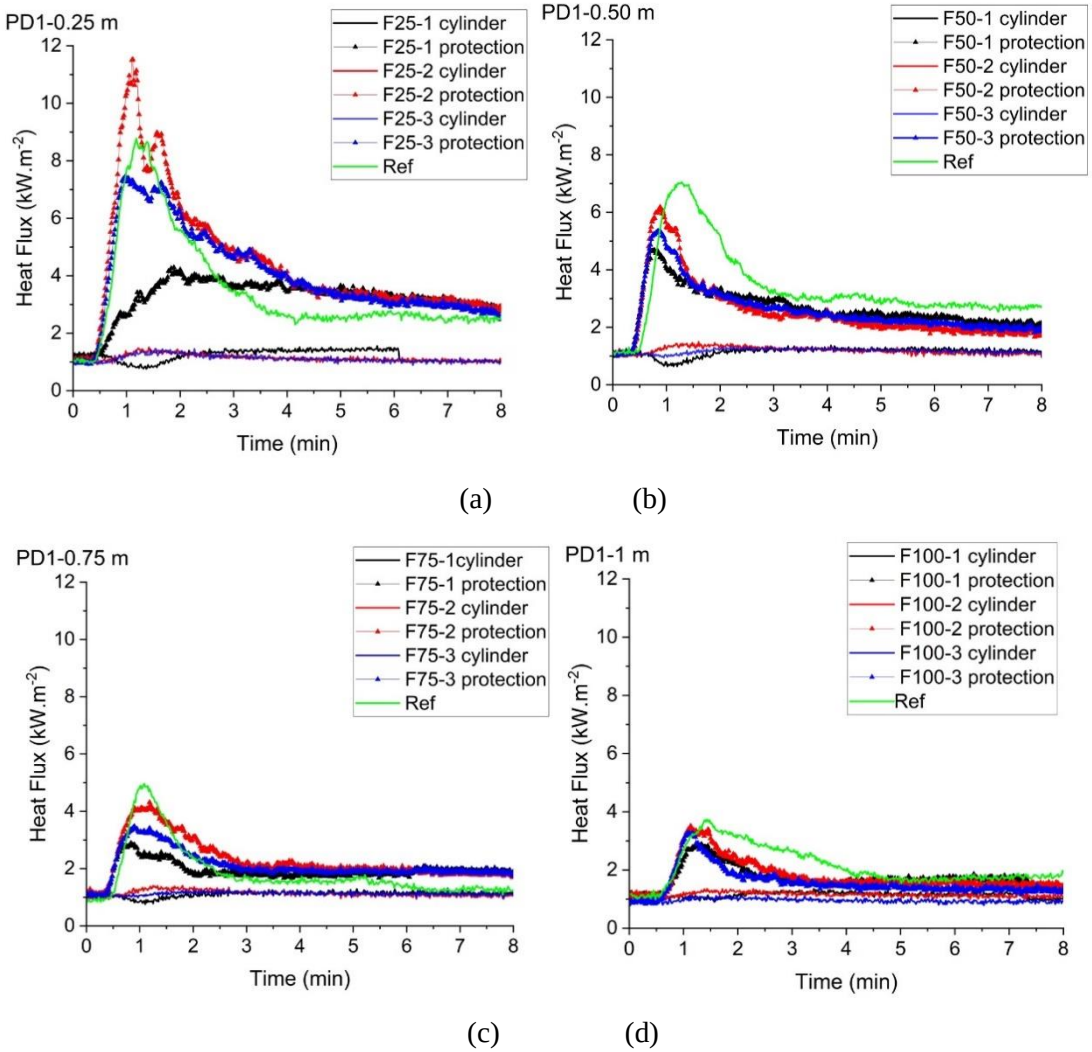

Figure 3- Heat flux on the protection, cylinder, and reference tests at (a) 0.25, (b) 0.50), (c) 0.75, and (d) 1 m from the basket fuel

In all tests with the protective device and during the time of fire exposure, the cylinder surface temperature remained close to the laboratory environmental temperature (Figure 4). Thus, the LPG cylinder was not heated and stayed under safe conditions, even when the fabric was reached by the intense heat flux of up to 12 kW· m^{-2} .

Figure 4 shows the temperature on the cylinder´s surface (Cylinder) and the temperature on the fabric´s surface (Protection). There is a great difference between the cylinder and fabric surfaces, reaching 80 °C. The cylinder´s surface temperature was kept at safe values, close to the laboratory temperature, and below the temperature

needed to cause high pressure and open a pressure relief valve (26 bar). The temperature registered in the reference tests (Ref) without protection and the temperature on the cylinder´s surface under protection (Cylinder) shows a significant difference in the cylinder´s temperature, up to 80 °C (Figure 4).

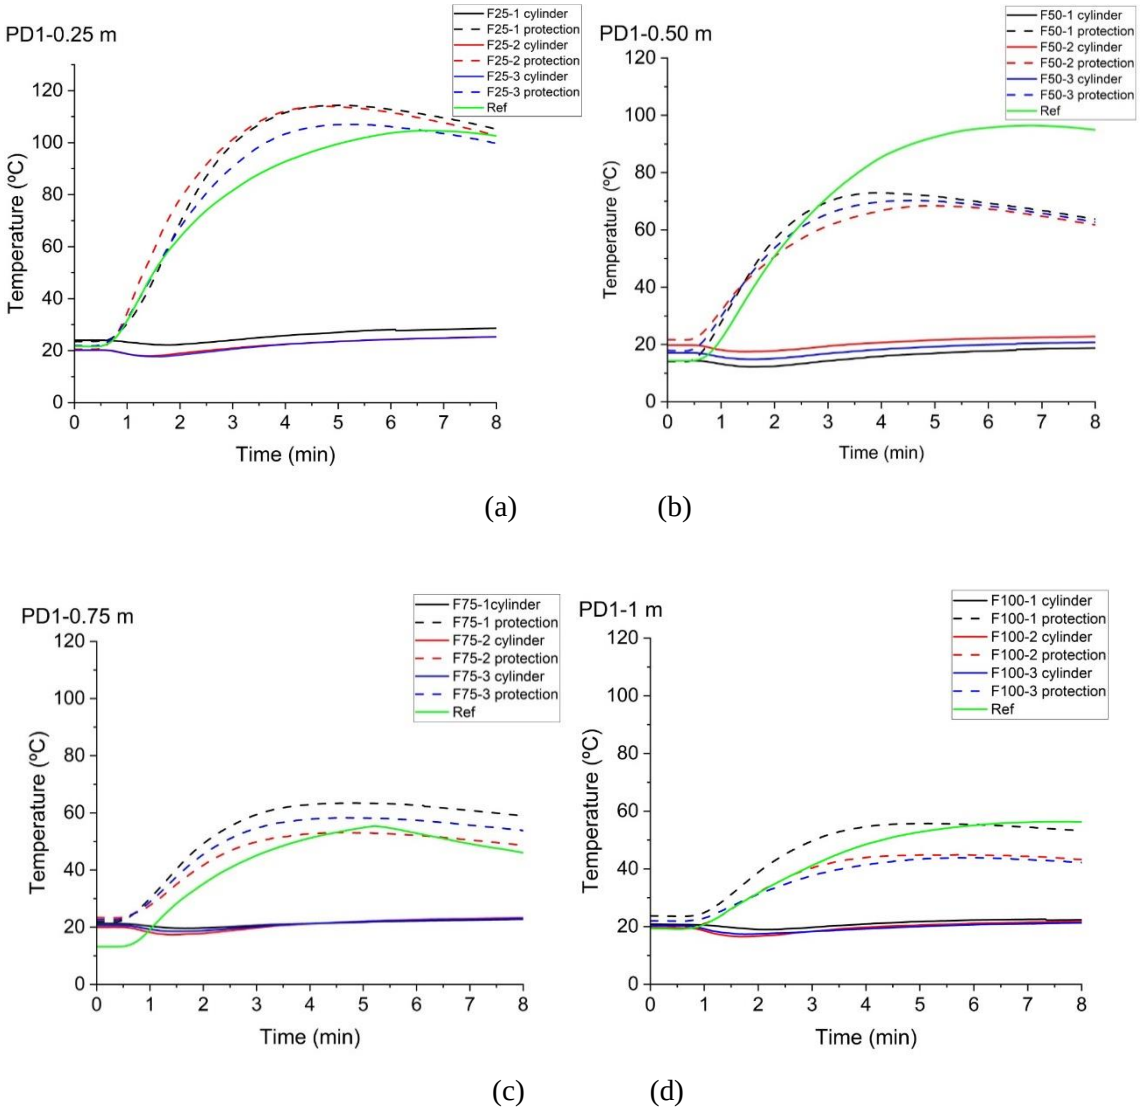

Figure 4- Temperature profile in the laboratory, on protection, cylinder, and reference tests at (a) 0.25, (b) 0.50), (c) 0.75, and (d) 1 m from the basket fuel

3.2. Field Test

In the field test, the behavior of the cylinder and protection was similar to the laboratory tests. There was a large difference between the temperatures of the cylinder´s surface and the fabric's surface, and the same occurred for the heat flux (Figure 5). On the outer face of the protection, the thermal radiation peak was 7 $kW \cdot m^{-2}$ and the peak temperature was 174 °C; on the face of the cylinder, the radiation peaked at 2.5 $kW \cdot m^{-2}$, and the surface temperature had a maximum of 51 °C.

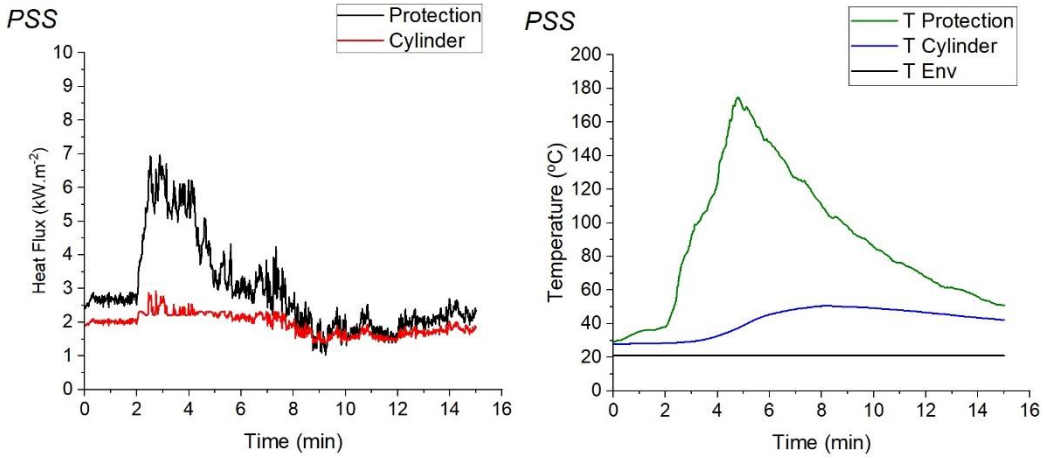

Figure 5- Field test (PSS): (a) Heat Flux and (b) temperatures on the surfaces of the protection and cylinder

4. Conclusion

WUI fires are frequent events, and they may cause accidents related to LPG stored. In this work, the efficiency of a protective device manufactured in an insulating fabric with a reflective external surface to cover an LPG cylinder and block the heat flux when a WUI fire occurs was assessed.

Laboratory and field tests were carried out with the protective device at different distances from the fire to find the block rate of the heat flux and determine if the protective device works in a real fire event.

The protective device could block up to 87% of the heat flux and keep the cylinder's temperature close to room temperature even under high heat flux and at a short distance from the flame.

Regarding the accidents mentioned, the protective device tested in this work could have avoided these burst vessel cases. It shows the importance of a protection system and how positive its use can be in avoiding the heating of the fluid, and hence the material rupture, decreasing the probability of extreme events, such as a BLEVE. The proposed protective device is an alternative to prevent accidents related to LPG cylinders in WUI fires.

Mega fires; PyroCb; Meso-NH model; ForeFire model.

Abstract

The development of PyroCumulonimbus (PyroCb) clouds during mega fire events has high impact in the evolution of the fire fronts and have been observed more frequently in the last years. In 2017, Portugal was affected by several episodes of extreme wildfires with associated cloud systems. The present study aims to investigate the development of pyro-convective activity during the Pedrógão Grande episode. The study used the reference fire propagation deduced from the official investigation (forced fire) as well as reference boundary condition from atmospheric analysis to simulate the coupled simulation with a mesoscale atmospheric model at high temporal and spatial resolution. The Meso-NH model has been configured into three nested domains with horizontal resolutions of 2000 m, 400 m and 80 m. The emission of heat and vapour into the atmosphere was made using the ForeFire model. The results highlight the importance of the use of cloud resolving models configured with very-high spatial and temporal resolutions for representing the development of phenomena associated to pyro-convective activity, namely those occurring in the micro-scale from the cloud microphysics processes, like very-localised microbursts.

1. Introduction

Extreme wildfires are frequently associated with strong convective processes due the heat and moisture released from the fires. Such a fire-atmosphere coupling environment lead the formation of convective clouds, also referred as PyroCumulus (PyroCu) or PryroCumulonimbus (PyroCb) clouds. The first are more common and can form as relatively small clouds above fire plumes. The second can be observed in plume dominated wildfires characterized by an intense convection column, above which a cloud resembling towering cumulonimbus (Cb) may form. The microphysics processes, as condensation of moisture in the fire plume can enhance convection by releasing latent heat, for example. Their updraughts manage, sometimes, to penetrate into the stratosphere. PyroCb activity can have a significant impact on fire behaviour through feedback processes between the atmosphere and the fire, including the increase of burn and spread rates by strong variations in surface wind direction and speed associated with convective inflows and downdraughts, and ignition of new fires by PyroCb lightning (e.g., Tory et al., 2018; Dowdy et al., 2019).

In 2017, an extreme fire season affected Portugal. The first deadly event occurred in June in the region of Pedrógão Grande and caused more than 60 fatalities (e.g., Couto et al., 2020; CTI Report, 2017). In mid-October, extreme wildfires spread across the Central region of Portugal mainland resulting in 48 fatalities (Guerreiro et al., 2018). The present study aims to investigate how a wildfire can influence the occurrence of violent pyro-convective activity.

2. Methodology

In general, the atmospheric models do not account for fire-atmosphere interactions. To investigate the pyroconvective activity, a numerical simulation was run with the Meso-NH model coupled to the ForeFire model. The Meso-NH is a non-hydrostatic model able to represent the atmospheric motions in different scales, and implemented with a rather complete parametrization package of physical processes in the atmosphere (Lac et al., 2018), whereas ForeFire is a fire propagation model (Filippi et al., 2009, 2018). The present study considers the wildfires occurred in Pedrógão Grande and Góis on June 17, 2017. The fire propagation map was constructed based in the fire propagation map presented in the CTI Report (2017).

In order to resolve the development of the fire/weather system, the two-way nesting capability of the Meso-NH model was used with three nested domains (Figure 1). Several simulations were made aiming to obtain the more realistic scenario of the event. The horizontal grid size is 2000 m for the outer domain covering 600 km × 600 km. The inner computational grids have grid increments of respectively 400, 80 m, covering a total area of respectively 120 km × 120 km, 24 km × 24 km for the innermost model. The time step is 10 s for the outermost model and decreases to 2 s, 0.5 s for the finer models. Initial and lateral boundary conditions for the outer domain are provided by ECMWF analysis, with updates every 6 h. The simulation with the coarsest resolution began on 17th June 2017 at 0600 UTC, with a progressive downscaling up to the finest resolution beginning at 1300 UTC. The vertical resolution is identical for all the nested domains, with 50 levels up to 20 km and a first level above the ground at 30 m height. All the nested models used the one and a half order closure turbulence scheme with a prognostic TKE: the two finest resolution domains use the 3D version of the scheme, while the first one only considers the 1D version, neglecting the horizontal turbulent fluxes.

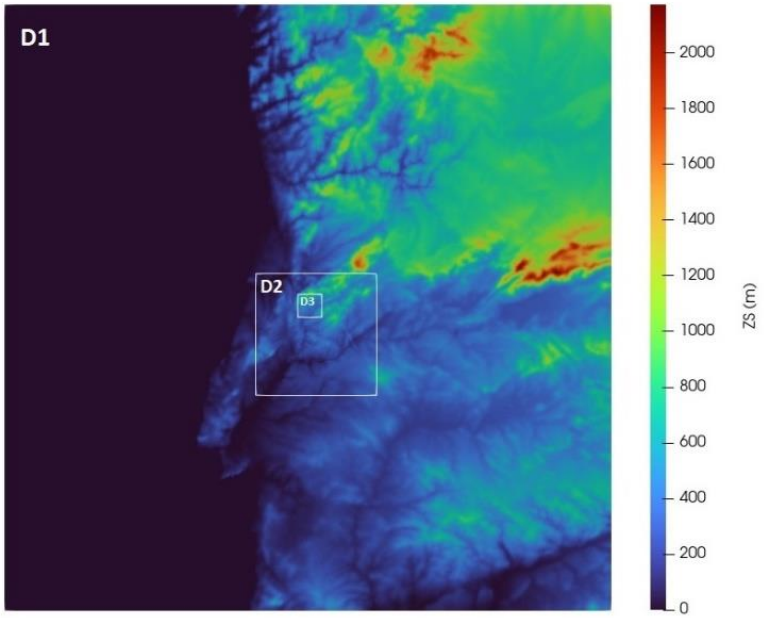

Figure 1- Meso-NH configuration with orography obtained from the SRTM database.

3. Results

Figure 2 shows the fire line representing the fire front propagation as well as the strong fire-atmosphere interaction, with the fire leading to intense convective updraughts. The role of the fire in this episode is presented by the development of a deep convective cloud. In the figure, the plume is associated with a PyroCb cloud, which result from condensation inside the plume. Such a cloud is represented by five hydrometeos species (e.g., cloud droplet, raindrops, graupel, snow or aggregates, pristine ice crystals). The convection was likely enhanced by the strong wildfire activity and penetrated into the higher troposphere above 10 km altitude. The extreme pyro-convective activity was also verified in the simulation by the development of microbursts originated from the PyroCb cloud (not shown).

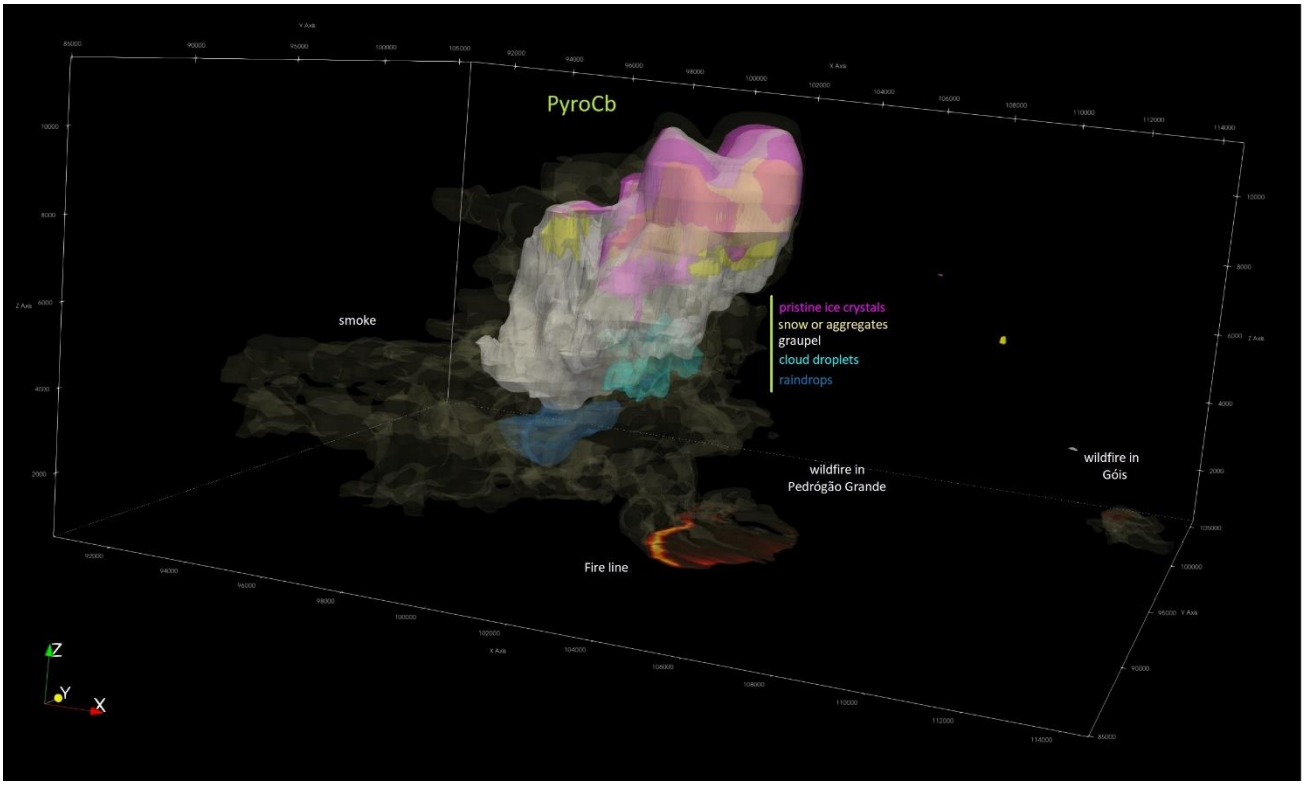

Figure 2- Anatomy of the PyroCb cloud simulated in the Pedrógão Grande mega fire episode. Animation available online at https://youtu.be/vn7PaFh88ss.

4. Conclusions

Fire spread associated with extreme pyro-convective activity is currently highly unpredictable and difficult to suppress. In this study, the findings show the benefits of the use of cloud-resolving models in order to assess the potential for dangerous fire conditions associated with pyroconvection. Moreover, the preliminary results indicate that the model, when configured in high temporal and spatial resolution, is able to represent the pyro-convective plume height from a wildfire and the main processes associated to the interaction of the fire with the atmosphere. In the Pedrógão Grande mega fire event, the violent fire-driven convection manifested as a PyroCumulonimbus cloud. It is important to note that one of the goals was to obtain a reference high resolution (10s, 80m) weather analysis for the reference fire line behaviour from the official report, so fire is forced in the simulation (the impact of the atmosphere in the fire front evolution is not represented).

The study is on-going and will help us to better understand pyro-convective events, namely the atmospheric processes in a micro-scale context, and also in terms of fire behaviour to associate local wind and temperature and humidity to the fire line evolution and local rate of spread. Overall, an improved understanding of these events is important for a range of fields related to the pyroconvection and extreme fire events.

Embers, Firebrands, WUI, ignition, building damage, safety, accumulation

Abstract

Windblown embers, also known as firebrands, can be generated in large numbers during wildfires and ignite fuels as far as kilometers away from their origin. Firebrands are often cited as the leading cause of building wildfire ignition in the wildland-urban interface. Building ignition via firebrands can occur directly, by landing on or inside the building, or indirectly, by igniting adjacent fuel and creating adjacent flame exposure. Studies have investigated firebrands generation from various fuels, wind-driven transport, and ignition mechanisms on different materials and building features. Less research has been conducted on how firebrands deposit and accumulate around buildings; this knowledge is critical in designing buildings safer to firebrand ignition. Here, we address this need and computationally investigate firebrand landing and accumulation in front of obstacles. We present work on a computational fluid dynamic Fire Dynamics Simulator (FDS) model simulating the published experimental data by Suzuki and Manzello measuring the firebrand accumulation region in front of a vertical wall under firebrand exposure generated by the NIST Dragon and varying wind speeds (4, 6, 8, and 10 m/s) (Suzuki and Manzello, 2017). T he simulated firebrand accumulation areas in front of the wall are compared to the experimental observations. The wall obstacle dimensions and wind speeds are varied; and the accumulation patterns and sizes are studied to define the critical design parameters affecting firebrand accumulation. Here we present the current progress, simulation results, and future vision for this research project.

1. Introduction

Wildfires pose a significant risk to life and property, and can cause extensive damage to residential communities. Understanding how wildfire spreads is crucial to mitigate this risk. There are three main wildfire spread pathways: flame radiation, direct flame contact, and firebrand ignition. Embers more generally describe small and hot carbon-based fuel particles; firebrands specifically describe airborne burning particles, which travel through wind-driven transport (Babrauskas, 2018). The type of fuel, flames, and surrounding conditions impact these particles' size, shape, and burning conditions. When firebrands land, they may ignite the target fuel they have contact with, this process is called spotting and the new ignited fires are called spot fires. Firebrand ignition of spot fires includes numerous sub-processes occurring on various spatial scales. Firebrands are first generated by flaming fuel, then transported in the wind, and lastly land of target fuel, possibly igniting it; these processes are illustrated in figure 1 and figure 2. Here we present Fire Dynamics Simulator (FDS) simulations of firebrand exposure of a simple geometric obstacle, a rectangular wall perpendicular to wind flow, under varying wind speeds and varying wall thicknesses. Results are compared and validated with published experimental results.

Figure 1: Schematic diagram of the five subprocesses of wildfire firebrand building ignition and damage: 1) firebrand generation, 2) wind-driven transport, 3) landing and accumulation, 4) building ignition and 5) fire spread.

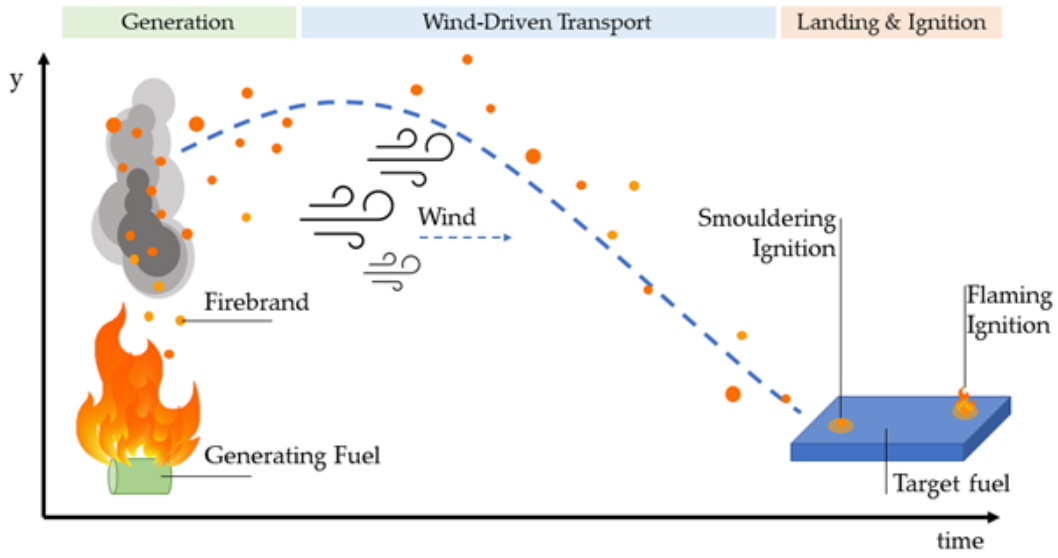

Figure 2: Schematic diagram of firebrand generation, wind-driven transport, and landing and ignition on target fuel, adapted from (Fernandez-Pello, 2017).

1.1. Firebrand Generation and Transport

Firebrands can be generated from a variety of fuels including both vegetative and urban fuel. Extensive research has been produced characterising the firebrand characteristics generated from specific fuels; including Douglas-fir trees (Manzello, Maranghides and Mell, 2007), full scale burning buildings (Suzuki et al., 2012), different roof materials and designs (Waterman, 1969), prescribed fires (El Houssami et al., 2016; Filkov et al., 2017) and actual wildland-urban interface fires (Manzello and Foote, 2014). Figure 3 is a photograph from the 2018 Delta fire in California, and shows the high number of firebrands which can be produced under certain wildfire conditions. Characterisation parameters include, mass and size distribution of firebrands, number of firebrands, projected area of landed firebrands; researchers stress the need for more data of firebrand characterisations from real wildfires and wildland-urban interface fires. The physical firebrand characteristics impact the forces acting on them during wind-driven transport, and therefore their trajectory; their physical and chemical characteristics, and initial conditions determine the type of combustion.

Figure 3: Firebrand shower during the 2018 Delta Fire in the Shasta-Trinity National Forest, California, USA. Photo courtesy of Noah Berger/Associated Press (noahbergerphoto.com). Photo shows numerous airborne firebrands and flames on the grass appears to be ignited by the landing firebrands

Models describing the breakage of firebrands during generation have been developed; Barr and Ezekoye used simple mechanical breakage models coupled with thermal decomposition model which predicts the size distribution of firebrands lofted from a fractal tree which can be combine with plume models to describe the breakage, transport, and mass loss of firebrands in wildfire conditions (Barr and Ezekoye, 2013). Tohidi et.al. studied the mechanical response of wooden elements under external loading after having been heated in wildfire conditions to mimic the firebrand breakage fuel during firebrand generation (Tohidi et al., 2017).

The breakage conditions determine the initial position and conditions of the firebrand's wind-driven transport. Extensive research has been conducted in the field of firebrand transport. Transport models calculated the maximum horizontal transport (spotting) distance for different firebrand conditions: firebrand particles lofted by transitory flaming group of trees (Albini, 1979), by the persistent flaming fuel piles (Albini, 1981) by the thermal fields transporting firebrands by the wind field (Albini, 1983).

Sardoy et al. calculated the wind flow trajectories and burning rates of disk-shaped firebrands initially lofted by crown fire plumes for carrying wind speeds and fire intensities (Sardoy et al., 2007). Anthenien et.al created a numerical model describing the burning and wind transport processes for spherical cylindrical, and disk firebrands lofted by fire plumes (Anthenien, Tse and Carlos Fernandez-Pello, 2006). Detailed review papers cover and compare the many firebrand transport and combustion models developed (Koo et al., 2010).

1.2. Firebrand Landing and Ignition

Firebrands can be transported to, and land on vegetative fuel or urban fuel; spot fires can spread wildfire in the wildland and to the wildland-urban interface (WUI) igniting homes and communities. Here we consider the landing and accumulation of firebrand in front of solid obstacles mimicking building components to investigate WUI fire ignition by firebrands. There are three main general pathways for firebrand ignition of buildings:

1. Indirect ignition: firebrands ignite vegetation or combustibles near the building, the flaming fire spreads and ignite the building.
2. Direct ignition - building interior: firebrand enter the building structure through openings and ignite combustibles inside the building.
3. Direct ignition - building exterior: firebrands accumulate on the building exterior and ignite the building exterior material

Experimental research has characterized firebrand ignition conditions of various objects and materials. the NIST dragon is an experimental apparatus which creates a continuous feed of adaptable speed airflow with burning firebrands (Manzello and Suzuki, 2013). The dragon generates firebrands which match the size and mass flux distribution of real wildfire scenarios, thus allowing the experimental investigation of realistic firebrand exposure. The NIST dragon has been used to study the response of many building targets including: roofing assemblies (Manzello et al., 2010), wall sidings and eaves set ups (Manzello, Suzuki and Hayashi, 2012), decking assemblies (Manzello and Suzuki, 2014), fences (Suzuki et al., 2016). IBHS has used an adaption of the dragon to test full scale buildings in a wind tunnel under various conditions.

For a firebrand to be able to ignite spot fires, the firebrands must heat the target fuel to ignition temperature. Studies have investigated the necessary firebrand mass and temperature to ignite various materials including: structural wood (Santamaria et al., 2015), and fuel beds with varying properties, including: water content, vegetation, geographical origin (Hadden et al., 2011)(Viegas et al., 2014)(Urban et al., 2019).

1.3. Modelling Landing and Accumulation

Models calculating firebrand landing locations and distributions considering varying surrounding conditions and firebrand material and combustion properties have been developed. Such models allowed calculation of ground level mass distribution of disk-shaped firebrands for varying fire intensities and wind speeds (Sardoy et al., 2008). To investigate more specficially at firebrand landing patterns near or on buildings, and the various material fire responses possible, requires more detail. Research has started focusing on firebrand landing position and distributions, around solid obstacles resembling building constructions or building components.

Ngyugen investigated the accumulation patterns of particles resembling firebrands on different rooftop deisgns in wind tunnel experiments and found numerous complex factors, including roof design details, wind speed and wind direction, which determined where and how firebrands land and accumulate on rooftops (Nguyen and Kaye, 2021). Experiments looking at the response and accumulation patterns in front of obstacles and in between

cuboid obstacles representing inter-building distance in the WUI (Butler et al., 2017; Suzuki and Manzello, 2017; Mankame and Shotorban, 2021).Results advance understanding indirect ignition, and direct ignition of building exterior, by increasing insight on where and for how long firebrands are most likely to land under varying conditions and ignite buildings. Firebrand deposition around cubic obstacles has been modeled using Large Eddy Simulations for turbulence and Lagrangian particle tracking for firebrand trajectory (Mankame and Shotorban, 2021).

With the objective of investigating how building design parameters affect the firebrand landing and accumulation around buildings, here we use the Fire Dynamics Simulator (FDS) to model firebrand exposure and ground level distribution with varying windspeeds perpecndicular to a vertical wall of varying heights. We model the experimental set up conducted by Suzuki and Manzello in 2017, to compare results and validate this model (Suzuki and Manzello, 2017). By comparing the landing distribution of firebrands with published experimental results, and varying obstacles shapes, we comment on using models to determine the most hazardous designs and conditions for firebrand ignition in wildfire conditions.

2. Methodology

2.1. Simulation parameters

We present FDS simulations mimicking the experimental set up of a published study investigating firebrand accumulation zones in front of walls (Suzuki and Manzello, 2017). In the experiment, Douglas-fir wood firebrands are fed continuously toward a wall 7.5 m away, perpendicular to feed. The wind tunnel speed and the wall dimensions are varied to test the effect on firebrand accumulation pattern in front of the wall. The experimental set up is shown in figure 4 by a schematic diagram and photos from (Suzuki and Manzello, 2017). The area of the firebrand accumulation piles, and the distance between the pile and the wall were measured and presented. Different FDS computational domain dimensions were tested in order to minimize computational resources, without compromising result accuracy. Figure 5 presents a schematic and screenshot of the final FDS computational domain dimensions. Table 1 compares the properties of the firebrands, wind flow, and wall obstacle in the experimental investigation, and in the FDS simulation.

The wind profile, and firebrand positions are calculated by FDS, and MATLAB image analysis is used to calculate the accumulated area of firebrands. The wall size and shape is varied as in the experimental investigation: sizes 2.4 m x 2.4 m and 1.3 m x 2.4 m were first simulated. The wind speed was also varied as in the experimental investigation; wind speeds 4, 6, 8, and 10 m/s are considered. Simulations with varying wall length and width, and additional solid obstacles will be conducted when the model is validated.

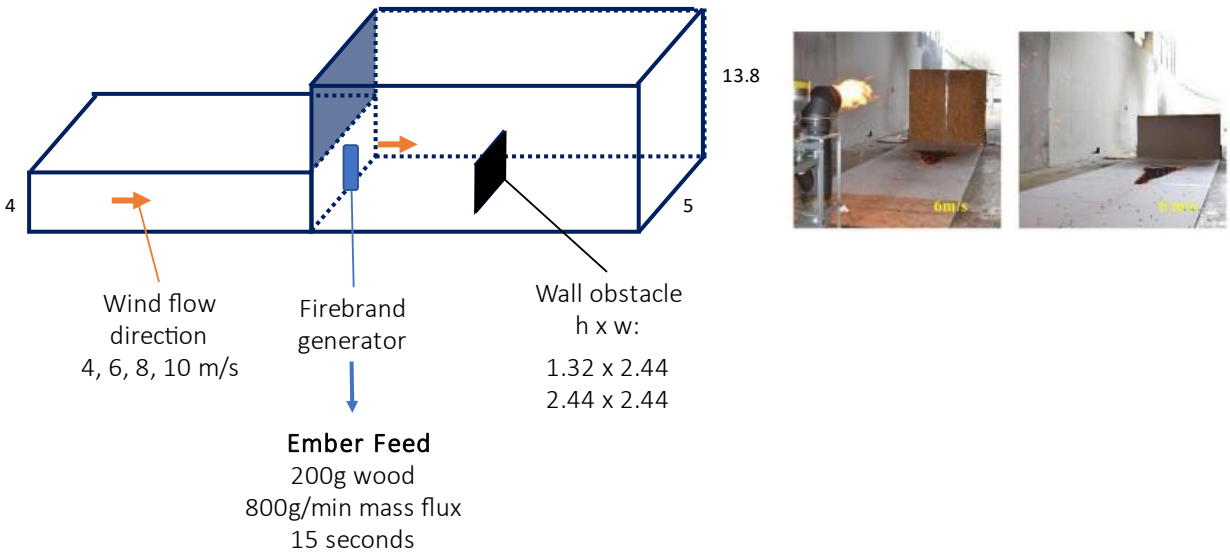

Figure 4: (left): Schematic of wind tunnel, with dimensions in meters, and experimental set up (right:) Photos of experimental set up from (Suzuki and Manzello, 2017)

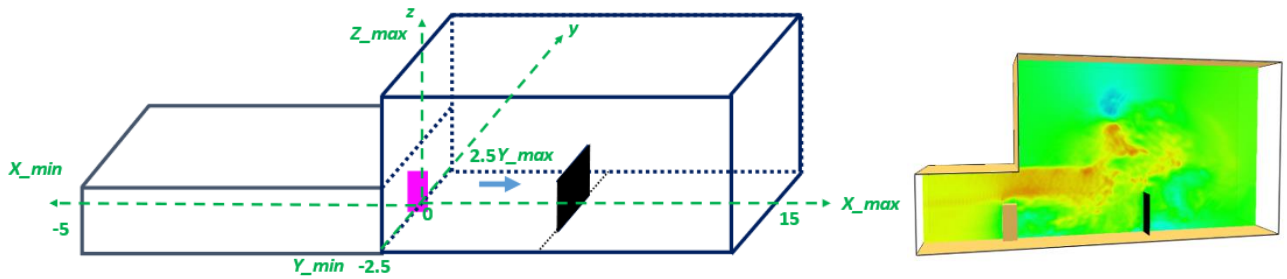

Figure 5: (left): Schematic of FDS computational domain (right:) FDS computational domain with wind speed of 4 m/s at y=0 and t=5 seconds

Table 1: Properties and parameters of the firebrand particles, wind speed, and walls, tested in the experimental investigation, and simulated in this FDS simulation

	Experiment: (Suzuki and Manzello, 2017)	**FDS simulation**
Firebrand *[Size, shape, mass flux, material]*	7.9 mm x 7.9 mm x 12.7 mm Cuboid 17.1 g/m^{2}s Douglas-fir wood	D = 8 mm, L = 13.5 mm Cylindrical 17 g/m^{2}s Includes particles with both wood and char densities to simulate range of possible particle weights (further physical and chemical properties are defined in model)
Wind speed	4 m/s, 6m/s, 8m/s, 10m/s	4 m/s, 6m/s, 8m/s, 10m/s
Wall *[Size]*	2.44 m x 2.44 m 1.32 m x 2.44 m	2.4 m x 2.4 m 1.3 m x 2.4 m

2.2. Particle Tracking and Turbulence Model

FDS uses Lagrangian particle tracking to calculate particle position and trajectory in the computational domain, and Large Eddy Simulation (LES) to calculate turbulent flow. By default firebrand particles are modelled as cylindrical particles. Simulated particles do not experience thermal degradation, to mitigate this limitation particles with both unburned wood densities, and wooden char densities are introduced to simulate a spectrum of possible particle densities. Lagrangian Particle Tracking method computes a force balance on each singular particle based on Newton's second Law, given in Equation 1. The momentum transferred from particles to surrounding gas is calculated in FDS by Equation 2; and the acceleration of the particles is solved via Equation 3. Where m_p is the particle mass, u_p is the particle velocity, f_b is the momentum transferred from particles to gas, ρ_f is the fluid density, C_D is the drag coefficient, u_f is the fluid velocity, ρ_p is the particle density, A_p is the particle surface area, g is the gravitational constant and V_p is the particle volume.

$$m_p \frac{du_p}{dt} = F_{drag} + F_{bouyancy} + F_{other} \quad (1)$$

$$f_b = \frac{1}{V}\sum[\frac{\rho}{2} C_d A_{pc}(u_p - u_f)|u_p - u_f| - \frac{dm_p}{dt}(u_p - u_f)] \quad (2)$$

$$\frac{du_p}{dt} = g - \frac{\frac{1}{2}(\rho C_d A_{pc})}{m_p}(u_p - u_f)|u_p - u_f| \quad (3)$$

In FDS, turbulence is calculated with LES, with the default Deardoff model. The default near-wall model in FDS uses Wall-Adapting Local Eddy-viscosity model. All solid boundaries are set to have no slip conditions, and wind is introduced and exited in the domain via open boundary conditions.

3. Results

The modeling and data analysis of this project is ongoing. This section current results and explains the result objectives for future work.

3.1. Firebrand Accumulation Distribution

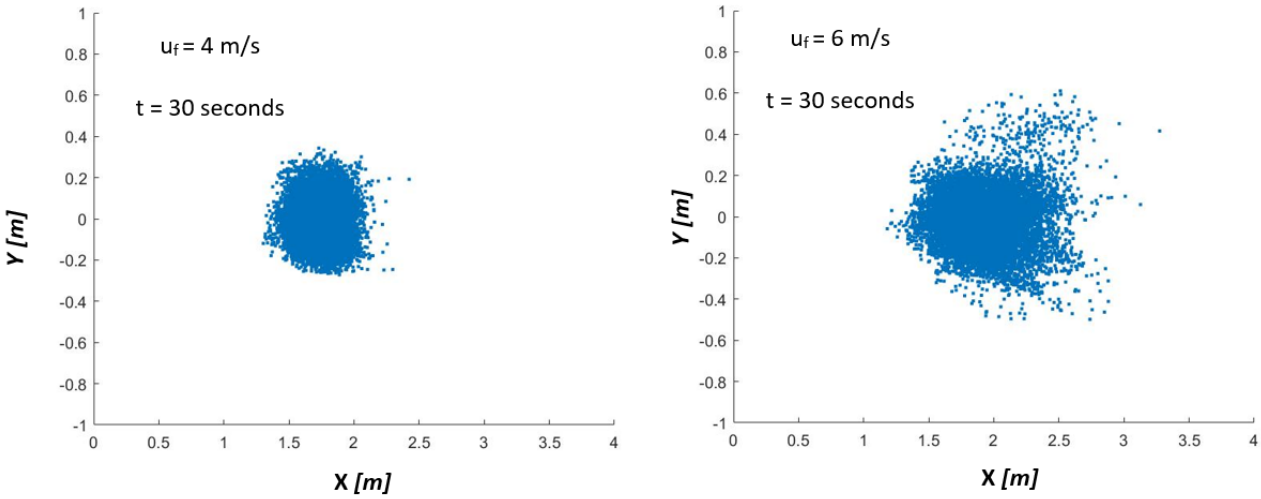

Figure 6: Particle distribution on the floor (z = 0) after 15 seconds of firebrand exposure under 4 m/s wind (left) and 6 m/s wind (right).

Figure 6 presents the particle distribution on the floor (z = 0) after 15 seconds of firebrand exposure under 4 m/s wind, and 6 m/s wind produced in the FDS simulations. These results show that the accumulated area increases as the wind speed increases, this is the opposite trend presented in (Suzuki and Manzello, 2017). Authors are investigating which parameters are determining this disagreement in simulation results, and experimental observations; especially focusing on the solid boundary conditions of the computational domain, and the particle geometry and related drag coefficient – which have been simplified in the simulation to conserve computational resources.

3.2. Separation Distance

The distance between the firebrand accumulation zone, where firebrands land and stop moving, and the side of the wall facing the firebrand feed is measured in both the experimental investigation, and in the FDS simulations computed. For the FDS simulations, the separation distance is calculated from the final firebrand particle positions at the end of the simulations; these are graphed for each particle in for wind speed of 4 m/s and 6 m/s in figure 7. For a wind speed of 4 m/s the separation distance ranges from 5.1m to 6.2m, for 6 m/s wind the separation distance ranges from 4.2 m to 6.2m. These distances greatly overestimate the separation distances reported in (Suzuki and Manzello, 2017). Furt hermore, FDS inaccurately the trend direction of changing separation distance for changing wind speed: experimental measurement confirm that separation distances increase as the wind speed increases, while FDS calculates the opposite trend.

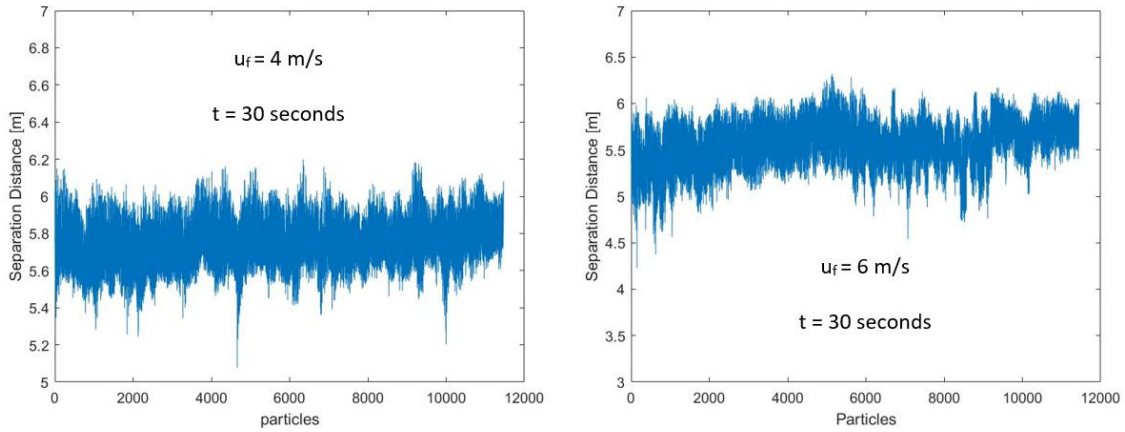

Figure 7: Separation distances between all particles at the end of the simulation (t = 30 seconds, after 15 seconds of firebrand exposure) and wall obstacle (located at x = 7.5m), for 4 m/s wind (left) and 6 m/s wind (right).

3.3. Upcoming Work

MATLAB image analysis is being conducted to calculate the projected area of firebrands that have landed and accumulated at z = 0 in front of varying obstacles. Numerous simulations varying significant parameters are being carefully analysed to conclude the most significant parameters to simulate firebrand accumulation. Especially, changes to the wind profile simulated in the wind tunnel, and more accurate firebrand particle geometries and drag coefficients are being studied to improve model accuracy.

If the model can be successfully validated with experimental measurements, it will be used to study the building design significance in affecting firebrand accumulation patterns. By varying the wall dimensions, and adding additional solid obstacles to the simulation, the impact of varying building design on firebrand exposure (separation distances, projected area, mass accumulation profile) will be presented. Studying the impact of design considerations on the landing distribution of firebrands in front of walls and sidings is important in designing wildfire resistant WUI buildings and communities.

Abstract

This article presents a validation study of the numerical model for assessing the moisture content of a pine tree based on experimentally obtained results, considering the surrounding external environmental conditions. In this work, the moisture content of the leaves of a pine tree is evaluated, taking into account the air temperature and the relative humidity conditions around the tree. The experimental work consisted of collecting maritime pine leaves, measuring their moisture content with a moisture analyzer and recording the environmental conditions, obtained by a meteorological station, at the time of this collection. In this work, data obtained during the year 2021 are considered. The experimental results obtained in the meantime were compared with the results obtained numerically. The numerical simulation was done by a research software developed by the authors called Hygrothermal Tree Modelling. In the conceiving of the numerical model, the processes of water circulation and energy transmission were included. The values of leaf moisture content predicted by the numerical model differ slightly from the values obtained experimentally, whose relative error calculated was 1.45%.

1. Introduction

Mass and heat transmission processes must be known when evaluating the thermal response and existing water circulation in trees. Phenomena such as water distribution, diffusion, transpiration and temperature are taken into account in this type of process.

Studies carried out by Janott et al. (2011), Wang et al. (2012), Simon et al. (2018), and Green et al. (2003) present very relevant models for understanding and simulating phenomena concerning the way in which mass transmission takes place in trees. Janott et al. (2011) proposed a concept of water flow in soil-plant systems. Wang et al. (2012) defined a model of tree structure and functioning to include biomass production, organ sharing and water availability solutions to simulate plant and environment interaction. Simon et al. (2018) developed a model to evaluate leaf temperatures and transpiration rates of trees. Green et al. (2003) presented a soil water balance numerical model.

Vegetation moisture and dry matter content can be used as important indicators in fire spread models and also to predict how fire evolves (Adab et al., 2016). For example, Adab et al. (2016) concluded that the scaling up of moisture content indices could be useful to apply as a previous forest fire alert system. Evaluating forest fire risk is a challenge task due to several uncertainties such as fuel flammability and ignition potential (Rao et al., 2020). In research works of Lifang et al. (2019) and Nolan et al. (2020) and Rao et al. (2020) the application of moisture content indices, their implications, challenges and details of use in this type of forecast were evaluated.

The model of water transfer, used in the study presented in this paper, includes the distribution, diffusion and transpiration processes. This model was developed from models of blood and water flow processes in the human body (Conceição and Awbi, 2021).

The grid generation is important to evaluate the temperature distribution and to feature the thermal phenomena (by conduction, evaporation, radiation and convection) that occur in the tree. The grid generation theory applied

in this is founded on that used to obtain the geometries of buildings, vehicles or human bodies, utilized to assess the radiative exchanges (Conceição and Lúcio, 2010; Conceição et al., 2010).

The thermal response model of the pine tree used here is founded on thermal and radiative numerical models applied to other type of geometries, such as buildings (Conceição et al., 2018) and vehicles (Conceição et al., 2000).

The objective of this study is to validate the sub-model of the Hygrothermal Tree Modelling numerical model used to calculate the moisture content, mainly in the leaves, of a pine tree. Therefore, a periodic collection of pine leaves and subsequent measurement in the laboratory of their moisture content were carried out over the last two years. The experimental results obtained during the year 2021 were chosen to be compared with the results obtained numerically, maintaining the same external environmental conditions as those recorded experimentally.

2. Numerical Model

The numerical model is based on a system of equations of mass and energy transmission. The conduction, convection, radiation and transpiration phenomena are considered when establishing the system of energy transmission equations. The water mass evaluation, the water distribution, and the processes of diffusion and transpiration are considered when establishing the system of mass transmission equations.

The pine tree three-dimensional (3D) geometry model consists of cylindrical elements used to define the trunks, branches and leaves. The dimensions of each cylindrical element, consisting of several layers, are given by its length and diameter. This 3D geometry model will be an input of the pine tree thermal response numerical model.

The pine tree thermal response numerical model is founded on the human thermal response numerical model (Conceição and Lúcio, 2001), removing the thermoregulatory system and arising new pathways for water circulation. This numerical model considers a set of balance integral equations of energy for the pine tree body tissues and of mass for the water in the pine tree. The solution of the system of equations thus constituted is obtained by applying the Runge-Kutta-Fehlberg algorithm with error control.

The following phenomena are considered by the tree thermal response numerical model:

- Heat conduction existing between the various layers of each element of the tree;
- Heat convection existing between the outer surface of the elements and the surrounding air environment;
- Heat evaporation, assuming simultaneously the mass and heat transfer and the water phase change, existing between the outer surface of the elements and the surrounding air environment.

The following phenomena are considered in the mass transmission:

- Water distribution: the water is conveyed from the trunk to the branches and leaves;
- Water diffusion: water is conveyed within the trunk from the internal tissues to the external tissues; in this calculation, the cylindrical elements that constitute the trunk are divided into several layers (one inner, one outer, and a set of central layers located between them);
- Water transpiration: water is evaporated by convection from the outer layer to the environment, considering evaporative phenomena.

3. Methodology

Numerical simulation was carried out considering only one pine branch and its 90 leaves. Figure 1 presents the grid generation of this branch with its leaves. As input data for the numerical simulation, the average values of wind speed, ambient air temperature and ambient air relative humidity were considered, corresponding to the average of values recorded experimentally throughout the year 2021. These values are as follows:

- Average ambient air temperature: 20.60ºC;
- Average air relative humidity: 58.39%;

- Average wind speed: 4.29 m/s.

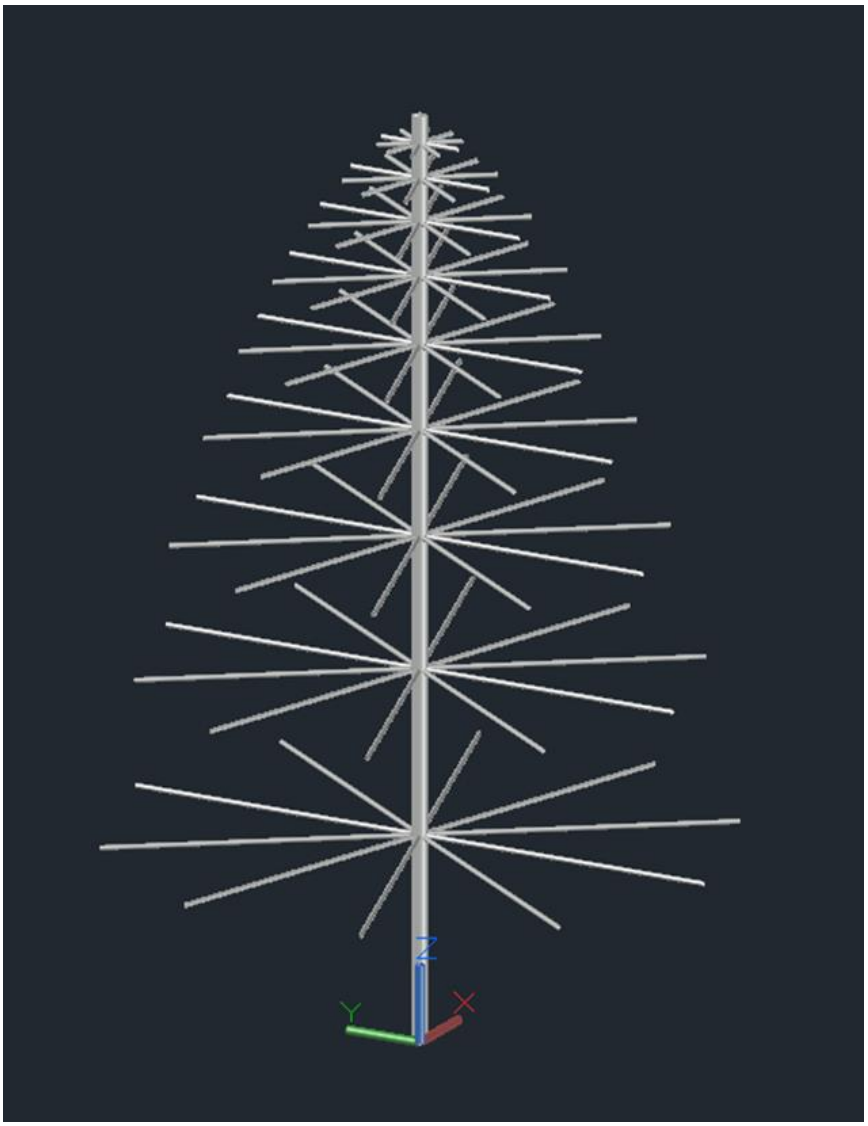

Figure 1 – Grid generation of the pine branch with its leaves.

The experimental work involves a periodic collection of a sample of maritime pine leaves, among other tree species, in a previously delimited area. This collection work has been going on since June 2019. This sample is taken to the laboratory in a closed environment for experimental tests. Upon arrival at the laboratory, its moisture content is measured. The tests carried out later are not presented in this work. Moisture content measurement is done using a Kern moisture analyzer. During this process, records of air temperature, relative humidity and wind speed measured on the day of collection are obtained by a weather station located in the vicinity of the collection area.

4. Results and Discussion

The experimental data obtained are shown in Table 1. The experimental results chosen to be analyzed and compared with the numerical results refer to the year 2021. From the measurements carried out, 61 were selected to be analyzed. Table 1 shows the monthly average values obtained from the measured moisture content of maritime pine leaves, as well as the monthly average of air temperatures and relative humidity recorded on the days of leaf sampling.

The average numerical moisture content obtained in the leaves of the pine branch was 56.41%. Note that this value corresponds to the numerical simulation carried out considering the mean values of air temperature and relative humidity obtained experimentally (see Table 1).

The numerical average results of the moisture content in the leaves are very similar to the monthly average results obtained experimentally in the measurement of the moisture content in the leaves. Comparing the numerically calculated value of the moisture content of the leaves with the annual mean value of the experimental measurements, it appears that the relative error is 1.45%. It can be concluded that the numerical model implemented in the calculation of the moisture content of the leaves of a pine tree allows to obtain results very close to the real ones, so the use of this numerical model is considered valid.

Table 1 – Experimental data obtained during 2021 (average monthly results).

Month	Moisture content (%)	Air temperature (ºC)	Relative Humidity (%)
1	55.20	15.10	83.00
2	55.29	16.03	78.29
3	54.76	17.54	62.20
4	55.32	17.95	65.50
5	54.24	21.10	55.00
6	54.06	25.82	44.00
7	57.87	26.71	38.11
8	56.60	26.42	53.67
9	54.53	26.50	48.00
10	61.85	22.74	50.60
11	54.14	17.70	53.00
12	53.38	13.63	69.33
Average	**55.60**	**20.60**	**58.39**

5. Conclusions

This article introduced a numerical model developed to calculate the moisture content available in the leaves of a tree, considering the surrounding external environmental conditions given by air temperature, relative humidity and wind speed. In this study, in particular, maritime pine leaves were used. The results obtained numerically were compared with experimental measurements done under similar environmental conditions. Experimental data used throughout the year 2021 were used.

The main conclusion reached is that the numerical model proposed here allows obtaining results on the moisture content of maritime pine leaves very close to those obtained experimentally. Comparing the numerical result with the annual average value of the experimental results, it is verified that there is a relative error of 1.45%.

Therefore, the authors consider that the numerical model proposed in this work can be effectively used to calculate the moisture content of tree leaves and, particularly, of maritime pine.

Abstract

In the forthcoming years, self-protection of communities will be a first priority over fire suppression in order to tend to more fire-resistant and resilient WUI communities. All around the world, countries facing WUI fires apply different recommendations or regulations often issued from post-fire surveys. Still, more efforts are necessary to understand how and why dwellings are damaged or completely destroyed under WUI fires attack. In particular, there is a need to quantitatively assess the effectiveness of the current legal prescriptions for homeowners concerning the defensible space around dwellings. Three-dimensional, time dependent, computational fluid dynamics fire behavior models can take into account the factors interacting and contributing to WUI fires (i.e., weather conditions, terrain configuration, fire, vegetation and structures). Moreover, they allow the spatially-explicit modelling of vegetation elements (i.e., trees, shrubs, etc.). Thus, they can be supporting tools to quantitatively assess the heat (radiative and convective) exposure of structures during the approach of a WUI fire, in order to investigate how the characteristics of the defensible space can protect a dwelling or not against such a fire. This study addresses the characterization of heat exposure conditions of a dwelling in common Mediterranean WUI scenarios by using the three-dimensional, time dependent, computational fluid dynamics forest fire behavior model WFDS. To this purpose, WUI fire simulations have been carried out at the landscape scale, taking into account the different zones that a fire burns before it might approach and reach a home structure. This is, a forested area and the defensible space or cleared area around a dwelling. Two different scenarios have been studied, where different spatial patterns for the raised vegetation at the defensible space have been considered. One vegetation pattern has a low level of aggregation corresponding to a sparse spatial distribution of plants, whereas the other vegetation pattern has a higher level of aggregation representative of a clumpy distribution of plants. Both scenarios, in agreement with the current regulations in Corsica, have the same amount of available fuel load, as well as, the same number and characteristics of raised vegetation elements. Fire simulations for these two scenarios have been carried out at different wind and ambient conditions representatives on one side of normal dry summer conditions and on the other side of severe dry summer conditions. Heat exposure conditions have been characterized in terms of radiative and convective heat fluxes received by the structure. Special attention has been given on the role of fire – vegetation – wind interactions for the results and discussion.

1. Introduction

Fire events occurring at the Wildland Urban Interface (henceforth WUI), are responsible not only for important structure losses but also for human fatalities. In order to plan successful mitigation actions, it is necessary to understand the complex interactions between weather conditions, terrain configuration, fire, vegetation and structures during a WUI fire.

The existing wildfires risk mitigation strategies and the associated regulations concern different scales, from community scale (i.e., land use and fire regulations) to individual dwelling scale (i.e., building codes) (Duerksen et al., 2011). However, the susceptibility of a dwelling to undergo wildfire damages is strongly determined by its characteristics in relation to the immediate surroundings (Calkin et al., 2014), as already demonstrated by several studies (Cohen 2000; Cohen & Stratton, 2003; 2008).

The most common strategies to reduce dwelling's loss at individual property scale involve building construction materials (i.e., combustible, non-combustible, fire resistant), building design features (i.e., details of its different

parts and the weak points in the building envelope like openings), and a defensible space around the dwelling by clearing ornamental vegetation and other material or secondary structures (i.e., sheds, fences, etc.) which can burn and impact the dwelling. However, self-protection plans of WUI settlements mainly concern the defensible space around dwellings since generally, building policies at WUI are only mandatory for new structures.

In the forthcoming years, self-protection of communities will be a first priority over fire suppression in order to tend to more fire-resistant and resilient WUI communities (Pastor et al., 2020). All around the world, countries facing WUI fires apply different recommendations or regulations often issued from post-fire surveys (Laranjeira & Cruz, 2014; Intini et al., 2019). Still, more efforts are necessary to understand how and why dwellings are damaged or completely destroyed under WUI fires attack. In particular, there is a need to quantitatively assess the effectiveness of the current legal prescriptions for homeowners concerning the defensible space (Mell et al., 2010).

Three-dimensional, time dependent, computational fluid dynamics fire behavior models can take into account the factors interacting and contributing to WUI fires (i.e., weather conditions, terrain configuration, fire, vegetation and structures). Moreover, they allow the spatially-explicit modelling of vegetation elements (i.e., trees, shrubs, etc.). Thus, they can be supporting tools to quantitatively assess the heat (radiative and convective) exposure conditions of structures during the approach of a WUI fire, in order to investigate how the characteristics of the defensible space around a dwelling can protect it or not against such fire.

This study addresses the characterization of heat exposure conditions of a dwelling in common Mediterranean WUI scenarios by using the three-dimensional, time dependent, computational fluid dynamics fire behavior model WFDS (Mell et al., 2007; 2009; Pérez-Ramirez et al., 2017). Heat exposure conditions have been characterized in terms of radiative and convective heat fluxes received by the structure, paying special attention to the openings in the building envelope (e.g., windows, shutters, etc.). It is worth noting that even though different exposure conditions are responsible for dwellings damage at WUI, this is, flame radiation, direct flame contact and firebrands (Caton et al, 2017), only the two first mechanisms have been considered in this study.

2. Numerical Modelling

WUI fire simulations with WFDS have been carried out at the landscape scale to take into account the different zones that a fire has to burn before the fire front might approach and reach the home structure. This is, a forested area and the defensible space around the dwelling. The defensible space includes ornamental vegetation in the immediate surroundings of the dwelling and a cleared area.

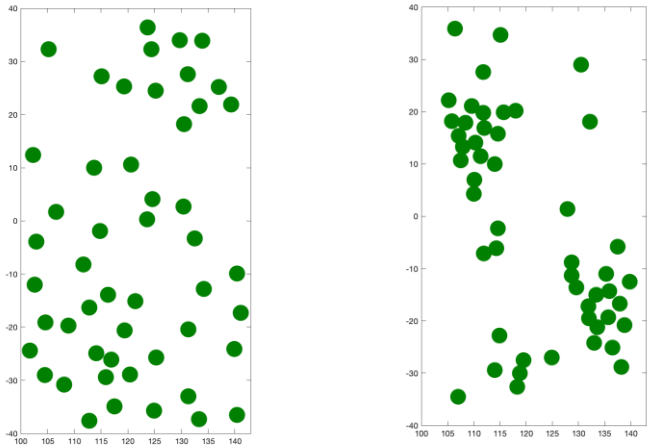
2.1. Vegetation modelling

The forested area implemented corresponds to a high-density cork oak forest, composed by a canopy stratum of cork oaks (*Quercus suber*), a shrub layer of plants of rockrose (*Cistus monspelliensis*), tree heath (*Erica arborea*) and strawberry tree (*Arbutus unedo*) and a litter layer. To model the cork oak forest, data from field sampling, as well as, from the literature were used. Several hypotheses were considered to model trees and shrubs; this is, plants per species have the same dimensions and they have a uniform distribution of fine particles in the crown. Spatial patterns of raised vegetation plants were modelled by using spatial statistics and in particular a point process based on a hard core pairwise interaction model.

The defensible space was modelled by taking into account the current regulation in Corsica which concerns its dimensions (i.e., distance between the house and the forest), the specifications on tree thinning and the required tree spacing (i.e., trees/shrubs and/or hedges spacing in this area). The immediate surroundings to the dwelling are composed by grass and a hedge, which is a common ornamental vegetation structure used in Mediterranean WUI communities to delimit properties. The area in between the forested area and the immediate surroundings of the dwelling is the result of the clearing of the cork oak forest stand, and is thus constituted by a canopy layer of cork oaks and the resprouting of the shrub layer (i.e., 20 cm height).

The same hypothesis and methods were used for the modelling of the canopy layer in the cleared area. Two different vegetation patterns in terms of the spatial distribution of cork oaks were tested in this area, resulting in two different scenarios. These two vegetation patterns are in agreement with the regulation in Corsica but present a different level of aggregation for the canopy layer. One vegetation pattern has a low level of aggregation (cleared area type 1) corresponding to a sparse spatial distribution of trees, whereas the other

vegetation pattern has a higher level of aggregation (cleared area type 2) representative of a clumpy distribution of trees (Figure 1). Both scenarios have the same amount of available fuel load, as well as, the same number and characteristics of trees. Consequently, only the spatial distribution of trees changes between these two configurations.



a) *b)*

Figure 1 – Vegetation spatial patterns in the cleared area. a) Sparse distribution. b) Clumpy distribution.

2.2. Numerical cases setup

Fire simulations for the two scenarios (i.e., forest – cleared area type 1 – ornamental vegetation – dwelling and forest – cleared area type 2 – ornamental vegetation – dwelling) were carried out for different wind and ambient conditions. Two wind velocities were tested corresponding to a mild to moderate wind and a strong wind, representative for more extreme conditions. In the same way, two sets of ambient conditions and fuel moisture content were studied, one set being characteristic of normal dry summer conditions and the other set being representative of severe dry summer conditions. Fuel moisture content values for the different species considered were obtained from historical records of the French operational network called "Reseau Hydrique" (Martin-StPaul et al, 2018). Table 1 summarizes the different scenarios and conditions tested in this study.

Table 1- Specifications of the different scenarios and conditions tested (RH: Relative Humidity, FMC: fuel moisture content on dry basis)

Forested area	**Cleared area**	**Wind conditions**	**Ambient conditions – Fuel moisture content**
High-density cork oak forest stand	**Vegetation distribution type 1**	**Low-moderate wind**	**Dry conditions**
	Low aggregation pattern	25 km/h	32°C, 20 % RH 52 % - 81 % FMC
	Vegetation distribution type 2	**Strong wind**	**Severe dry conditions**
	High aggregation pattern	45 km/h	40°C, 10 % RH 23 % - 60 % FMC

The computational domain size was 275 m x 80 m x 70 m (Figure 2). The domain was subdivided into two area, the first one covering all the surface of the domain up to 32 m height, and the second one covering the upper part of the domain. In the first area, where combustion takes place, the grid cell size was $\Delta x=\Delta y=\Delta z=25$ cm, whereas in the second area the grid cell size was $\Delta x=\Delta y=\Delta z=50$ cm. A 1/7th power law profile was used at the inlet of the domain to implement the wind condition. Ignition was delayed to allow the wind field to fully develop in the whole domain. Periodic conditions were applied at both left and right sides of the domain. A free slip conditions was used for the top boundary, while an open boundary condition was prescribed at the outlet of the domain.

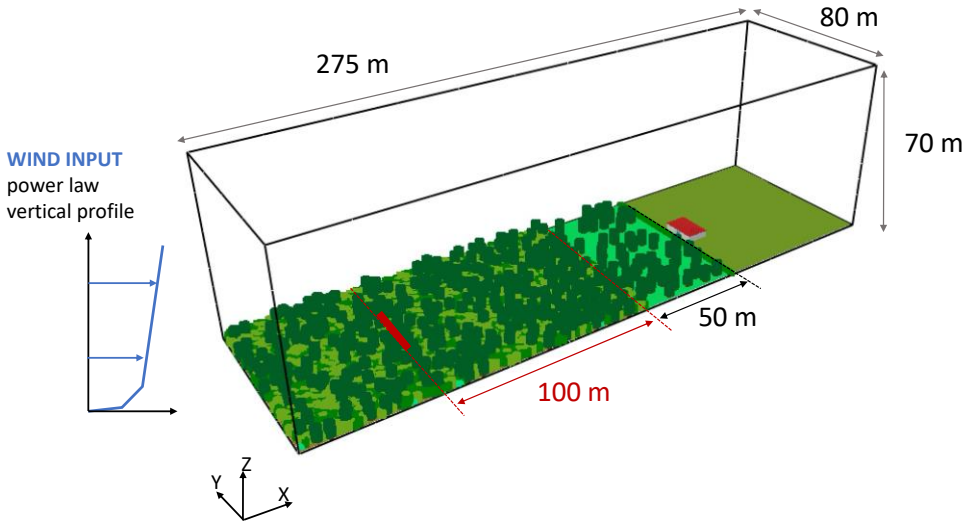


Figure 2 – Numerical domain implemented

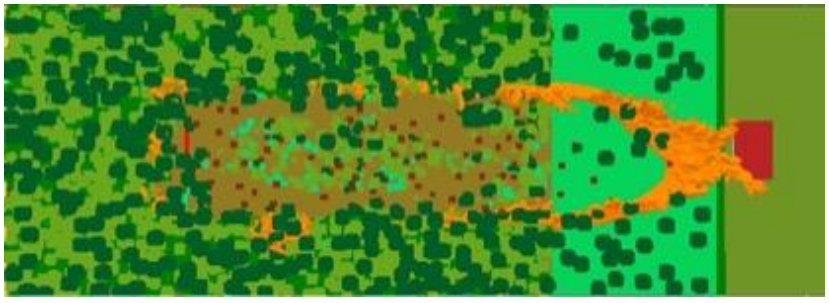
Surface fuels (i.e., litter, grass and the shrubs regrowth in the cleared area) were implemented by using the fuel boundary model coupled with a linear pyrolysis sub-model for the thermal degradation of the solid-phase. The other vegetation elements were implemented by using the fuel element model combined to an Arrhenius type model for solid-phase degradation including char oxidation.

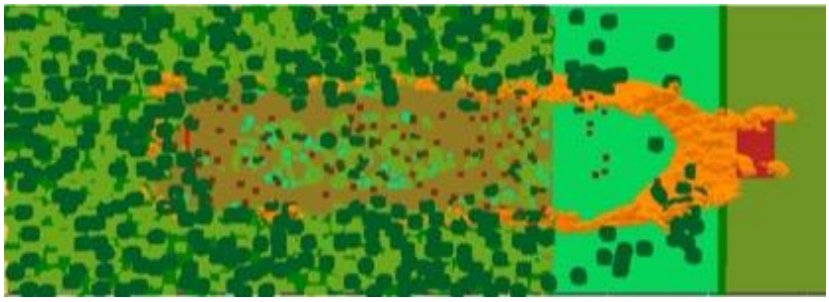
Different openings were implemented in the dwelling façade the most exposed to the fire, this is, a central French window and two windows on both sides of the French window.

3. Results and Conclusions

The distribution pattern of trees in the cleared area affects the wind patterns nearby the dwelling, which in turn affect the burning dynamics. As it can be seen in Figure 3 for the worst-conditions cases, this is cases spreading under a strong wind and very dry conditions, the position of the fire front and its shape at the same instant of time differ from one case to another. For the vegetation pattern corresponding to a low level of aggregation (Figure 3a)) the fire front shape is not symmetric to the centerline and thus the heat exposure conditions vary from one window to another (Figure 4a)). For the other vegetation scenario (Figure 3b)), the fire front profile is almost symmetric to the centerline so that the heat exposure conditions in terms of the duration and maximum heat exposure of windows are similar even though some differences are observed that can be explained by the presence of a group of trees in front of one of the windows (Figure 4b)).

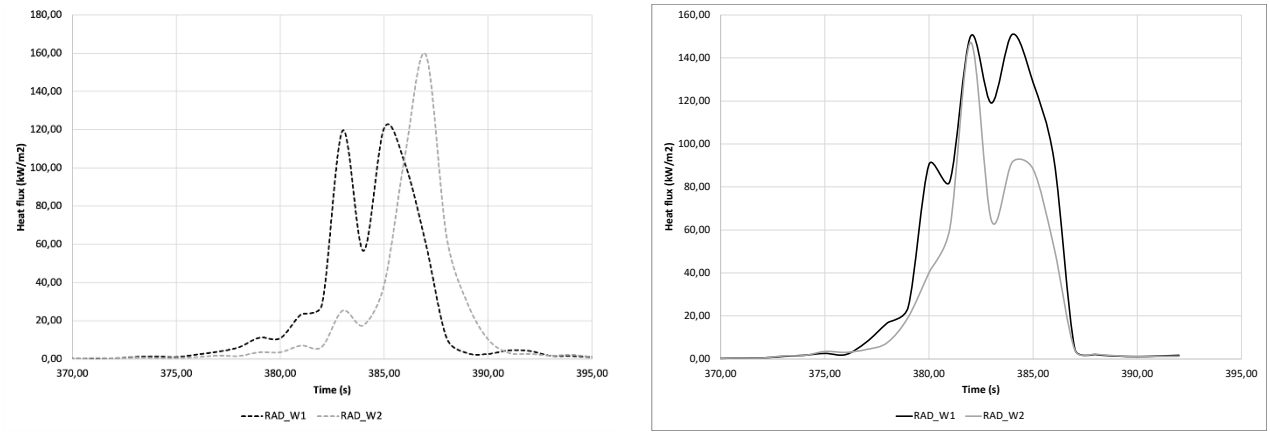


a)



b)

Figure 3 – Snapshots as rendered by Smokeview for the worst-conditions cases at the same instant of time. a) Vegetation distribution type 1. b) Vegetation distribution type 2.



a) *b)*

Figure 4 – Total heat fluxes received by side windows for the worst-conditions cases. a) Vegetation distribution type 1. b) Vegetation distribution type 2.

As illustrated in Figure 5, heat release rate tendencies for both cases are similar during the combustion phase in the forested area and differences are observed once the fire front reaches the cleared area (at about 340 seconds) due to the differences in combustion dynamics in this area. Results for the cases run in the other conditions (Table 1) are in agreement with these results.

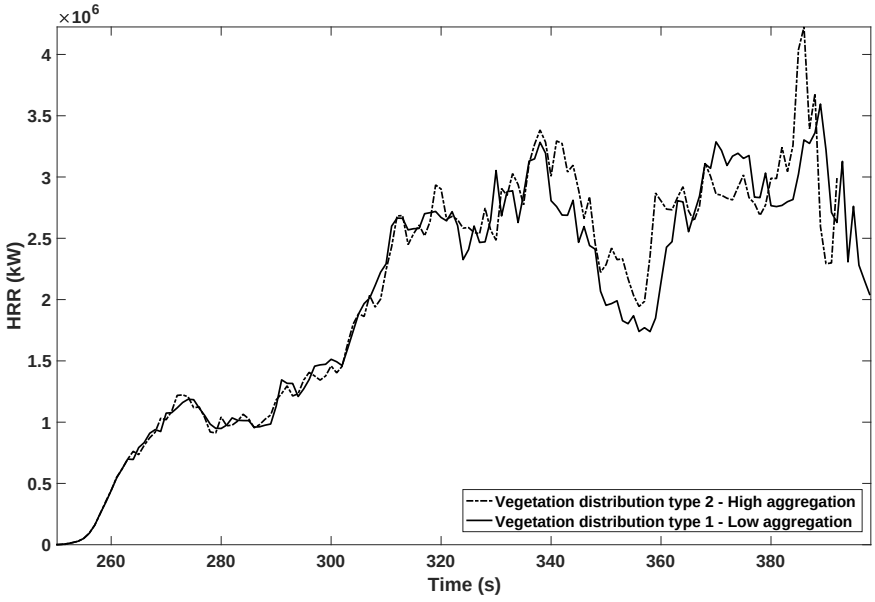


Figure 5 – Heat Release Rate for the worst-conditions cases

This study highlights the role of heterogenous patterns of vegetation on the burning dynamics for a WUI fire scenario and thus on the thermal exposure conditions of a dwelling, due to the interactions between vegetation, wind and fire itself. However, a deeper analysis including simulations of other vegetation patterns, is need to obtain statistically significant conclusions.

Wildfire; wind-driven surface fire; wildland-urban interface; LES; FireFOAM

Abstract

This paper presents an investigation into the impact of wind speed on the interaction of wind driven surface fire with an idealized building structure. The open-source large eddy simulation (LES) fire dynamic solver, FireFOAM, was used to simulate fires burning with an intensity of 10 MW/m under different wind speeds. The numerical data was validated using a wind only simulation which compared aerodynamic data to the previous full size experimental and numerical studies. The results show the aerodynamic flow characteristics and their interaction with the idealized structure located downstream of the fire source. Increase in wind speed showed a linear relationship to increase in the coefficient of lift on the building. The local coefficient of pressure on the building was calculated which indicated significant risk of damage due to aerodynamic lift caused by buoyant fire updraft. The results also show that at a constant fire intensity, increasing wind speed leads to an increase in the average temperature of the domain downstream of the fire to a certain value and then decreases.

1. Introduction

Wildfires are a natural disaster which can cause significant damage to the local environment, both natural and man-made. Whilst many plants and animals have adapted to wildfire and require regular fires to maintain biodiversity (Walker et al., 2019), urban structures face high risk of damage and destruction. With large wildfires becoming a more likely occurrence (Theobald & Romme, 2007) and urban sprawl into wildland areas, there is a need for continued study into reducing the risk wildfires pose to urban structures in the wildland-urban interface. Research in this area is useful for improving the design of wildfire resistant buildings, thereby reducing the socioeconomic impact of wildfires in the future.

Wildfire studies using CFD solvers have been used since the 1980s when Grishin and his team developed the first fully physical multiphase wildfire model (Grishin, Zverev, & Shevelev, 1986). From this model more advanced wildfire simulation software has been developed including Wildland Fire Dynamics Simulator (WFDS) (Mell, Charney, Jenkins, Cheney, & Gould, 2013) and FIRETEC code (Frangieh, Accary, Morvan, Méradji, & Bessonov, 2020; Morvan, Accary, Meradji, Frangieh, & Bessonov, 2018; Pimont, Dupuy, Linn, & Dupont, 2011). Several wildfire prediction software programs have been developed to provide fast predictions in an operational environment through simplification of wildfire spread. These are tools based on the Rothermel model (Rothermel, 1972), BehavePlus (Andrews, 2007) and FARSITE (Finney, 1998). These programs perform well during a wildfire but cannot provide accurate data to help improve the understanding of fire spread and damage to buildings on a small scale. This is where accurate fire modelling CFD tools are required, as they provide data that are rather difficult to obtain experimentally. He and his team were the first to carry out a numerical analysis of wind-driven wildfire interaction with an idealized building in 2011 (He, Kwok, Douglas, & Razali, 2011). Since then, studies by Fryanova and Perminov (Fryanova & Perminov, 2017), and Pimont, Dupuy, and Linn (Pimont, Dupuy, & Linn, 2014) investigated the likelihood of structure ignition and the minimum clearing distance to avoid ignition caused by radiation and convective effects. In 2020 Ghaderi and his team used fireFOAM to investigate wind-driven wildfire interaction with an idealized building focusing on the radiative heat flux experienced by the building (Ghaderi, Ghodrat, & Sharples, 2020). Further research is

required into the interactions between wind-driven wildfires and urban environments to prevent loss of life and property. In the present study, the effect of wind speed, at a constant fire intensity, on the fire-line dynamics, downstream temperature, and local pressure coefficient along the centrelines over the front, top and rear surfaces of an idealised building investigated. The results of this research will help inform decisions in building design in the Wildland Urban Interface.

1.1. Model description

1.1.1.Case design

The modeling case was designed to be a simplified representation of a wildfire interaction with an idealised building. The line fire is a fixed mass flow rate inlet of methane. The mass flow rate is fixed to produce a 10 MW/m line fire intensity, representing a typical grassland fuel fire propagating at a rate of spread of 0.75m/s and a fuel load of 0.4kg/m^2 (Byram, 1959). The idealized building was chosen to be a six-meter cube, as was used in several previous studies on wind-building interactions (Castro & Robins, 1977; Ghodrat, Shakeriaski, Nelson, & Simeoni, 2021; Richards & Hoxey, 2012). This provides reference data for qualitative and quantitative validation of the modeling case. The size of the computational domain was chosen to be 50 ×30 × 25 m to minimize adverse boundary condition effects as per the recommendations by Richards and Norris (Richards & Hoxey, 2012) in their work on LES modelling of unsteady flow around the Silsoe Cube (Figure 1a). The five-meter distance from the inlet to the line fire was chosen to provide proper boundary layer development and reduce the sensitivity to the inlet velocity profile at the price of greater simulation cost.

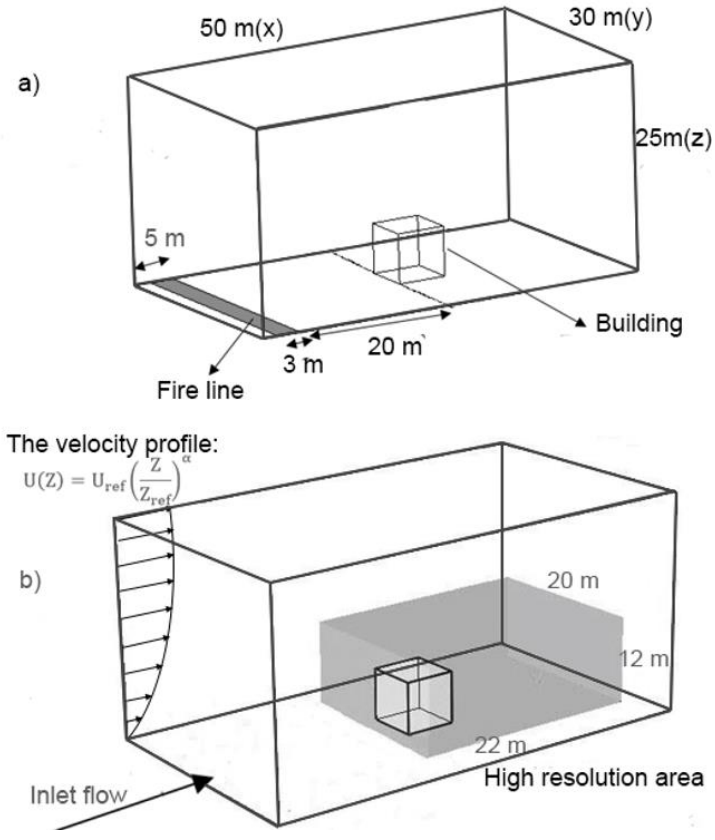

Figure 1- Schematic of the computational domain and the location of fire source and the building. (a) the calculated domain (b) Subdomain configuration

The inlet velocity profile is a power-law inflow velocity profile superimposed with random noise to simulate a realistic turbulent wind (Equation 1). This equation simulates the expected boundary layer formation, allowing for a reduction in the length of the flow development section prior to the fire, thereby reducing simulation cost (Bonnet, Delville, & Lamballais, 2003; Lund, Wu, & Squires, 1998).

$$u^* = \frac{U(Z)}{U_{ref}} = (\frac{Z}{Z_{ref}})^{\alpha} \quad (1)$$

Where u* is the velocity at each height, U_{ref} is the reference velocity, Z_{ref} is the reference height (6 m). γ is an exponent which corrects for terrain characteristics and assumed to be 0.16 based on the terrain at the experiment site (Lund et al., 1998). The roof and outlet of the simulation were set at atmospheric pressure to allow inflow and outflow as required. The walls are set to be free slip boundaries as suggested by Launder and Spalding (Launder & Spalding, 1983).

The mesh was created using consecutive reginal refinement. First a subdomain of size 22×20×12m was determined all over the building to make sure the complex vortical flow structures generated behind the building were recorded precisely (see Figure 1b). The next level of mesh refinement was arranged to sort out the near-wall regions around the building. In addition a high-resolution mesh near the floor was defined and provided all over the domain.

1.2. Numerical modeling

In the present paper, FireFOAM, as a well-known computational tool in fire research, was employed. FireFOAM is an open-source CFD code based on OpenFOAM, capable of being used for diffusion flames modeling. It has been successfully used for many practical applications such as solid fuel pyrolysis (Liu, Wang, & Zhang, 2020), fire suppression (Myers, Trouvé, & Marshall, 2018), and fire-wall interaction (Ren, Wang, Vilfayeau, & Trouvé, 2016).
The Favre-filtered formulation of the fully compressible Navier-Stokes equations representing the fire dynamics in the most common form is written as a set of conservation equations of mass, momentum, energy, and chemical species mass fraction (Poinsot & Veynante, 2005):

$$\frac{\partial \bar{\rho}}{\partial t} + \nabla.(\bar{\rho}\tilde{u}) = 0 \quad (2)$$

$$\frac{\partial \bar{\rho}\tilde{u}}{\partial t} + \nabla.(\bar{\rho}\tilde{u}\tilde{u}) = -\nabla\bar{p} + \nabla.\left[\left(\mu + \mu_{sgs}\right)\left(\nabla\tilde{u} + (\nabla\tilde{u})^T - \frac{2}{3}(\nabla.\tilde{u})I\right)\right] + \bar{\rho}g \quad (3)$$

$$\frac{\partial \bar{\rho}\widetilde{Y_k}}{\partial t} + \nabla.(\bar{\rho}(\tilde{u} + \tilde{u}_c)\tilde{Y}_k) = \nabla.\left[\left(\frac{\mu_{sgs}}{Sct} + \bar{j}_k\right)\nabla\widetilde{Y_k}\right] + \overline{\dot{\omega}_k'''} \quad k = 1, \dots, N_s - 1 \quad (4)$$

$$\frac{\partial \bar{\rho}\widetilde{h_s}}{\partial t} + \nabla.(\bar{\rho}\tilde{u}\tilde{h}_s) = \frac{D\bar{p}}{Dt} + \nabla.\left[\left(\alpha + \alpha_{sgs}\right)\nabla\tilde{h}_s\right] - \nabla.\overline{\dot{q}_r''} + \overline{\dot{q}_c'''} + \nabla.(\alpha\sum_{k=1}^{N_s}(h_{s,k}\nabla\tilde{Y}_k)) + \nabla.(\sum_{k=1}^{N_s}(\bar{j}_k h_{s,k})) \quad (5)$$

In these equations, ρ, P, u, h_s, Y, Sct are the density, pressure, velocity, sensible enthalpy, mass fraction, and turbulent Schmidt number. The symbols "–" and "~" show spatial and Favre filtering. $\overline{\dot{q}_c'''}$ is the heat generated by combustion (assuming complete combustion, i.e., $\chi = 1$) and $\overline{\dot{q}_r''}$ is the total radiation heat transfer emission intensity (W/ m^2) of the gas mixture. The eddy dissipation concept (EDC) (Magnussen & Hjertager, 1977) was used for combustion modeling. The infinitely-fast reaction assumption was applied to determine the reaction mechanism as the EDC in coupled with the infinitely-fast combustion model reveals higher superiority in modeling well-ventilated diffusion flames (Wang, Chatterjee, & de Ris, 2011).

1.3. Validation

Two methods of validating the numerical model were used to ensure both simulation accuracy and grid independency. Validation of simulation accuracy of the aerodynamic component of FireFOAM was achieved through a wind-off test. The coefficients of pressure measured on the building were compared to previous experimental results and numerical results by Castro and Robins (Castro & Robins, 1977) and He et al. (He et al., 2011), respectively. Both tests were run in a similar condition with an identical building (6 m cube) and wind speed (U_{ref}= 6m/s), and the measured and calculated coefficients of pressure can therefore be directly compared. Experimental data to validate grid independence was created by running three cases with differing mesh refinement. The grid numbers were set to 6, 8, and 10 million. The result of the validation cases showed

good similarity in the area from 0-1 and 2-3 but not between 1-2. The three mesh refinements produced very similar results and therefore the 8 million cell grid was selected for all simulations.

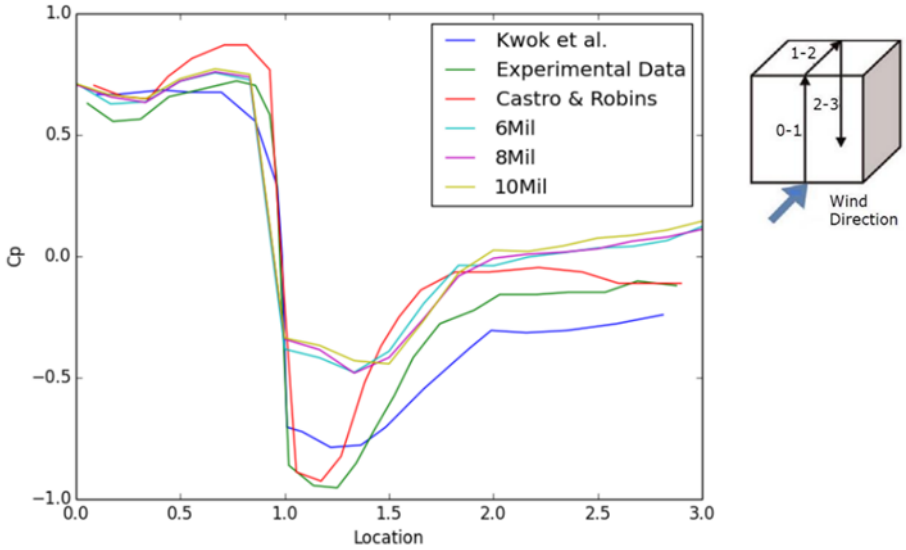

Figure 2- Comparison of the measured mean pressure coefficients on the building centreline, U_{ref}=6 m/s (no-fire case).

2. Results and discussion

The present study examined the simulated impact of a dynamically varying wind-field on a motionless heat source, correspond to a line fire configuration. The modeling results allowed analysis of the transient fire behaviour under different wind velocities (4.5 m/s, 6m/s and 7.5 m/s) and constant fire intensity of 10 MW/m. Figure 3 shows the time dependent flow pattern of wind speed variation in the fire field. As shown, increasing wind speed leads the fire front to be leaned towards the ground downstream of the line-fire bed. This is largely associated with the inertia forces becoming more dominant in this region with rising wind speed. Furthermore, as can be seen from the wind speed contours, air entrainment hooked on the turbulent surface line fire generates a low-pressure zone in the flame-ground area in front of the fire and due to this the fire plume is accelerated and create an area attached to the ground.

(b)

(c)

Figure 3- Vertical transects of instantaneous streamwise wind speed component and corresponding velocity vectors at different lateral locations. (a) U_{ref}=4.5 m/s (b)U_{ref}=6 m/s (c) U_{ref}=7.5m/s

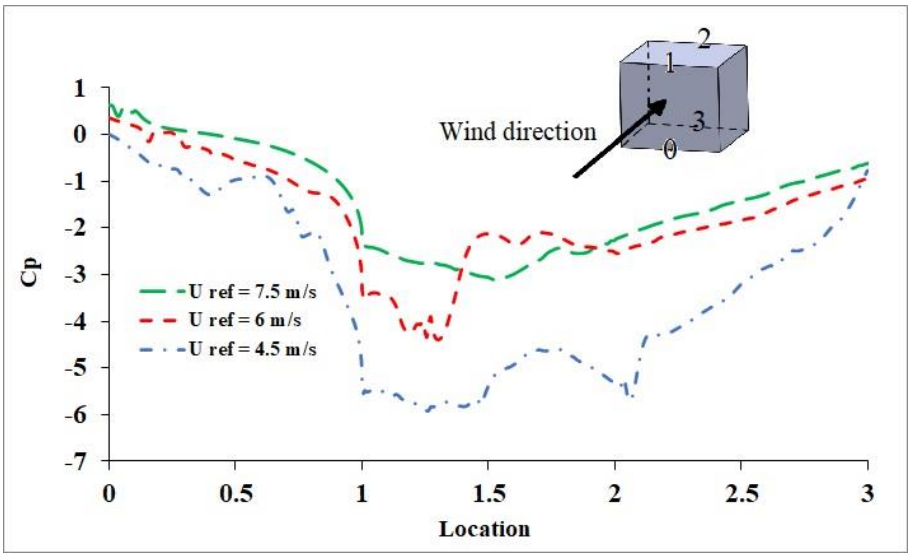

Figure 4- Coefficients of pressure on different location on the building under different wind speed

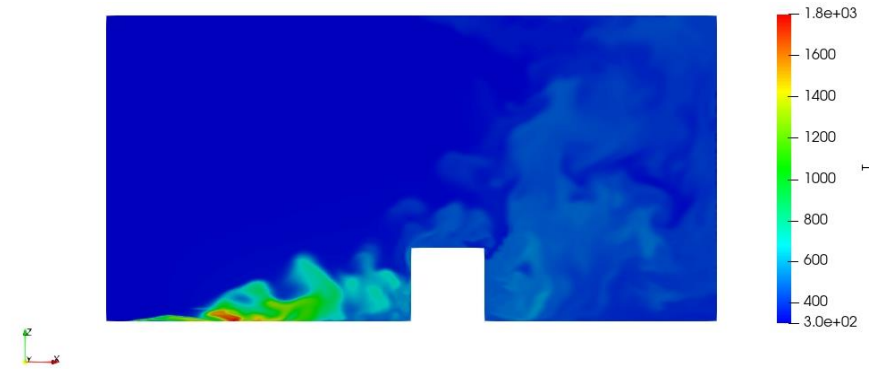
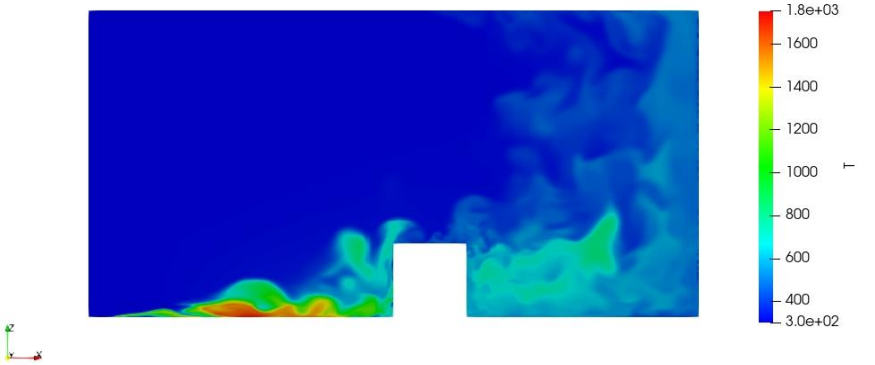
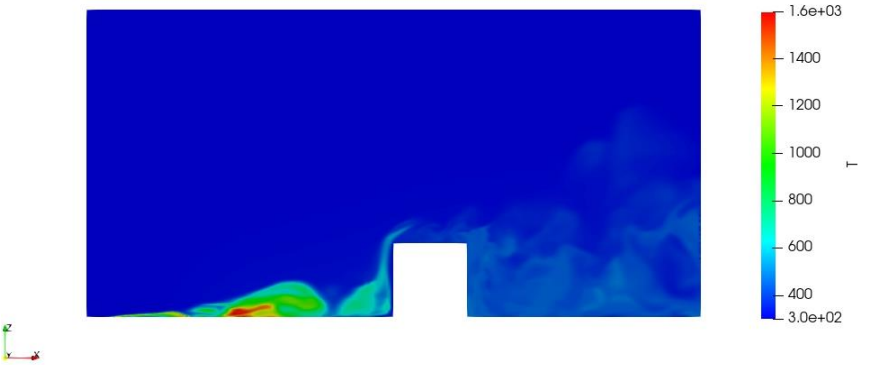
Figure 4 compares the coefficients of pressure on different location of the building with the focus on the front and back surface and the roof of the building during the three test cases for three wind velocities. The result shows strong negative coefficient of pressure primarily on the roof of the building, between locations one and two. The strong updraft created by the buoyant fire combined with the vortex's development on the roof of the building, seen in the visual analysis above, are responsible for creating this. The lowest negative coefficient of pressure decreases with increasing wind velocity, meaning higher wind velocities generate more lift on the roof and may have the potential to cause both window and roof failure (Castro & Robins, 1977).



(a) 4.5 m/s



(b) 6m/s



(c) 7.5 m/s

Figure 5- Temperature profile downstream of the line-fire source under different wind speed

Figure 5 shows the effect of wind speed variation on the temperature distribution downstream of the fire source at constant burning intensity of 10 MW/m. As can be seen in this figure increasing wind speed causes the flame to tilt further towards the building. Comparing the temperature contours under wind speed of 4.5 m/s and 6 m/s highlights that both average and local temperature intensified with raising wind speed and reached to a maximum value at wind speed of 6m/s (Fig. 5 a). Further increase in wind speed up to 7.5 m/s decreases the temperature of domain downstream of the fire source as the convective cooling become (Fig 5 c).

3. Conclusion

This paper detailed a numerical investigation into the effect of varying wind velocity in a simulated idealised structure using FireFOAM. The results show the flow characteristics expected in the wildfire structure interactions as well as the associated effects. The coefficient of pressure on the roof decreases dramatically with increased wind speed creating a large lifting force which has the potential to cause failure. The results also show

that at a constant fire intensity, increasing wind speed leads to an increase in the average temperature of the domain downstream of the fire to a certain value and then decrease.

Physics-based simulation, Thermal stress, WFDS, WUI

Abstract

Over the last decades, urban expansion and global warming have increased the occurrence of wildland fires propagating at the vicinity of buildings at WUI. In this scenario, ornamental vegetation is one of the vectors of fire propagation close to habitations, which can significantly increase the risk of damage (Maranghides et al (2009), Maranghides et al (2015), Etlinger et al (2004), Ganteaume et al (2013)). In such context, it is necessary to quantify the thermal stress generated by an ornamental plant over a building to predict the vulnerability of construction materials. To this end, numerical simulation is a good candidate to easily multiply burning cases at field scale and explore the effects. The present study focuses on the predictions of the thermal stress induced by the burning of an ornamental vegetation over targets facing the fire.

The study involves a numerical modelling of the burning of rockrose hedges at field scale using the physics based code WFDS. The solver uses a large eddy simulation approach for fluid dynamics and energy transfer through the fluid phase. The thermal degradation of the solid fuel is modelled (dehydration, pyrolysis, char oxidation) by a three steps mechanism with Arrhenius laws (Mell et al (2009)). The raised vegetation is represented with a Fuel Element approach, which models the solid fuel as a set of static Lagrangian particles of different sizes and distributed within the volume to reproduce the arrangement of the shrub. The ability of WFDS to reproduce the combustion of plants has already been studied at laboratory scales (Mell et al (2009), Perez-Ramirez et al (2017), Morandini et al (2019), Sanchez-Monroy et al (2019), Moinuddin et al (2020)) but investigations at field scale involving raised vegetation are few.

A set of experiments was carried out at field scale. Fire tests consist of the burning of reconstructed rockrose hedges of 6m length, 1m width and two heights (1m and 2m). The geometry mimics the typical shape of ornamental hedges that can be found to separate buildings in south of France. Visible cameras are distributed around the setup to capture the geometry of the flame front. Four couples of heat flux meters are positioned at 3m in front of the centreline and side of the hedge, which represents the theoretical position of the wall of a building according to the current fire safety regulation in France.

Comparison between predictions and experimental data shows good agreement for the local measurement of the heat stress at the location of the targets. Total and radiant heat fluxes fit with experimental data during the fire growth and the fully developed phases, which represent the period where the thermal stress is the highest. Peaks of total and radiant heat flux are the same order value but can be overestimated depending of the location of the sensors due to the wind dynamics that is not fully implementable in WFDS. Results show that the accuracy of the numerical model is satisfying to predict the thermal stress received by targets during the fully developed fire at field scale. It could be used to numerically determine the vulnerability of material buildings in different scenarios.

1. Introduction

The combination of climate change and cities expansion have risen the risk of fire at wildland urban interfaces (WUI) which can lead to house damages and human fatalities. Indeed, one of the identified vectors of fire spreading nearby a dwelling is ornamental vegetation, which can significantly increase the risk of material failure depending of their distance to the walls (Maranghides et al (2009), Maranghides et al (2015), Etlinger et

al (2004), Ganteaume et al (2013)). Predicting material thermal stress under wildland fire conditions is a key challenge to help authorities make more efficient fire safety regulations and facilitate the work of firefighters. To achieve this, numerical simulation is a suitable tool that allows to easily multiply fire scenarios at field scale in addition to experiments. While field experiments can be time consuming and expensive, numerical simulations are easier to deploy and lead to a larger number of physical quantities to analyze. However, numerical modeling can involve strong hypothesis compared to actual ambient conditions, especially at field scale since reproducing variable wind conditions is always challenging. Thus, it is required a first step to validate the predictions of the model at field scale by direct comparison with dedicated experiments, which is the topic of the present study. Consequently, this paper is focused on the numerical prediction of the thermal stress induced by the burning of an ornamental vegetation over targets facing the fire and the comparison to experiments. The paper is organized as follow. First, a full description of the experimental scenario at field scale is given. The numerical model employed is then presented, followed by a comparison with the experimental results. Finally, the paper ends with concluding remarks.

2. Experimental setup.

The main goal of this set of experiments is to quantify fire risk incurred by a facade that faces a burning ornamental hedge during summer for two configurations: one that is in accordance with the fire safety regulation in France, and another which is not. The quantification of such risk is directly estimated by measuring the heat flux received at the location of the wall.

Field scale experiments involved a rectangular reconstructed rockrose hedges of 6 m long and 1 m width with 2 different heights (1 m and 2 m) which reproduces the geometry of a common ornamental hedge used to separate buildings in south of France. The hedges were made with steel cages filled with dried rockrose branches rearranged to mimic the natural shape of a shrub. Rockrose (*i.e: Cistus Montpeliensis*) is a common species that can be found in the south of France and which contributes in propagating wildland fires during summer. A $6 \times 2 \times 0.2$ m^3 litter made of commercial wooden wool was positioned upstream of the reconstructed hedge to generate a surface spreading fire that ignited the rockrose by direct contact of the flame. The two setups involved 48 kg and 96 kg of vegetation fuel for respectively 1m and 2m height of the hedge, which represents a bulk density of 8 kg/m^3. Rockrose branches were weighted using a weight cell and meticulously introduced into the cage to have the required mass of fuel. Beforehand, rockrose was dried at ambient air to achieve a moisture content on dry basis of 10% in order to consider fuels in extremely dried conditions.

Experiments were carried out during summer under dry atmospheric conditions ($T_{air} = 37.93° \pm 0.37$, $RH_{air} = 16.6\% \pm 1.2$) and low wind conditions ($U_w = 2.29\ m/s \pm 0.17$). Tests were conducted during the same day to avoid variations of weather conditions between 2 consecutive days. Table 1 summarizes the three cases studied. The significant change in wind direction during the tests explain the difference between case n°1 and the others.

Three visible cameras were located around the hedge (2 on the sides, 1 at the back) in order to record the flame geometry. Four couples of radiant and thermal heat fluxes were positioned at 3 m in front of the hedge to assess the heat stress. This distance between the hedge and the heat fluxmeters corresponds to the minimal distance required between an ornamental vegetation and the wall of a building according to the current fire safety regulation in France. The first two couples of fluxmeters were aligned with the hedge centerline at heights of respectively 1 m (R1+T1) and 1.5 m (R3+T3) from the ground. The last two couples were aligned with the side of the hedge at the same z-coordinate i.e. 1 m for (R2+T2) and 1.5 m for (R4+T4). Each couple of fluxmeters was wall-mounted over an $1 \times 0.6 \times 0.05$ m^3 insulator plate to protect the wiring and the electronic from the fire. During each experiment, time history of upcoming wind velocity and direction was also recorded using an anemometer placed 15 m upstream from the setup and 2 m height from the ground. The cameras, the fluxmeters and the anemometer were recorded synchronously at 1 Hz using a data logger. Figure 1 presents a photo (a) and a layout (b) of the experiment setup.

Table 1 – Cases setup for the experimental burning of rockrose hedges at field scale

Case n°	Hedge dimension (m^3)	Accordance with Regulation?	Wind speed (m/s)	Wind direction (°)	Relative air humidity (%)	Temperature of air (°C)
1	6 × 1 × 1	Yes	2.34 (±0.73)	-12 (±33)	16.6	37.9
2	6 × 1 × 1	Yes	2.47 (±1.3)	47 (±51)	18.1	37.5
3	6 × 1 × 2	No	2.06 (±0.73)	44 (±43)	15.2	38.4

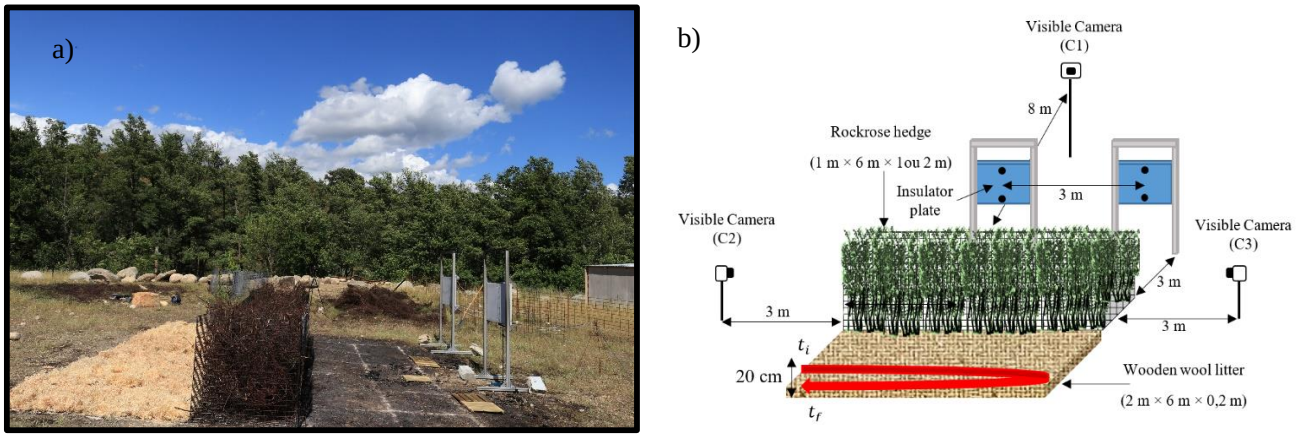

Figure 1 – Experimental setup at field scale: (a) photo of the setup, (b) layout of the setup.

3. Numerical modelling

Wildland-Urban interface Fire Dynamic Simulator (WFDS) is a physics-based CFD solver derived from NIST's code Fire Dynamics Simulator (McGrattan et al (2013a)) that includes the modelling of burning vegetation through a solid fuel approach [2]. Over the last decade, the code was widely use to simulate different types of vegetation fires, ranging from the burning of pine needles at laboratory scale to wildland fires at field scale walls (Mell et al (2009), Perez-Ramirez et al (2017), Morandini et al (2019), Sanchez-Monroy et al (2019), Moinuddin et al (2020)).

WFDS solves a solid-gas phase problem over a numerical domain discretized into a Cartesian grid mesh using the conservation equations of mass, momentum and energy transport. The turbulent gas phase is modelled with a Large-Eddy Simulation (LES) approach and a low-Mach formulation of the Navier-Stokes equations. The solid phase is represented by a "Fuel Element" (FE) approach, which consists in modelling the raised vegetation as static Lagrangian particles of different sizes and properties distributed within a volume that represents the plant. The heat transfer, drag force and thermal degradation for each particle of vegetation are approximated with a one-dimensional approach (thermally thin elements). The degradation of the solid fuel is represented by a three steps mechanism including dehydration, pyrolysis and char oxidation. Each stage is modelled with an Arrhenius law. The combustion of the pyrolysis gas is simplified by a single step combustion equation of a $C_xH_yO_z$ fuel. More details about the solver are in Mell *et al* (2009).

In order to simulate the experiments of the burning hedges, the volume of the numerical domain was set to $50 \times 50 \times 50$ m^3 with the hedge positioned at the center. This domain size allows avoiding any interaction between the boundary conditions and the numerical solution close to the hedges. The domain was meshed using two different sizes of hexahedral cells to save computational time. For a zone of $20 \times 20 \times 10$ m^{3}around the hedge, the cell size was $\Delta x = \Delta y = \Delta z = 12.5$ cm which was the best compromise between accuracy and computational cost. In the rest of the numerical domain, the mesh size was $\Delta x = \Delta y = \Delta z = 25$ cm. To reproduce the wind conditions of the experiments, a 1/7th power law profile was used at the inlet for which the averaged wind velocity and direction recorded during the test was considered. At the outlet, an outflow condition was set. On the top and bottom, a free-slip and a wall condition were respectively used. On the sides of the domain, periodic boundary conditions were considered to take into account the wind direction. The rockrose hedge was modeled using a Fuel Element approach and was decomposed into 6 classes of particles: flowers,

leaves, twigs of 0-2 mm, 2-4 mm, 4-6 mm and 6-25 mm in diameter. Characteristics and spatial distribution of each particle class were obtained from laboratory measurements. The Arrhenius coefficients associated to the thermal degradation process came from Morandini *et al* (2019). The wooden wool litter was also modeled with a fuel element approach using a three-step thermal degradation model with Arrhenius coefficient taken from Sanchez-Monroy et al (2019). Numerical heat flux sensors (radiant and total) were positioned at the same location as the experimental ones. Figure 2 presents snapshots of the simulations using the rendering of software SmokeView for both cases of hedge height.

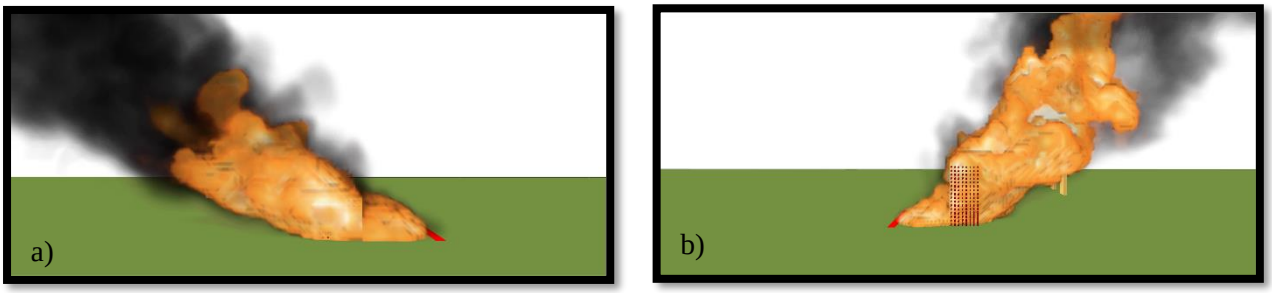

Figure 2 – Snapshots (200 kW/m^3 isosurface) of numerical simulation of burning hedges for two heights: (a) 1m, (b) 2m, rendered in Smokeview

4. Results and discussion

Experimental results show that three combustion stages mainly occur during the burning of the hedge: growth, fully developed fire and extinguishment. The present study focused on the heat fluxes during the developed fire stage. Figure 3 presents an example of the comparison between experiments and simulations for sensors T3 and T4 for case n°1. Red and black dashed lines represent the extinguishment time for the simulations and the experiments respectively. The first observations show that predicted heat fluxes fit better the experiments for the sensors facing the hedge centerline than those located at the side in terms of magnitude and curve shape tendencies.

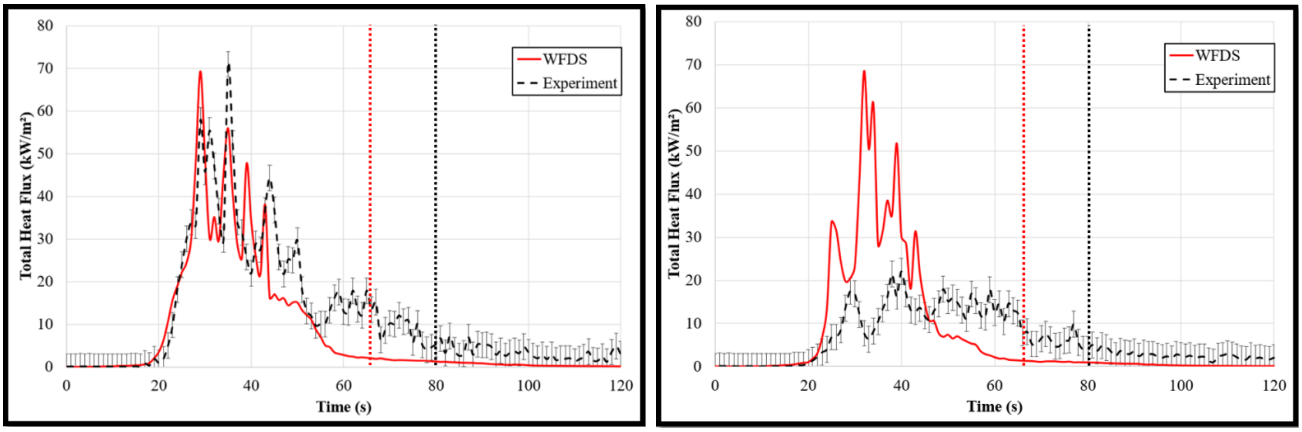

Figure 3 – Comparison between simulation and experiment for the total heat flux line for case n°1: left sensor T3; right sensor T4.

For the sensor T3, the numerical model predicted well the heat flux impinging on the sensor during the first half of the fully developed stage, which shows the highest magnitude of the heat flux. During the second half of the stage, the simulation failed to reproduce the particle collapse observed in the experiments, which deviates the prediction from the measurement. This also causes fire extinguishment occurring 19% to 33% faster in the simulation depending on the case simulated. The edge effects mainly explain the overestimation of the heat flux magnitude received by the numerical sensor at the side. Indeed, experiments have shown that the heat fluxes received by the sensors located at the edge of the hedges are more sensitives to the flame dynamics, and even more when large changes in wind direction occur and lean the flame away from the sensors. The current version of WFDS do not allow reproducing changes in wind speed and direction over time. This leads to a constant orientation of the simulated flames that point toward sensor T2 and T4 during the numerical simulation. The

predicted heat fluxes are therefore overestimated the heat fluxes for theses sensors. Overall, comparisons between simulations and experiments are in agreements with observations made by Perez-Ramirez & al (2017) and Meerpeol-Pietri & al (2022) at laboratory scale for pine needles and reconstructed hedges respectively.

Table 2 – Comparison between experimental and numerical exposure times for sensor T3 for each cases at different heat flux threshold.

Heat flux threshold (kW/m²)	Exposure time for sensor T3 (s)								
	Case n°1			Case n°2			Case n°3		
	Experiment	WFDS	E (%)	Experiment	WFDS	E (%)	Experiment	WFDS	E (%)
5	62	36	-42	49	37	-24	89	34	-62
8	52	33	-37	39	33	-15	62	31	-50
12	41	30	-27	32	30	-6	51	27	-47
15	33	27	-18	28	28	0	49	26	-47
30	14	11	-21	20	19	5	31	16	-48
35	10	9	-10	18	18	0	26	15	-42
40	7	7	0	14	16	14	20	12	-40
	Average relative difference (%)		-22%	**Average relative difference (%)**		-5%	**Average relative difference (%)**		-48

To evaluate the thermal stress due to the hedge burning, we choose to quantify the exposure times for different heat fluxes thresholds at the sensor location (Meerpoel-Pietri (2021)). Table 2 presents the average predicted and measured exposure time at sensor T3 for each case estimated from the total heat flux curves. According to literature, exposure time measured and predicted are high enough to damage PVC. For instance, for 5 kW/m², the loss of mechanical properties for PVC windows or gutters occurs for an exposure time higher than 32 s. This value was exceeded for the experiments and the simulations for all the cases studied.
With regard to the accuracy of the predictions, for all the cases, the accuracy increases when heat flux increases. The hedge collapsing which leads to a longer period of low heat flux measurement during the experiments that cannot be reproduced by WFDS induces this result. In addition, it can be observed that simulation results for case n°3 involving a 2 m high hedge, underestimate the exposure time from 40% to 62% depending on the threshold considered. The hedge collapse observed experimentally and not predicted by the simulation has more impact on the overall hedge combustion for this case. Predictions of the exposure time for cases n°1 and 2 show good agreement. While average relative difference is around 5% for case n°2, case n°1 underestimates the exposure time by 22% in average and up to 42% for the lower heat flux because of changes in wind dynamics as explained previously. According to these results, this study validates the capability of WFDS to be used for the prediction of material failure at field scale for cases that includes vegetation up to 1 m height.

5. Conclusion

Comparison between dedicated experiments and numerical simulations were carried out to demonstrate the capability of WFDS to predict thermal stress induced by the burning of reconstructed hedges at field scale. Three sets of experiments involving 2 sizes of hedges were carried out in summer to reproduce two configurations: the first one that corresponds to the current fire safety regulations in France and the second one that does not agree. Results are in accordance with literature and show that WFDS gives good predictions of the total heat flux received and the exposure time at the hedge centerline during the period where the fire is the most intense. However, predictions deviate from the experimental data when changes in wind direction occur during the experiment and for the 2 m high hedge which strongly collapsed during the burning phase.

6. Acknowledgments

The experiments were supported by the projects "MED-STAR" (Strategie e misure per la mitigazione del rischio di incendio nell'area Mediterranea) and "INTERMED"(Interventions pour gérer et réduire le risque d'incendie à l'interface habitat-espace naturel) financed by the fund PC IFM 2014-2020 (http://interreg-maritime.eu/fr/web/med-star).

The field scale simulation of this research was supported by the project "Structure Heat Exposure – Simulations and Experiments", contract number 21-IJ-11261987-002, funded by the USDA (US Forest Service).

Embers, flame-impingement, deck, wildfire

Abstract

Attached decks are a vulnerable component of a building in wildfire-prone areas. Once ignited, decks can expose a building's cladding (siding), exterior wall components such as windows and doors, and the under-eave area to flames and radiant heat. This exposure can result in severe damage or destruction of the building.

In a wildfire, decks are typically exposed to embers (firebrands) on their top surface and flame impingement to their bottom side. In this research, the vulnerability of decks to ember attack on the top surface and flame impingement at the bottom was investigated. Moreover, the ability of the current deck standards (State Fire Marshal (SFM) Standard 12-7A-4A and ASTM E2632) to predict the performance of different decking assemblies during a wildfire was assessed from experimental and computational perspectives.

Deck research at IBHS began with the evaluation of the vulnerability of decks to wind-blown embers. This research provided evidence that the top surface of redwood (Sequoia sempervirens) decks was particularly vulnerable to ignition by embers. Ignition typically occurred from ember accumulation in gaps between deck boards at joist crossings, which is an area where wind-blown vegetative debris can accumulate. This finer fuel can facilitate ignition by embers. After ignition, fire propagated both parallel and perpendicular to the test building. Although the mechanism was different, propagation did not depend on the orientation of the deck boards (or support joists).

The research on decks was followed up by testing deck assemblies exposed to under deck flame impingement. Several combinations of substructure (i.e., the structural support system) and walking surfaces were evaluated. These results highlighted the vulnerability of joists in the deck assembly. In North America, a wood or plastic composite walking surfaces installed over a wood substructure is the most common decks are built. Our tests showed that once the joist ignites due to the initial flame impingement exposure, it can burn for an extended period and expose the bottom side of the deck boards to flames. It was observed that if a joist was not engulfed in flames, the boards above them do did burn. Hence, one major finding from this study was regarding the impact of the substructure overall deck performance and the importance of explicitly considering the structural support system in any standard test method used to evaluate performance. It also supported the benefit of advocating the use of a noncombustible structural support system in new construction.

While using metal substructures significantly reduced the vulnerability of decks to wildfires (considering both ember and flame exposures), it might not be an affordable option to retrofit existing decks. To address this issue, different types of walking surfaces were tested. It was concluded that continuous noncombustible walking surfaces such as no-gap metal boards or a concrete slab surface limited the availability of oxygen and stalled flame spread in the under-deck area.

1. The IBHS Research Center Test Chamber

The Insurance Institute for Business & Home Safety (IBHS) is a non-profit corporation that operates a natural hazards research facility located in Richburg, South Carolina. The experiments take place at the center square of the test chamber, measuring 145 ft x 145 ft (44.2 m x 44.2 m). The west wall of the chamber is equipped with 105 fans. Each fan is 5.5 ft (1.68 m) in diameter and collectively can create a time history of fluctuating wind speeds from 12 mph (5.3 m/s) to 120 mph (53m/s). The test chamber is also equipped with eight ember generators, each one with the capacity to produce about 120 embers per second with mass between 0.01 to 1 gram. Figure 1a and 1b show IBHS test chamber. Figure 1c shows a snapshot of a deck exposed to embers [Alfano et al. 2017].

2. Ember Exposure to Decks

This series of experiments investigated the ignition potential of eight different types of deck boards exposed to wind-blown embers. The materials evaluated included solid wood and plastic composite deck board products. Six of the products evaluated complied with the provisions specified in Chapter 7A of the California Building Code [CBC 2019], but two did not. Each deck was subjected to an ember exposure of up to one hour and both quantitative and qualitative observations were made. Overall, most of the decks performed well in that they did not ignite and transition to flaming combustion. At locations where embers accumulated, however, smoldering was often observed.

The medium-density softwood product (CBC Chapter 7A compliant) and one of the plastic composite products (CBC Chapter 7A non-compliant), exhibited sustained flaming when subjected to an ember exposure. Transitory flaming was observed in the high-density hardwood decking product (CBC Chapter 7A compliant). The time-to-ignition (flaming) for the decking products varied from 12 minutes for the non-FRT softwood deck to 47 minutes for one of the plastic composite products. Photographs of ignited non-FRT softwood deck is shown in Figure 2. Although neither the number nor mass flux of the ember exposure was quantified, this variation in time-to-ignition provides relative information on the susceptibility of decking products to ignition from wind-blown embers. It was observed that for decks where joists were installed perpendicular to the building, once ignition occurred the fire spread in a smoldering phase along the joist toward and away from the building under an average wind speed of 18 mph. At the deck board gaps, the smoldering combustion transitioned to flaming as a result of airflow between the deck boards. This allowed fire to continue to propagate all the way to the building.

Figure 2. Top of deck (left) and under-deck (right) views of ignited decks during the ignition potential series of experiments. Table 1 tablulates a summary of all the ember exposure tests.

Table 1. Summary of the ember exposure tests

Deck Name	Chapter 7A Compliant	Density[1] (g/cm^3)	Performance	
			Replication 1	Replication 2
PVC Composite	Yes	0.68	Smoldering	Smoldering
PE Composite 1	No	0.97	Smoldering	Sustained Flaming[2]
PE Composite 2	Yes	1.19	Smoldering	Smoldering
PE Composite 3	Yes	1.03	Smoldering	Smoldering
PE Composite 4	No	1.21	Smoldering	Smoldering
High-Density Tropical Hardwood	Yes	1.15	Smoldering	Transitory Flaming[3]
Medium-Density Softwood	Yes	0.51	Sustained Flaming	Sustained Flaming
FRT Wood	Yes	0.50	Smoldering	Smoldering

1. Nominal moisture content, 8% (oven dry basis). Density on current mass, current volume basis.
2. Continuous flaming for more than five seconds.
3. Continuous flaming for less than five seconds

It was also observed that embers dropped into and through the gap, onto the surface below and had the potential to ignite fine fuels underneath (Figure 3). This highlights the risk of underdeck flame impingiment and importance of removing combustible materials from the under-deck área, even if vertically enclosed around the deck perimeter.

(a) (b)

Figure 3. Ember penetration through gaps between deck boards; (a) embers falling to ground and (b) resulting in the ignition of pine needles that accumulated under the deck.

3. Underdeck Flame Exposure to Decks

Although maintaining the under-deck area is necessary to reduce the vulnerablity of decks in a wildfire, post-event investigations have shown that these recomendation are often overlooked. Depending on the frequency of maintenance around a building, a noticeable amount of fuel can accumulate under a deck. If this fuel is ignited

by wind-blown embers, the flame might be tall enough (depending on fuel load, wind speed, and deck height) to reach the deck structure. People also store combustibles, such as firewood, under decks [Maranghides et al. 2015]. Ignition of these materials intensifies the under-deck flame exposure. In this case, the under-deck flame exposure would be more intense and may last longer than exposure from burning wind-blown debris.

Provisions in Chapter 7A of the California Building Code allow the use of many combustible deck board products. These materials include non-fire-retardant treated wood (e.g., redwood and western red cedar) and plastic composites. These decking products can be installed over combustible or noncombustible joists. Whereas the current standard test method includes the substructure in the tested assembler, the arrangement is fixed, and therefore does not consider the substructure system as a variable. To sumarize, the current standard test method evaluates a (1) 2ft x 2.4 ft deck, (2) a "no wind" condition and (3) does not consider the structural support system as a variable[CBC 2019].

To assess the efficacy of the current test methods, all three of the above-mentioned assumptions were challanged by more realistic wildfire conditions. Six-foot by six foot (1.8 x 1.8 m) deck assemblies were exposed to under deck flame in the presence of a 19 mile per hour (8.5 m/s) constant wind speed. The deck assemblies had different combinations of substructure and walking surfaces. Metal and Southern yellow pine substructures were tested with redwood, plastic composite and metal deck boards. It was observed that all the currently compliant deck boards burn extensively and expose the cladding adjacent to the under-deck portion of the attached building to a high thermal insult. Figures 4 and 5 show the progression of fire for redwood deck boards installed over southern yellow pine and the respective wall temperature for different products respectively.

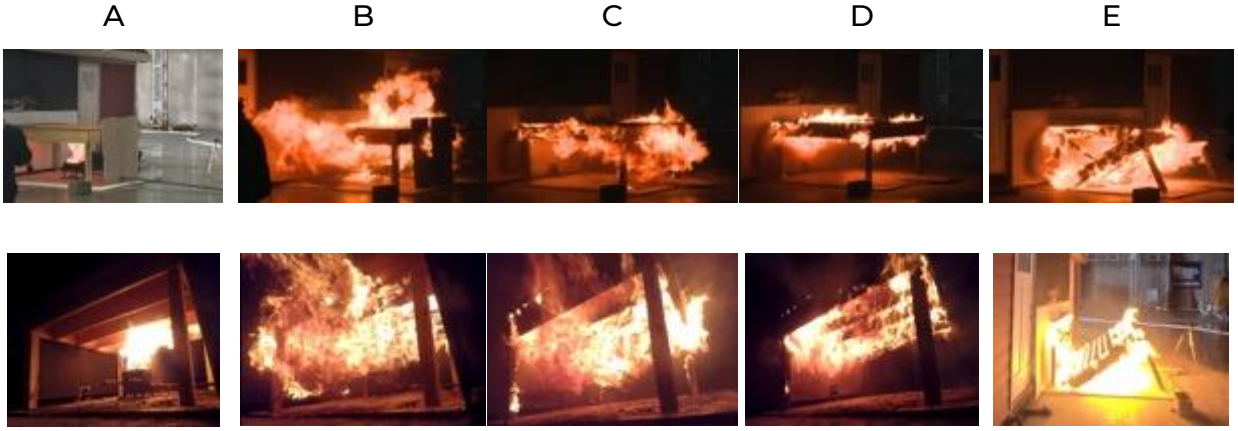

Figure 4. Time-lapse of a redwood deck with Southern Yellow Pine joists test from two angles. (A) After 5 seconds. (B) After 2 minutes. (C) After 5 minutes. (D) After 7 minutes. (E) After 10 minutes

These tests highlighted the contribution of the deck's substructure in the fire. It was observed that if a joist was not engulfed in flames, the boards above them do did burn. To evaluate this observation in detail, the wood and plastic composite combustible decks boards were installed over a metal substructure and exposed to the same under-deck fire source. Figures 6 and 7 show the progression of fire for redwood deck boards installed over southern yellow pine and the wall temperature for different products respectively.

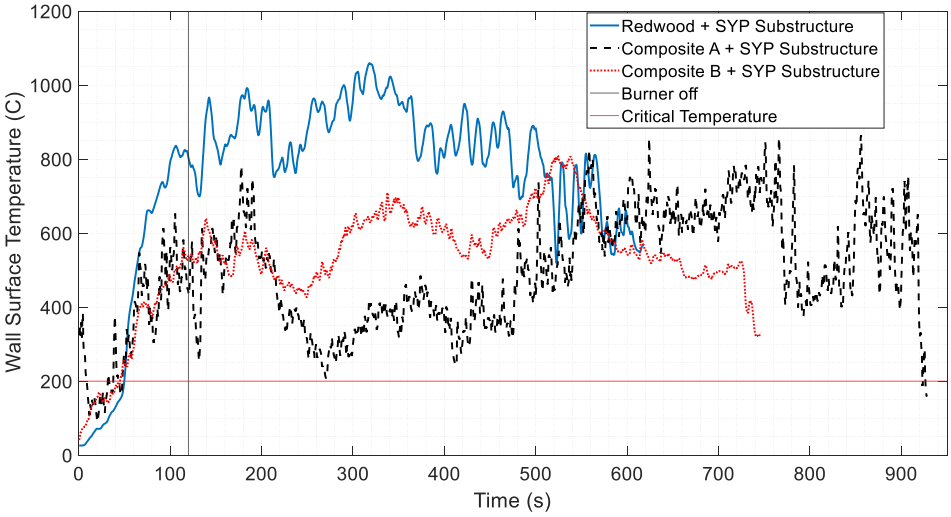

Figure 5. Siding temperature at the under-deck area for different deck boards over Southern Yellow Pine structure.

A (start of the test) B (after 5 minutes) C (after 15 minutes)

Figure 6. Time-lapse of redwood (first row), composite A (second row), and composite B (third row) decks with metal joist test.

The ignition temperature of wood depends on samples' thermophysical properties (moisture content, geometry, ,density, and some external parameters such as the test apparatus, and piloted/autoignition conditions. The resuts of ignition temperature of wood show a wide span of ignition temperatures of 210–497_C for piloted ignition and 200–510_C for autoignition. [Babrauskas 2002]. From these observations, it can be concluded that that "if a wood specimen is ignited under external heating barely sufficient to ignite it, it will ignite at approximately 250_C regardless of the type of heating arrangement [Babrauskas 2002]."

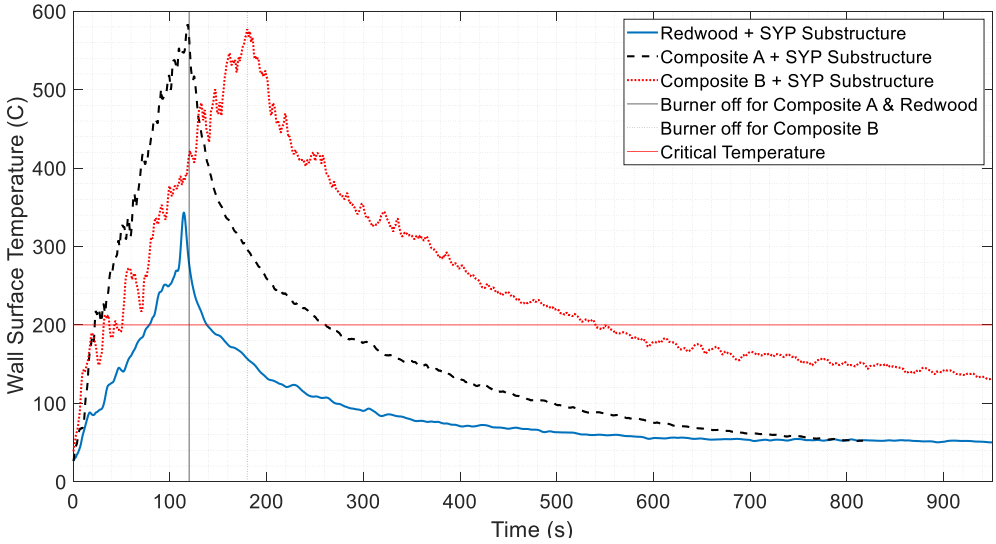

Figure 7. Siding temperature at the under-deck area for different deck boards over metal structure (exposure duration for Composite B is 1 minute longer).

Comparing the wall temperature variations in Figures 5 and 7 shows the contribution of a combustible substructure in the fire. After shutting off the burner after 2 or 3 minutes, in all cases (as shown in Figure 7), the temperature rapidly dropped. The results of these experiments demonstrate the benefits of using metal substructures for new decks. However, for existing decks changing the entire substructure could be cost prohibitive. To address this issue, the performance of two types of metal deck boards were evaluated. The Type 1 walking surface was aluminum and marketed as a waterproof product. The installation instructions for this product specified that there be no spacing between boards. These deck boards are engineered to properly address water drainage and thermal expansion. The Type 2 walking surface was also an aluminum product, however, installation instructions called for spacing between deck boards. Figure 8 shows the status of decks during the experiment from two views. As can be seen, the intensity of the fire between walking surfaces Type1 and 2 were notably different. For the Type1 walking surface the fire was in a smoldering phase while for Type2 walking surface the flames length extnding form under the deck was observed to be as high as two feet (0.6 m).

Physics-based modelling, firebrands, wildland fire, bushfire attack level, AS3959

Abstract

The mechanisms of wildfire attack on structures are classified into direct flame contact, radiant heat, firebrand attack and a combination of two or all of them. Arguably, airborne firebrands play a vital role as one of the main causes of structure ignition and fire propagation by forming spot fires far from the fire front. Firebrand flux (the number of firebrands landed on a unit area per unit time) and the heat load are important parameters to calculate the wildfire risk on structures. Australian Building Standard AS3959 is developed based on radiation heat flux and it does not quantify the effects of firebrand flux on structures to assess the wildfire risk completely. To improve the assessment of the Bushfire Attack Level (BAL) in AS3959, there is a need for the quantification of firebrand flux at different scales of wildfires. Lacking information about firebrand generation from various vegetation species under different environmental conditions creates a gap to estimate the firebrand flux accurately. In this study, we aim to use a physics-based model to quantify the firebrand generation rate of Eucalyptus dominant forest vegetation at different severities of wildfires expressed by the Fire danger indices (FDI) of 100, 80, and 50. The wind speed was chosen while keeping the temperature, relative humidity, and drought factor as constants to obtain the focused FDIs. A 40 m height Eucalyptus forest was modelled with 25 t/ha understorey and 10 t/ha canopy fuel loads as per AS3959 forest vegetation classification. The forest fires were prescribed with the intensities of 53.4, 43.1, and 27 MW/m with 100 m length to replicate the fire events explained by FDIs. The depth of the fireline was approximated according to the fire residence time and the spread rate. The firebrand size, shape, and quantity were taken from our previous firebrand generation study (Wickramasinghe et al. 2022) and the particles were injected randomly through the forest volume which is engulfed by the fire. The distances between the modelled structure that follows an Australian standard house design and the vegetation were maintained according to the BALs. We obtained the radiative heat flux on the houses close to the algorithm provided in AS3959 for each BAL. In this study, both firebrand and heat flux were quantified at strategic locations of the house. We find a logarithmic relationship exists between firebrand flux and radiative heat flux in the range of R2 0.96 to 0.99. Hence, for a certain BAL, the firebrand flux increases with the FDI similar to radiative heat flux. Results from this study can be used to quantify the firebrand flux on various house patterns from different vegetation fires, which may improve the design standards and construction requirements of buildings to mitigate the vulnerability of houses at the wildland-urban interface (WUI).

1. Introduction

Firebrand generation from burning vegetation is a potential threat to people and infrastructure in the wildland-urban interface due to the unpredictable nature of spotting[1]. This phenomenon can be severe with the scale of the wildfire and structural ignition becomes harder to control. Postfire investigations reveal more than 50% of houses destroyed by the wildfires are from firebrands and 2/3 of homes ignited directly or indirectly by the wind

[1] The phenomenon of ignition and starting a new fire front by burning material like wood chips, bark, twigs, leaves, or nuts ahead of the central fire front.

dispersed firebrands (Maranghides & Mell, 2011). Leonard et al.(2004) claim firebrands caused the ignition of over 90% of houses in Australia during a number of wildfire events.

The firebrand generation has received the least attention compared to the latter three aspects of the key processes of firebrand studies: transport, spotting, and secondary ignition. It is difficult to build an integrated system to replicate a realistic wildfire scenario and quantify the risk without adequate knowledge of firebrand generation. Safety issues, the need for advanced instruments, and large financial and human resources to measure firebrand generation at the fire front make the quantification of firebrand generation more difficult. However, physics-based modelling is identified as a viable alternative to finding the firebrand generation associated with the influence of vegetation species and different environmental conditions. Some physics-based models show the capability of predicting firebrand transport and short-range spotting through validation processes (Wadhwani et al., 2017). The validation of physical models requires thermophysical properties of vegetation, characteristics of firebrands including shapes, size, number, the intensity of the fire, the environmental conditions such as wind, fuel moisture content (FMC), and relative humidity, temperature etc. Various bench-scale and field-scale experiments have been conducted to understand the importance of these parameters to use in physics-based models.

Collecting firebrands from tree torching and management scale fires is a widely used technique to investigate the morphologies, characteristics and landing distribution of firebrands. The effects of vegetation species, fuel load, FMC, and wind speed are examined to understand the firebrand generation and their ignition propensity. Manzello et al.(2007) , Hudson et al.(2020) and Adusumilli et al.(2021) found firebrand collection significantly increases with the decrement of FMC. Most of the vegetation species investigated by Bahrani et al.(2020) show the number of firebrands collection increase with the wind speed. The parametric studies conducted through physics-based models by Thurston et al.(2017), Bhutia et al.(2010), and Tse et al.(1998) conclude the significance of firebrand characteristics, wind speed, and intensity of the fire for spotting. The relationship between fire intensity and the firebrand flux was firstly investigated by Thomas et al.(2017) through a prescribed forest fire experiment. With these experimental data of Thomas et al.(2017) the firebrand generation of a Pitch Pine forest was estimated through physics-based modelling by Wickramasinghe et al.(2022) using an inverse analysis technique. This modelling maintains fire intensities, wind climate, fuel properties, and firebrand characteristics (shape, size, composition) to replicate the field experiment and found the firebrand generation rate as 4.18 pcs/MW/s (pcs: pieces).

To the best of the authors' knowledge, there is no standard document that provides quantitative information about firebrand flux on structures in the WUI. Having a substantial understanding of firebrands flux is important to establish building standards to mitigate the wildfire risk with fidelity. Australian standard AS3959 – the prescription for constructing buildings in wildfire-prone areas – qualitatively presents the increment of firebrand attack with the radiative heat flux. The radiative heat flux is expressed in terms of Bush fire Attack Level (BAL) which describes the safe distance to the structure from the edge of the vegetation.

In the present work, we conduct a series of physics-based simulations to quantify the firebrand flux on structures incorporated with the radiative heat flux given in AS3959 for forest vegetation classification. As firebrand attack is the main cause of house ignition during wildfires in Australia, including quantified firebrand flux correlated to the current radiative heat flux is important to implement the BAL of AS3959 standard to better counter the wildfire risk on houses in WUI.

2. Methodology

The simulations are conducted using a physics-based model Fire Dynamic Simulator (FDS) (McGrattan et al., 2005) which is a product of National Standards Technology, USA. FDS uses the multiphase modelling technique, and the gas phase is simulated by Large Eddy Simulation (LES), while the solid firebrands are introduced in the domain by Lagrangian particle-based transport scheme.

2.1. Firebrand generation rate calibration for vegetation species, wind, and FMC

The firebrand generation rate (4.18 pcs/MW/s) found for Pitch Pine at 31% FMC and 2 m/s wind speed (Wickramasinghe et al., 2022) is used as the base information for calibration of the firebrand generation rate for Eucalyptus. The Eucalyptus and Pitch pine vegetations are relatively similar species in terms of the average tree

height, crown shape, orientation of leaves etc. Due to the scarcity of data, we assume the firebrand generation rate of Eucalyptus is the same as the Pitch pine at the same wind speed and FMC. Therefore the numerical effect of vegetation species in between these two fuels for firebrand generation could be approximated as 1:1. To calibrate the effect of wind speed for firebrand generation of Eucalyptus, we use the experimental data of Barani et al.(2020) obtained for the Loblolly Pine at different wind speeds. The physical appearance of Loblolly Pine and Eucalyptus are similar to use in the analysis. It shows increasing wind speed results in a higher number of firebrand production. Based on these experimental data, we obtain the mathematical relationship as presented in equations 1(a) and 1(b), for the number of generated firebrands against the wind speed to estimate the firebrand generation number at the wind speeds for FDI 100, 80, and 50:

$$fb_{generation} = 33.39 \times U_{wind} + 202.03 \;\; when \; 0 < U_{wind} < 8.19 \; ms^{-1} \quad 1(a)$$

$$fb_{generation} = 575 \;\; when \; 8.19 \; ms^{-1} \; < U_{wind} \quad 1(b)$$

where $fb_{generation}$ is the number of firebrand generation and U_{wind} is the wind speed at the burning vegetation. The firebrand generation ratio is calculated in reference to the number of firebrands generated at 2 m/s as shown in Table 1.

Table 1: Firebrand generation ratio according to the wind conditions for FDIs 50, 80, and 100.

Similar vegetations	Firebrand generation rate (pcs/MW/s)	Wind speed (m/s)	Number of firebrands	Generation ratio to 2 m/s
Loblolly Pine	4.18	2.00 (reference)	298	(298/298)=1.00
		5.48 (FDI 50)	454	(454/298)=1.52
Eucalyptus	(Pitch Pine at 2 m/s)	8.88 (FDI 80)	575	(575/298)=1.93
		10.38 (FDI 100)	575	(575/298)=1.93

The effect of FMC is evaluated as per Hudson et al.(2020) where higher FMC is associated with a lower number of firebrand production. Ponderosa Pine is the matching vegetation species to Eucalyptus in this tree burning experiments and the relationship between firebrand production and FMC is mathematically derived as presented in equation (2):

$$fb_{generation} = -4.7 \times FMC + 538.32 \quad (2)$$

where FMC is the dry basis fuel moisture content. By that, the firebrand generation ratio of Eucalyptus is estimated reference to the 31% of FMC as shown in Table 2.

Table 2: Firebrand generation ratio according to the FMC for FDIs 50, 80, and 100.

Similar vegetations	Firebrand generation rate (pcs/MW/s)	FMC (%)	Number of firebrands	Generation ratio to 3.84% FMC
Ponderosa Pine	4.18	31 (reference)	393	(393/393)=1.00
Eucalyptus	(Pitch Pine at 31%)	3.84 (all FDIs)	520	(520/393)=1.33

The final firebrand generation rates are approximated by the multiplication of the quantified individual generation ratios of species, wind, and FMC with the reference firebrand generation rate of Pitch Pine. Hence, the firebrand generation rates of forest vegetation for FDI 50, 80, and 100 are found as 8.43, 10.68, and 10.68 pcs/MW/s to use as inputs in the FDS model.

2.2. Model set up

The simulation domain size is chosen as 336 m× 102 m × 90 m with a 1.5 m grid size at the wind developing region and 0.75 m grid size at the area where fireline, firebrand generation and landing occur. These grid sizes are determined according to the grid convergence analysis of Wickramasinghe et al.(2022). Fig. 1 illustrates the developed wind flow introduced with eddies as per Jarrin et al.(2006), prescribed fire, fire-induced buoyancy, and the firebrand landing on the modelled house.

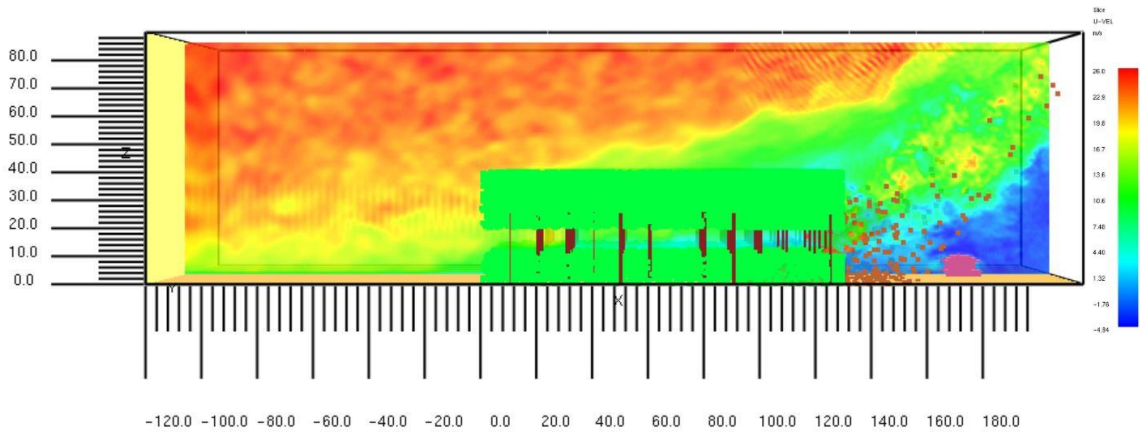

Figure 1- A Smokeview (the visual companion software of FDS) representation of the simulation of Forest fire at FDI 100 and BAL 12.5. The distance between the house and the forest edge is maintained as 50 m according to the BAL.

15 simulations were conducted varying the three different FDIs and five different BALs to calculate the firebrand flux and heat load on the house. The firebrand flux was measured at the strategic locations (gutter, deck, roof, window corners, sub-floor) of the house where firebrands can accumulate and start a secondary ignition. The radiative heat flux was also recorded at the same locations. The total firebrand flux is calculated based on the total number of firebrands received on a unit area of the house at a unit time. The maximum radiative heat flux is taken as the highest value obtained by a heat flux device at any strategic location. We plot the total firebrand flux against the radiative heat flux for FDIs as shown in Fig. 2. Each data point is related to a BAL (or the location of the house downwind).

3. Results and discussion

We use the maximum radiative heat flux and the total firebrand flux on the house to develop a mathematical correlation. According to Fig. 2, the firebrand flux on the house shows a logarithmic relationship with the radiative heat flux with an R^2 of 0.96, 0.98 and 0.99 for FDI 100, 80, and 50 respectively. Both FDI 100 and 80 curves are located over FDI 50 implying the higher firebrand risk for the same radiative heat flux. Although the curves are quite close for the lower three BALs, the FDI 100 has positioned above the FDIs 80 and 50 after BAL 29. This indicates that the firebrand attack is higher for FDI 100 than the FDIs 80 and for some BALs when the house is located close to the fireline.

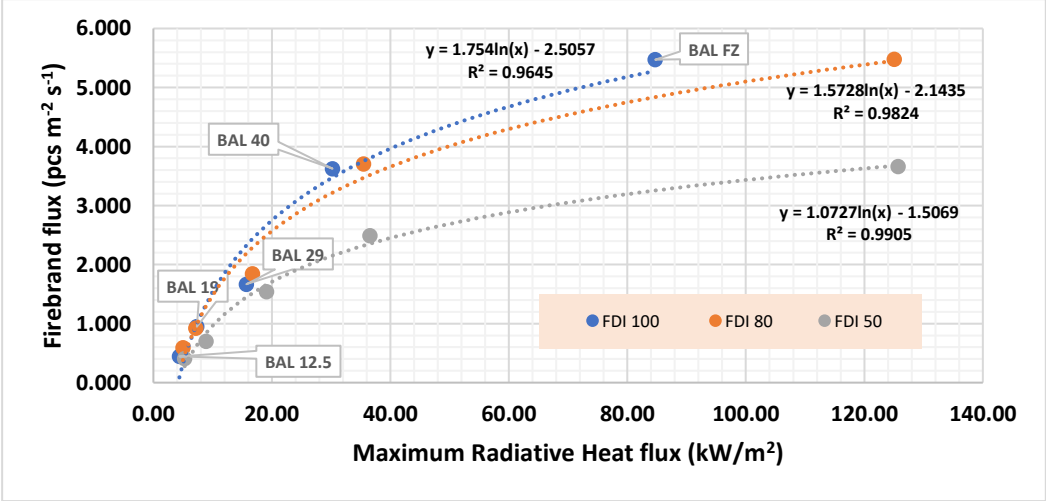

Figure 2- The correlation of the firebrand flux and the radiative heat flux for forest vegetation at FDI 100, 80, and 50.

4. Conclusion

A series of physics-based simulations have been conducted to quantify the firebrand flux on a structure located in the downwind direction of a burning forest. The influences of vegetation species, wind speed, and FMC were calibrated to find the resultant firebrand generation rate to use as inputs in the Eucalyptus tree burning model. The thermophysical data were taken from the literature and the model was set up according to the fuel loads, FDIs, and BALs as given in the AS3959 standard. The firebrand flux and the radiative heat flux on the house were calculated and found a logarithmic relationship between the two parameters. The quantification of firebrand attack was correlated with the existing radiative heat flux to improve the building construction requirements of AS3959 to mitigate the wildfire risk on buildings in the WUI.

Abstract

In highly anthropized Mediterranean environments, more intense and persistent droughts alter the characteristics of the soil substrate and consequently the water status of the vegetation. Causing an increase water stress of the forest stands implies an increase in dead fuel availability and fire risk. This situation together with the current trend of urbanisation in areas adjacent to forest areas, generating the wildland-urban interface (WUI) areas, represents a new field in the firefighting, which presents both regulatory and technical deficits. This paper presents a management model based on the water quantification of the soil-plant-atmosphere system that defines the optimal amount of irrigation needed to decrease fire intensity to a suppression stage in the WUI of La Vallesa forest in the Natural Park of Túria (Valencia, Spain). Mainly highlighted is the ability to manipulate the fire behaviour by intervening the water status of the system through prescribed irrigation. We report that by means of irrigation, the moisture content of the forest system can be increased by 5.49 ± 3.97 %, which translated to energy, implies an increase in the capacity of the system to absorb 14.24 ± 10.32 kJ/kg and this translates into a decrease in a potential flame length of 0.10 ± 0.26 m above its height.

1. Introduction

The tendency in the Mediterranean areas to urbanize in areas adjoining natural systems (mainly forests), has generated a territorial concept called the wildland-urban interface (WUI), which is susceptible to risk since it connects the territorial dynamics with the problem of forest fires (Martín, 2012). Therefore, a fire in a WUI has direct consequences on the adjacent population, which can translate into economic losses due to the burning of agricultural land, buildings, vehicles, etc., and even endangers the safety of the inhabitants.

Historically, social awareness of this problem has been lower to that of wildland fires, which may have influenced the lack of current legislation, technical methods, and experimental evidence to deal with this new situation (Vacca et al., 2020). One key aspect in this WUI context is the possibility to deploy irrigation-based protection systems (e.g. www.sideinfo.es).

This work aims to provide a vision based on eco-hydrology that addresses the problem of fires in WUI areas. The capacity to manipulate forest-water relationships and hence the hydration of the ecosystem can consequently reduce the risk and danger of fires. The main objectives considered are: i) relate irrigation dosage with the water status of the system and fire behaviour parameters and ii) quantify the effect of system hydration on fire behaviour.

Abbreviations

EHV	Eco-Hydro-Voxel	σ	surface-area-to-volume ratio (ft^2/ft^3)
RH	relative humidity (%)	σ_x	surface-area-to-volume ratio specific to each fuel size and fuel type (ft^2/ft^3)
1-h	dead fuel with a diameter of less than 0.6 cm	*wo*	oven-dry fuel load (lb/ft^2)
10-h	dead fuel with a diameter of between 0.6 and 2.5 cm	wo_x	oven-dry fuel load specific to each fuel size and fuel type (lb/ft^2)
100-h	dead fuel with a diameter of between 2.5 and 7.5 cm	δ	fuel bed depth (ft)

h	low heat content (btu/lb)	M_x	dead fuel moisture of extinction (%)
S_T	total mineral content (fraction)	M_f	moisture content (%)

p_p	oven-dry particle density (lb/ft^3)	F_B	flame length (m)

2. Material

2.1. Study area

The study area is located in a private forest called La Vallesa, which is part of the Turia Natural Park in the province of Valencia (Spain). The climate is typically Mediterranean with a marked summer drought. The main land use is forestry with some abandoned agroforestry areas. However, there is also a strong anthropic influence, as the forest is surrounded by residential developments, with an estimated potential impact of 15,000 inhabitants in the event of a fire. Research plots were established in the forest in a representative area dominated by a *Pinus halepensis* stand and constituting a TU2 fuel model (Scott & Burgan, 2005).

2.2. Water status monitoring

The plots have a network of sensors that continuously measure the variables necessary to know the water status of the system. The quantification and therefore monitoring of the actual water status of the forest is done through the "Eco-Hydro-Voxel" (EHV) concept. The EHV is a typified volume of space based on the SPAC, which allows quantifying the amount of water stored in the different compartments or tanks of the volume along the SPAC. Tanks are defined according to the most representative compartments of the SPAC: saprolite/deep soil, surface soil, duff/litter, scrub, trunks, branches, canopy/living leaves and atmosphere.

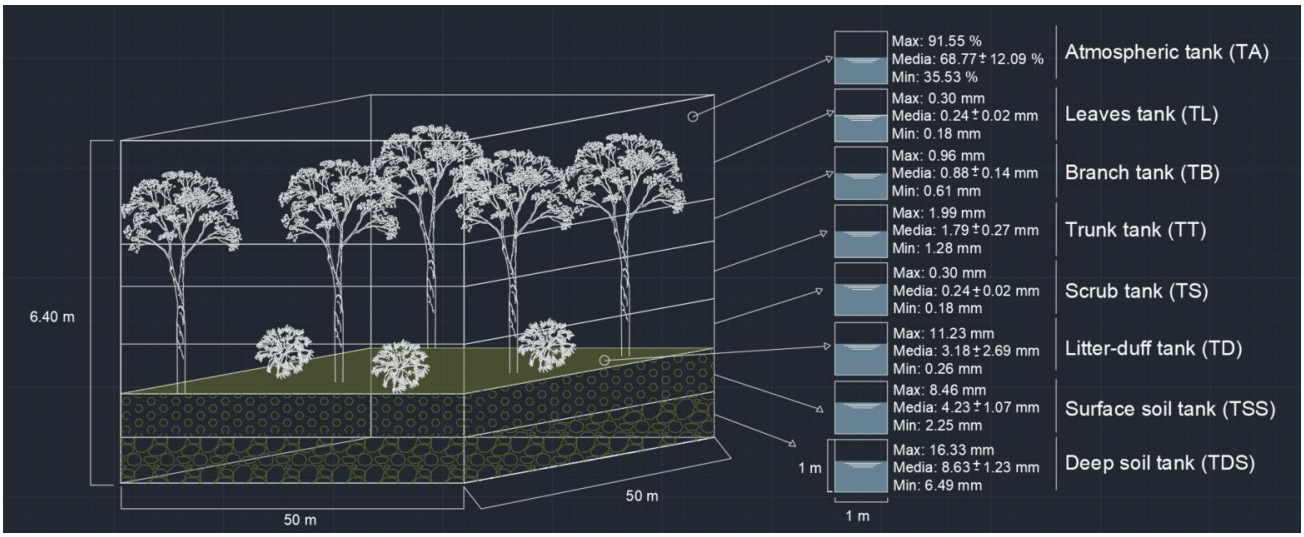

Figure 1- Schematization of the Eco-Hydro-Voxel (EHV) with its subdivisions or tanks. In addition, the basic statistics (maximum, mean ± standard deviation and minimum) of each water content of the tanks are presented.

For the present study, focusing on surface fire, duff/litter, scrub and atmospheric tanks have been used. Litter/duff tank moisture (%) is measured by soil moisture sensors installed between the litter layer and the decomposing organic horizon. Scrub tank moisture (%) is estimated by using an empirical model based on vapour pressure deficit, which was calibrated and trained with real measurements made in different sampling campaigns. Atmosphere tank moisture has the relative humidity (%) and vapour pressure deficit (kPa) as its main proxies for moisture content. These variables are measured by a weather station installed 2 m above the canopy, which also measures the wind speed (m/s) and the temperature (ºC).

Based on the EHV, the calculation of the moisture content (M_f, %) parameter is made, which is a measure of the amount of water in an environment available to a fire. Therefore, this parameter will be the link between the water status of the system and the energy of the fire. Classically this measure of M_f was composed of dead fuels (1-h, 10-h and 100h) and live fuels (herbaceous and woody). Specifically, 1h-moisture was estimated through the moisture content of litter/duff and the atmospheric tank (Rakhmatulina et al., 2021), and in this study it has

been considered that each tank represents 50 % of the total moisture content. The moisture of litter/duff tank that represents this 50 % was included without transformation, however, for the value of the atmosphere tanks, relative humidity and temperature were selected and these two variables were combined using the Baksic et al. (2017) procedure, thus obtaining the value that will represent the other 50% of the humidity of 1h. On the other hand, 10-h and 100-h moisture content dynamics were obtained following Balaguer-Romano et al. (2020). These authors consider constant proportions between the different dead moisture contents; thus, we follow this approach to calculate 10-h and 100-h moisture contents as a function of the 1-h moisture content. Finally, the moisture content of the live woody material is taken directly from the moisture content of the scrub tank.

2.3. Effect of irrigation on fire behaviour

The design of preventive (prescribed) irrigations is based on two fundamental objectives: i) to increase the operational capacity of the system and ii) to reduce the danger and potential risk of a fire. Operational capacity refers to the energy absorption capacity of the system through its moisture content. This concept has been studied through the heat of preignition (Q_{ig}, Rothermel, 1972), which is the energy required for one unit of fuel to reach ignition and it is directly related to its moisture content. Fire danger is represented by the flame length (F_B, Byram, 1959) i.e., the distance measured from the tip of the average flame to the center of the flame zone at the base of the fire, and has been considered as potentially dangerous when it exceeds 1.2 m. It is calculated as a function of fire intensity (I_B). For the inputs related to the fuel particle properties, we used standard values: h = 8,000 Btu/lb, S_T = 0.0555 lb minerals/lb wood, S_e = 0.010 (lb minerals – lb silica)/lb wood and p_p = 32 lb/ft3. Some fuel array properties were calculate based on weight method, where σ = 1813.42 ft2/ft3 [σ_{1h} = 2000; σ_{10h} = 109; σ_{100h} = 30] and *wo* = 0.22 lb/ft2 [wo_{1h} = 0.06; σ_{10h} = 0.10; σ_{100h} = 0.05; σ_{1h} = 0.01], the parameter δ was measured (0.33 ft or 10 cm), and the M_x = 30 % (TU2 model as in Scott & Burgan, 2005). Finally, the environmental parameters correspond to real measurements carried out in the experimental plots (weighted moisture content and wind velocity at midflame height). As the plot is very flat, a value of slope = 2.5 % is considered.

3. Results

Detailed quantification of the EHV water reservoirs has shown a clear response of fire behaviour to water input as related to seasonality. With the onset of dry season, the tanks had low moisture content values and Q_{ig} is low and therefore the F_B is high (Figure 2). The accumulated water input (precipitation) in this dry period (dehydrated system) was 60 mm; and the average M_f was 11.63 ± 3.17 %, (average litter/duff humidity of 4.63 ± 3.90 %, scrub humidity of 75.50 ± 7.35 % and atmospheric humidity of 68.33 ± 12.12 %), resulting in an average Q_{ig} of 611.69 ± 8.23 kJ/kg and F_B of 0.84 ± 0.16 m. However, in the humid period (hydrated system), there was a total precipitation of 320 mm, the mean M_f increased to 19.34 ± 3.86 % (litter/duff with 13.75 ± 3.84 %, scrub with 89.02 ± 4.57 % and atmospheric with 74.43 ± 15.26 %), Q_{ig} increased to 631.71 ± 10.02 kJ/kg and F_B decreased to 0.75 ± 0.29 m.

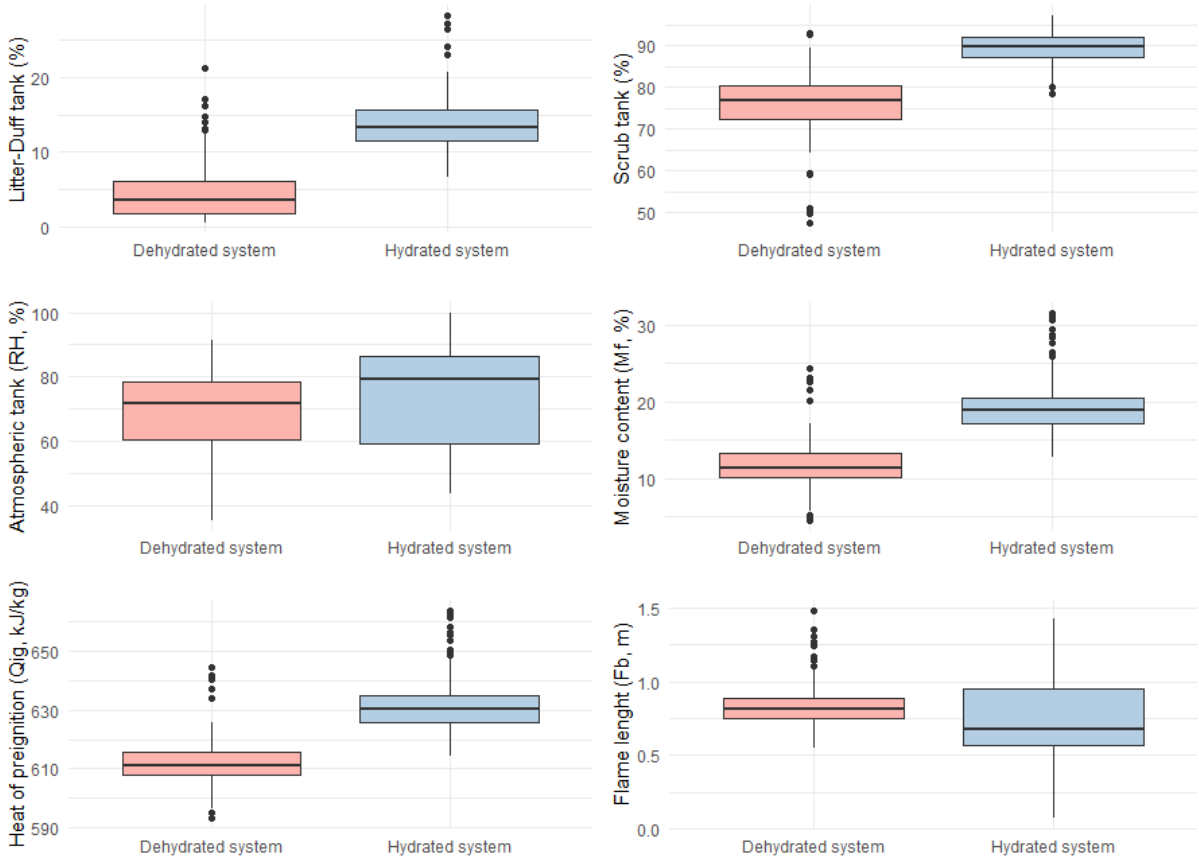

Figure 2- Comparison of the parameters studied in relation to a period of hydration and dehydration.

Regardless of the amount of precipitation and the previous hydration status of the system, the variation observed in M_f between the day before (dry condition) and the day of the water input suffered an increase of 5.49 ± 3.97 %, specifically the moisture content of the litter/duff increased 2.00 ± 3.87 %, the scrub 7.76 ± 7.21 % and the atmosphere 7.47 ± 8.57 %, this translates into a change in fire behaviour of an increase in Q_{ig} of 14.24 ± 10.32 kJ/kg and a decrease in F_B of 0.10 ± 0.26 m. In a particular case where a rainfall of 3 mm occurred (wind speed remained comparable, 1.24 m/s the day before and 1.06 m/s the day of the rain), the system in the day before had a litter/duff tank moisture content of 4.62 %, the scrub tank of 75.10 % and the atmospheric of 49.94 %, being a total M_f of 10.62 %, which makes its potential fire behaviour a Q_{ig} of 609.08 kJ/kg and an F_B of 0.90 m. However, after the occurrence of this precipitation, the system elevated its hydric status to a litter/duff moisture content of 5.82 %, 79.90 % in the scrub tank and 72.72 % in the atmospheric tank, with a total M_f of 12.81 %, implying an increase in Q_{ig} to 614.76 kJ/kg and a reduction in F_B , which became 0.80 m (Figura 3).

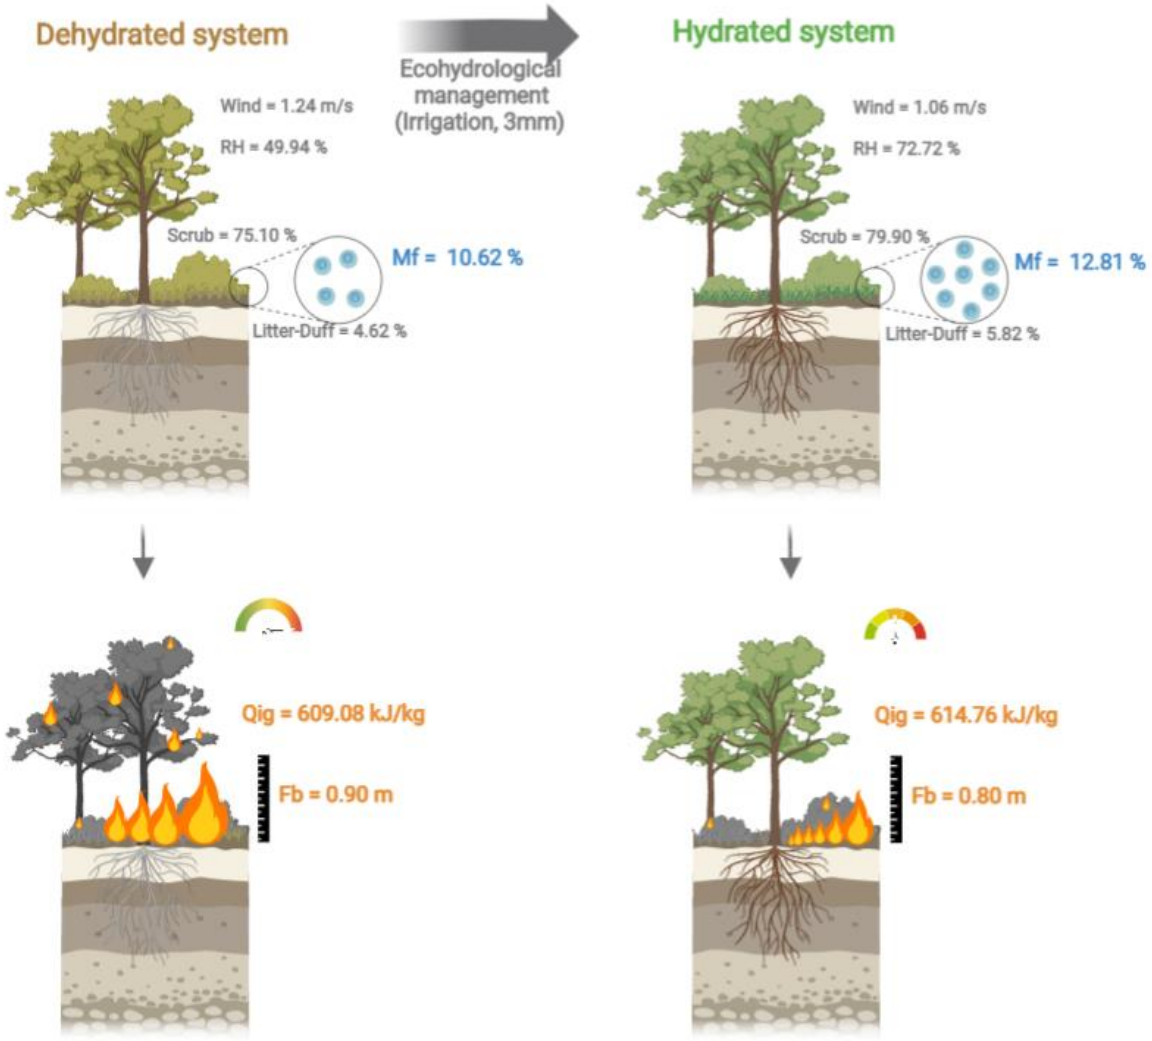

Figure 3- Case study of the change in moisture content (Mf), the EHV tanks used for its estimation (atmospheric or RH, scrub and litter-duff) and associated fire behaviour (flame length (Fb) and heat of preignition (Qig)) of the same system after a 3 mm rainfall.

4. Discussion

The EHV concept, through which the hydric state of the system has been quantified, has been a key point to study the irrigation-system-fire relationship. The main nexus of this relationship has been the transformation of system hydration into fire terms, i.e. the estimation of M_f (input for fire behaviour calculation) through the quantification of the EHV tanks (litter/duff, scrub and atmosphere). Furthermore, eco-hydrological monitoring of the system has allowed us to know the capacity and the real manipulation range of the hydration of the system through irrigation and thus the potential for the variation of fire behaviour.

The quantification of water and fire behaviour relationships is useful in fire-prone areas as it provides key information related to fire risk, availability of fuels, capacity for fire suppression, threats and danger to inhabitants as in the case of WUI areas. In this study it has been seen that through irrigation it is possible to increase the operational capacity of the system by 14.24 ± 10.32 kJ/kg on average, making a fire have to consume this additional heat amount before spreading, even decreasing the potential flame length by 0.10 ± 0.26 m on average, thus reducing the potential danger of the fire and increasing the probability to put the fire out. In addition, this approach that relates irrigation-fire makes it possible to develop irrigation algorithms, which will have the objective of minimizing the water supplied to obtain the greatest benefit of the characteristics of the fire behaviour (Blanco-Cano et al., 2022).

The practicality of the approach of increasing water status through irrigation could be a problem in areas affected by droughts, as water availability is low. This situation can be solved through: i) Use of reclaimed water, ii) eco-hydrological management: thinning and planting of green firebreaks. In reference to the use of reclaimed water the GUARDIAN project (https://proyectoguardian.com/) is a real-life solution and is currently installed in a semi-arid Mediterranean area. On the other hand, thinning, beyond reducing fuel load (which is the classic view in forest fire prevention), is known to increase the water status in the remaining trees (Del Campo et al., 2019; Manrique-Alba et al., 2020) and it should be included in the design of such treatments. Finally, the planting of green firebreaks consists of planting vegetation with low flammability and water retention mechanisms that allow them to have a relatively higher water content. In addition, these firebreaks can generate more humid and shaded areas, which allows for better water retention (Cui et al., 2019). This vision of hydric manipulation through eco-hydrological management for areas where water limitation is a critical factor in water supply through irrigation.

It can be concluded that fire management in WUI zones must bet on taking a pyro-eco-hydrological approach, understanding that the moisture content of the system can be modified and manipulated within certain ranges and that these modifications will have direct changes in the fire behaviour.

Rural Fires, victims, paradigm change, self-evacuation, risk factors

Abstract

Wildfires are the cause of many fatalities in Portugal and around the world. Extreme fire phenomena are increasingly rising to intense and uncontrolled fires, with dimension and destructive potential greater than what was used to be seen and dealt with.

In the past, "rural communities" had a history of peaceful coexistence with fire, and the population consider themselves to be prepared to fight it. However, the widespread abandonment of rural landscape, the decrease of the agricultural activities around the villages and the aging population, lead to villages no longer naturally protected and the wildfires get closer to the houses with increasing intensity. Generally, population still has a poor awareness of fire risk, making, sometimes, wrong last-minute decisions. Therefore, it is crucial to protect rural communities that are now more vulnerable to wildfire threat.

2017 comes with a milestone in the history of wildfires in Portugal due to the high number of fatalities, in two different occurrences spaced in time, but geographically close. In both events 92% of deaths occurred in urban forest interface areas. Analysing the location of mortal victims, it is possible to identify risk factors that lead to the death civilians in rural fires. This paper presents an analysis of the characteristics and causes of death of the victims of the June and October 2017 fires in Portugal, recognizing risk factors that led to their death.

1. Introduction

Rural fires with extreme and unpredictable behaviour are a growing and critical problem around villages, often requiring mass evacuations to protect people and ensure safety (Manzello, 2018). However, the application of these actions in Portugal needs a more detailed analysis because the type of construction is mostly safe. Severe fires cause high devastation in communities, which could include the loss of human lives. The safety of populations at risk depends on accurate risk assessment, emergency planning and the emergency management.

Portugal, like other Southern European countries, faces unparallel circumstances nowadays, where large and uncontrollable fires are becoming more frequent, exceeding the capabilities of existing suppression resources and increasing community exposure (Fernandes, 2017). Sociodemographic changes in rural areas, climate change issues and vegetation changes lead to unprecedented circumstances that require the adjustment of fire use strategies and planning tools (Oliveira, 2021).

Zones where humans and their development, as infrastructures, meet or intermix with wildland fuel, has the designation of urban-forest interface (UFI); called also by urban-rural interface (URI) by some authors due to the translation from the Anglo-Saxon bibliography, as wildland-urban interface (WUI) (Fidalgo, 2012). The UFI areas present the typical problems of urban management, simultaneously with those of forest land management, due to the interaction between the two types of land that in the absence of fires, would be advantageous. However, these areas also have high risk of rural fires. UFI Communities hardly recognise the potential for destruction of forest fires, before experience the fire approaching (Fidalgo, 2012). In Portugal, the interface problem is also an emerging problem, with increasing importance due to the increase of the various

factors associated with it: the aggravation of forest fires, the growth in population on the outskirts of large cities and the frequency of extreme risk situations of a meteorological nature (Ribeiro, 2016).

A recent study reviewed the susceptibility and danger of forest fires in Portugal, introducing new data and extending the study period (Oliveira et al., 2021). This study indicates that in Portugal about 2% of the municipalities have more than 90% of their territory classified as dangerous, while 32% of the municipalities have, on the contrary, less than 10% of classified dangerous area.

Until 2003, rural fires in Portugal were known for the destruction of large areas of forests that affected the population only indirectly through high income losses due to loss of eucalyptus or pine trees, but which only occasionally affected buildings leading to loss of dwellings and consequently of human lives. 2003 and 2005 were as remarkable years due to the civilian's losses. Until then, human losses in rural fires were mainly combatants. Loss of civilian lives as a result of forest fires is a recent reality in Portugal.

The study and discussion of the type of victim, and the conditions that led to their death, is essential for a better understanding of this phenomenon and, from there, to infer the processes of change to be adopted so that these types of situations do not happen again. This paper aims to identify the factors that lead to the loss of human lives during rural fires, studying the characteristics of the fatal victims of the 2017 fires in Portugal, trying to identify their last actions and their last choices, based on analysis of data from the Independent Technical Commission and from the Centre for Studies on Forest Fires of the University of Coimbra from both June and October fires of 2017.

2. Change in the paradigm of rural fires in Portugal

Climatic conditions related to the environment and meteorological surroundings have proved to be of great importance in the development of fire and its propagation conditions. Under certain optimal weather conditions, the probability of massive wildfires increases significantly, as in the case of Pedrógão Grande in 2017 in Portugal (Viegas et al, 2017). Extreme meteorological phenomena appear with increasing frequency giving rise to this type of fire. They are known to be severe and complex, capable of reaching a very large size and high intensity, causing major environmental and socio-economic impacts.

Portugal, like other Mediterranean countries, is experiencing a confluence of two long-term trends: the widespread abandonment of the rural landscape that has become economically irrelevant, together with a strong reluctance by governments to create effective policies to deal adequately with the fire.

According to the legislation of the Portuguese government, in Ordinance n. 301/2020 of 24 December, it is recognized that the divestment in forestry, which contributed to the emergence of a monocultural landscape with a high fuel load and fire risk potential, wich "*when in the presence of severe meteorological episodes, this situation has resulted in large fires, devastating extensive forest and agricultural areas, infrastructure and heritage and putting human life at risk. These episodes, in turn, feed the vicious circle of abandonment, with consequences in terms of ecosystem degradation and the social and economic vulnerability of these territories*." (Portaria nº 249/2020, 2020). It is assumed that the policies implemented so far have not been enough and that populations are increasingly vulnerable to both the social and economic aspects.

Additionally, Portugal is also characterised by dispersed urban agglomerations, mainly in the countryside. Thus, it is essential that rural fire risk assessments consider not only hazard and exposure, but also social vulnerability (Oliveira et al., 2021). Dispersed urban agglomeration was synonymous of small villages of compact construction, but isolated in the landscape. Especially in the north and centre of Portugal, there are other types of villages called "*Avulso*" and "*Espraiado*" settlements that also contributed to this dispersed urban agglomeration. "*Espraiado*" settlement is briefly characterised by being consolidated in a network of rural paths spread out in all directions and is also characterised by having a vegetable garden or farm at the back; while *Avulso* settlement is characteristically off-center, presenting a loose building on a rural matrix., many of them are used as second homes, without permanent occupation.

In the scope of rural fire risk, the affected people are generally in rural areas, but recent cases have shown that this is not always the case, and the fire has been increasingly taking on such a dimension that it crosses borders, incoming urban areas as well. In 2005, a fire devastated the outlying of Coimbra, even going into the urban area due to spotting. The fire started on August 19 in Vila Nova de Poiares, but it was a re-ignition that gave rise to

a new fire, which, covering several kilometres, entered the city of Coimbra on August 21. Ten years earlier, in August 1995, a similar event also affected the same city, causing the damage of an apartment and of some vehicles.

These events highlight a change in the exposure of populations to danger, as it is no longer just a problem in rural areas but also in some urban areas, where this risk is not yet considered. People who live in urban or residential areas, among patches of forests, hardly recognise the potential for destruction of forest fires, before experiencing a situation of an approaching fire (Fidalgo, 2012).

In rural areas, despite the high risk of exposure, residents are used to live with forest fires and over the years have developed ways to protect themselves against this problem. The villages were protected by surrounding natural containment strips (agricultural fields) and in case of fire the active population came together to protect the distressed housing. However, with the abandonment of agricultural practices and the exodus of younger people to urban areas, this natural protection is decreasing. Quite often the abandoned agricultural areas are replaced by forest plantations, bringing trees closer to the houses.

Additionally, elderly residents keep the same feeling that they are safe, but the context in which they live has changed. In this way, we can consider that the inhabitants of these villages may have a false sense of security, which will make them stay close to the houses and refuse to evacuate their village, thus increasing their vulnerability.

If, on the one hand, there is urban expansion in rural areas towards forested areas in some areas of the country, especially in the north and centre of Portugal, due to tourism and demand for country houses for second homes, on the other hand, the abandonment of activities such as agriculture and grazing, the depopulation of rural areas and the continuous exodus to large urban environments by young people, lead to the abandonment of these areas, leaving elderly populations vulnerable, even on the outskirts of cities, making the forest and areas of bush to get closer and closer to the buildings.

3. Human losses in wildfires in Portugal

The loss of a human life due to forest fires will always be the greatest loss regardless of the area burned by the fire or the cumulative number of fires each year. In Portugal, records of the loss of human lives due forest fires are available since 1966.

3.1. Historical wildfire deaths around the world

Year after year, wildfires are killing people around the world and some of the fires led to the loss of a large number of people in a single occurrence. In Greece in 2018, around 100 people died in just one event in the town of Matti; in Australia in 2009 at least 173 people died in several fires that occurred in what became known as Black Saturday and in Russia in 2010 where, during one of the hottest summers ever registered, wildfires killed 60 people in July. There would be many other examples, even in the more distant past, but the fire known as “Peshtigo Firemost” that killed at least 1200 people in the United States of America in 1871 has being recognized as the deadliest event in history.

In Portugal, this is a recent reality. Over the years, there are negative milestones in history, remembering the years of 2003 and 2005 where respectively 21 and 23 people died (Viegas, 2004) and the fateful year of 2017, with the loss of a total of 66 casualties in June and 57 in October. The year of 2017 was a milestone in history due to the high number of fatalities, in two different occurrences spaced in time, but geographically close, where most deaths occurred in urban forest interface areas.

Australia's Country Fire Authority (CFA) conducted a retrospective study of civilian deaths that occurred in the fires in Victoria. The investigation used the coroners' reports to determine the circumstances of each death. Many of the case studies illustrate the risk resulting from late evacuation and poor understanding of fire behaviour. Three categories of victims were identified:

-victims who recognized the real threat to their safety with enough time to save their lives, but chose an ineffective survival strategy;

- victims who did not recognize the real threat to their security in time to implement an effective survival strategy; and

- victims physically unable to implement effective survival strategies. (Handmer, 2005)

These victim typologies, according to the analysis of deaths related to the 2017 fire in Portugal, are remarkably similar.

3.2. Analysis of fatalities in the June 2017 occurrence in Portugal

The June 2017 fire complex will go in the history of rural fires in Portugal, as it caused 66 fatalities, making it one of the most serious fire disasters in our country, and one of the worst in Europe. It consisted of several events, the most critical being those that started in Pedrógão Grande, and in Góis, which were associated with three other fires that consumed a total area of 45,328 ha (Viegas et al, 2017).

Following these fires, the Portuguese government created, through Law nº 49-A/2017, of 10 July, the Independent Technical Commission (ICT) with a mandate to carry out an independent assessment of those fires. At the same time the Government requested to The Centre for Studies on Forest Fires (CSFF- ADAI) of the University of Coimbra to also carry out a study on the conditions of occurrence, initiation, and propagation of fire, with particular emphasis on the study of its propagation and the analysis of fatal accidents (Viegas et al, 2017). Both studies led in the same direction, and they are complementary.

The ICT report identified 64 fatalities due to the fire and carried out an exploratory analysis of the conditions and particularities of the human victims who died because of this fire. Note that the ADAI report counts one more victim accounting 65 victims because this report counted one victim who died two days later, following serious injuries. This victim was the only firefighter among the other victims, all civilians. Neither of the two studies count the number of injuries. Later one other injured person died in the hospital bringing the total number of fatalities to 66.

Analysing the age of the victims, most were between 30 and 70 years old, active people, without limitations in the process of escape or risk perception (figure 1). As for gender, the number of victims is very close, so it was not considered a risk factor or characteristics related to the cause of death.

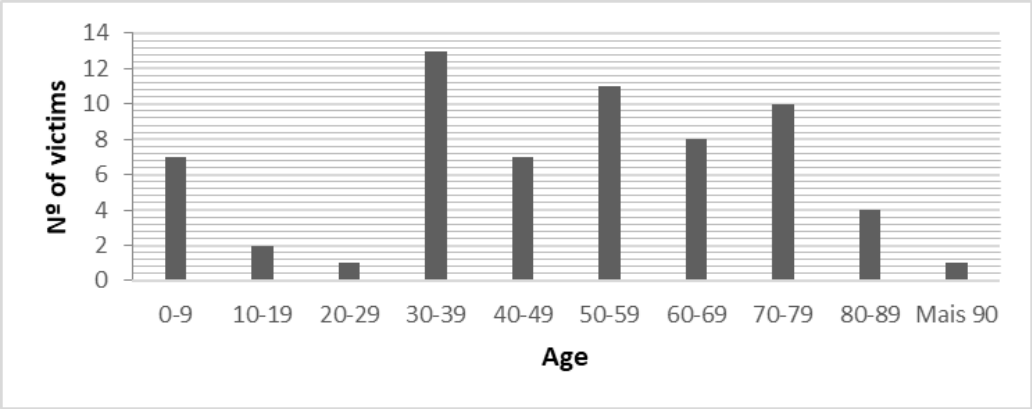

Figure 1- Distribution of the age of the victims– June 2017 (CSFF- ADAI 2017)

An important factor in this analysis is the relationship of the victims with the place where they died. According to the data of CTI report, half of the victims were residents of the villages affected by the fire. However, it is the high number of occasional visitors that needs special attention (figure 2).

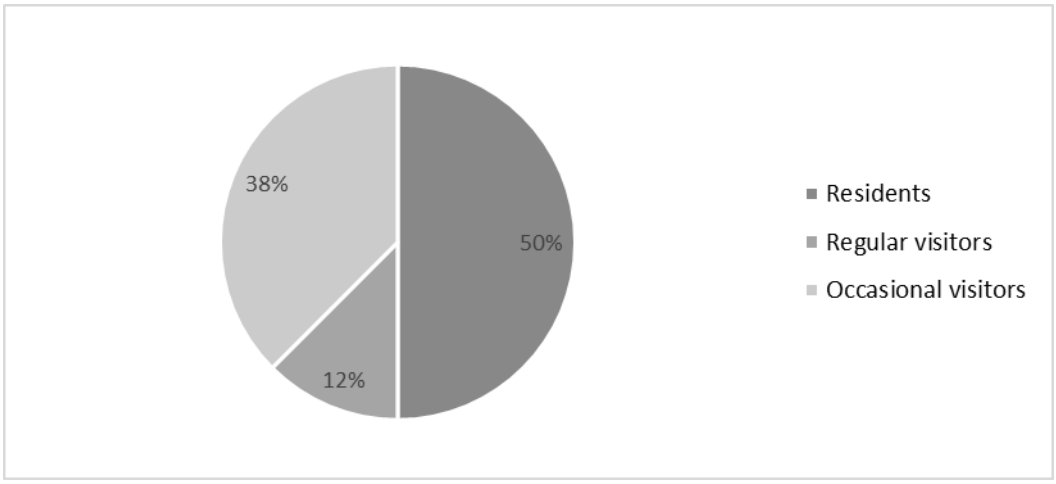

Figure 2- Relationship between the residence for the victims and the place of death – June 2017(ICT 2017)

It should be noted that this is a very popular zone in the summer, mainly for its river beaches and for leisure activities. The violence of the fire, the lack of knowledge of escape routes, self-protection measures for rural fire situations, combined with the lack of the presence of competent authorities to give indications, significantly increase the panic of these people, looking for escape routes became their way to death. Only 4 of the 66 victims died inside their homes.

Regarding the distance from the place of death to the victims' homes, 47% die more than 5 km from home. These victims are tourists and visitors, who, whether or not they have a relation with this zone, they were on a occasional visit (figure 3).

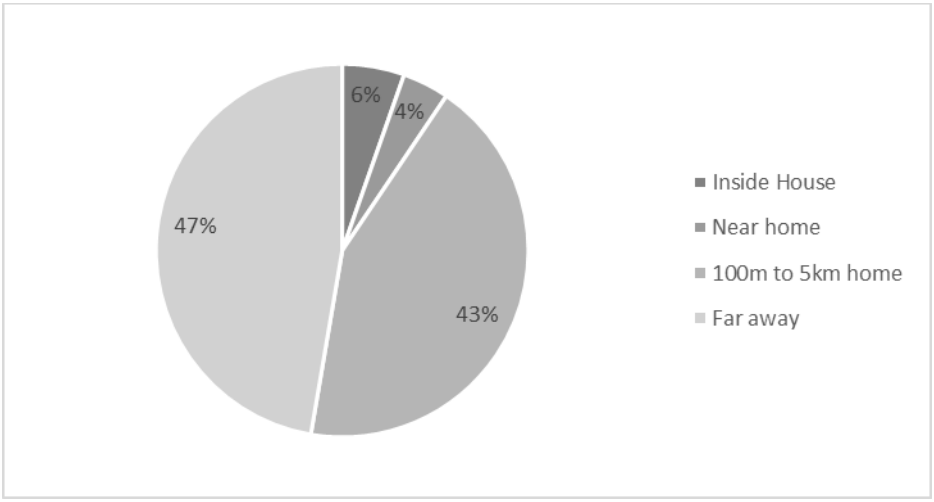

Figure 3- Relationship between the victims and the place of death – June 2017 (ICT 2017)

However, 43% of the victims died between 100 meters and 5 km away from their homes, which indicate that the victims tried to run away in the face of the approaching fire, considering that they were going to get safety. Additionally, regarding the circumstances of death, from the analysis of data, it is considered that 70% of the victims were running away from the fire (figure 4).

Figure 4- Relationship between leave and stay on the number of deaths - June 2017 (ICT 2017)

In the group of victims who did not run away the fire, the report identified evidence that, in addition to the 4 victims who remained in their homes and who were caught by the fire there, the remaining victims who were not running away were passing through that area, returning home or to their accommodation after a day of sightseeing in the mountains. Regarding how the victims fled the fire, the CSFF- ADAI report identifies that 89% of victims chose the car as a means of escape.

3.3. Analysis of fatalities in the October 2017 occurrence in Portugal

In the sequence of the June fires, also in the 15 October fires, the Portuguese Parliament also requested the constitution of the Independent Technical Commission and the Portuguese Government requested to CSFF-ADAI a study of the most relevant facts of these fires, with the Country still in the aftermath of the June fires and still in shock from this new disaster.

Although both reports work in the same direction, the number of victims identified in both is not coincident, and the CSFF- ADAI report identifies and analyses 51 fatalities and the ICT only recognize 48 victims. This discrepancy is mainly due to the fact that the ICT report considers the direct victims of the fire (and that were investigated by the Judiciary Police) only, while CSFF- ADAI report analysed victims directly and indirectly related to the fire, based on 40 accidents that resulted in these deaths.

While in the fires of June 2017, all victims perished in a short time and limited zone, in October 2017 the victims were dispersed for a complex of different fires. In the October fire, more than 50% of the victims were 50 years of age or older (Figure 5). This fact, important in the following analyses, shows that the victims of these fires were mostly elderly, in many cases with health problems and mobility difficulties. As for gender, in this complex of fires, 65% of the victims were men and 35% women.

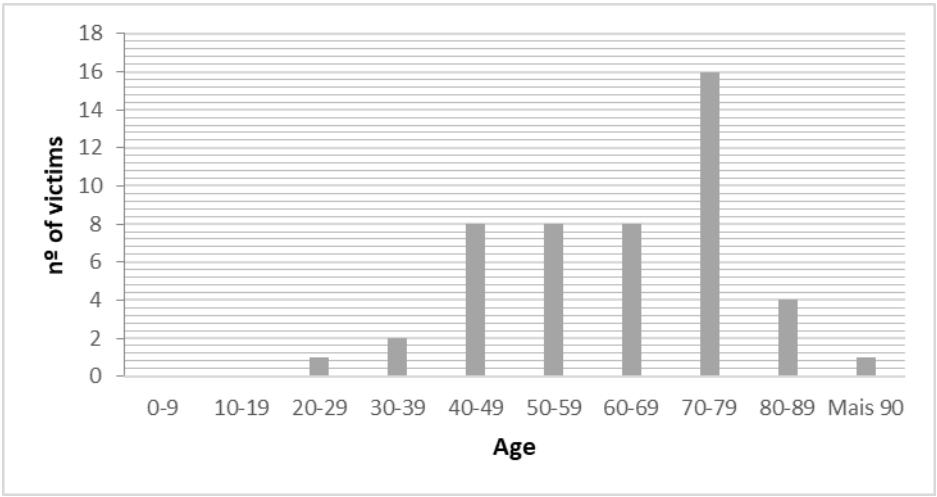

Figure 5- Distribution of the age of the victims– October 2017 (ICT 2018)

The analysis of the relationship of the victims with the place of death shows that 86% of the victims were residents in the area. In addition, since most victims were old people, they end up dying either inside their homes or nearby. (Figure 6).

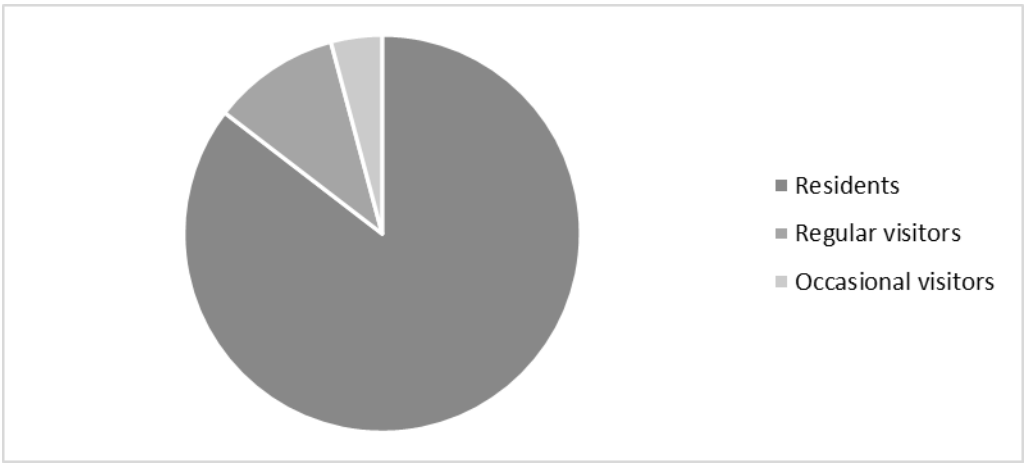

Figure 6- Relationship between the residence for the victims and the place of death - October 2017 (ICT report 2018)

The distribution of distances from the place of death to the home is more heterogeneous in October fire (Figure 7), allowing to conclude that there were different circumstances and decision-making by the victims.

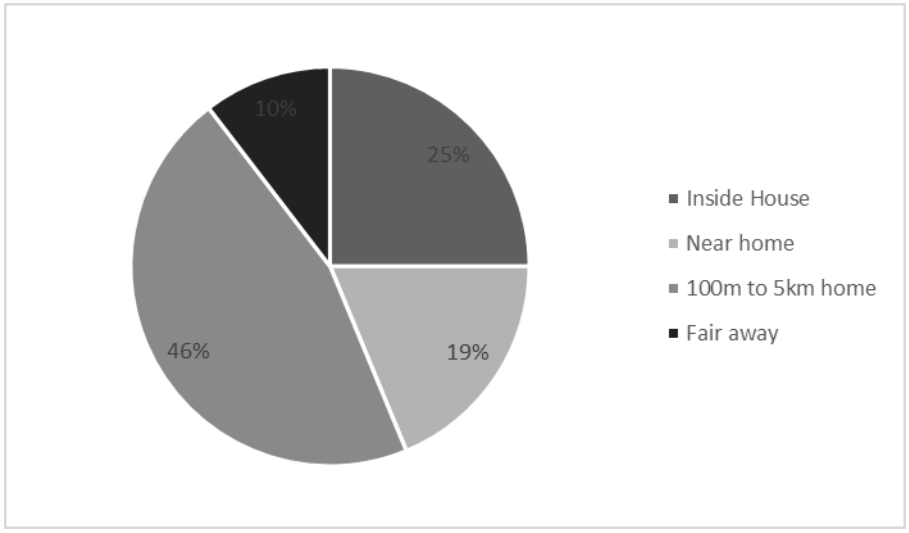

Figure 7- Distance between the residence for the victims and the place of death - October 2017 (ICT report 2018)

There are about 44% of victims who died inside or near houses, but a large percentage of people, about 46% tried to run away. It should be noted that, according to the ICT report, 60% of the houses of the victims of this fire did not burn. In this case, 63% of the people tried to run away (figure 8).

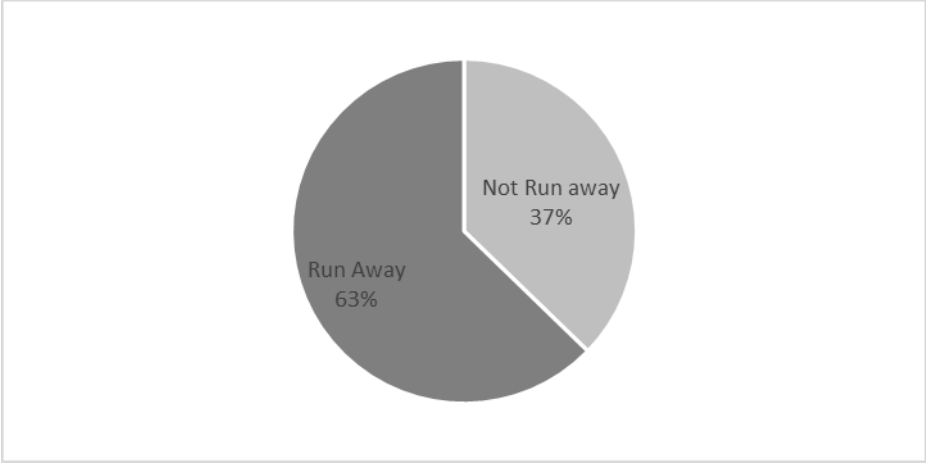

Figure 8- Relationship of leak with the death process – October 2017 (Viegas et al 2018)

After the June fires it was expected that people would have learned and chosen to stay in their homes and not choose to run away. But even so, a large percentage of people died while trying to run away.

4. Discussion of results

The analysis and discussion of the type of victims, and the conditions that led to their death, is an essential tool for a better understanding of this phenomenon and, from there, to infer the processes of change to be adopted in order to avoid such disastrous events. In this study and from both analysed fires, it was observed that the victims have very different characteristics.

The fire of June 2017 is a fire with great severity on the surface (CTI, 2017), and the fatalities were mostly young people and adults, who took advantage of a weekend for leisure activities. Many of them, faced with the imminence of a major fire, decided to use their vehicles and move away from the scene of the fire. With limited information about the area, they followed the only path they knew and were caught by the front of the fire along the way. Regarding the victims who lived in the area of the fire, it is observed that none of the houses of the victims who decided to flee were affected, and staying at home would have been the best option. These people would be safe, and the option of escape became their exposure factor, leading to their death.

From the analysis of both reports, the conclusions stated that after June 2017, the population would have been left with the idea that fleeing would be the most dangerous option. However, and not contradicting the validity of this thesis, it is important to understand here that the typology of victims is different in the occurrence of October 2017.

The victims of October 2017 were elderly people, some of them with limitations in perception and reaction to danger as well as in mobility. Thus, according to the reading and analysis of the survivors' reports, contained in the CEIF-ADAI report, a large number of victims were surprised by the flames already in the vicinity of their home or during the night.

It is also important to point out that, with the change in the fire paradigm, as mentioned above, the elderly populations maintain their belief that they are safe in the villages, not recognizing the risk situation they are in. Adding to this idea, the disbelief in the authorities of fire fighting forces, make the populations stay to the limit near their homes with the idea of protecting them.

In this way, and as a way of summarising the conclusions stated above, the following risk factors were identified:

- Growing demand for nature-based tourism: With the change in the dynamics of fires in Portugal, they take on more and more proportions and dynamics that are difficult to identify in advance. The high demand for rural and forested areas for tourism and leisure, essentially by residents of urban areas, significantly increases the number of people dispersed in these spaces. In addition, visitors are mostly people who are poorly prepared and unaware of the risk of forest fire, thus increasing their vulnerability.

- False feeling of inhabitants in rural areas: inhabitants in rural areas have become used to living with fires. With the abandonment of rural areas, the forest tends to invade the villages, significantly increasing the urban-forest interface. The feeling of safety that the inhabitants had before is no longer real and currently the rural settlements are very vulnerable to fires, being a relevant risk for their inhabitants.
- Demand for rurality and nature-based experience: although the exodus of permanent inhabitants from the villages in the countryside in recent decades, there is an increasing demand for accommodation and/or housing in rural areas, essentially by foreigners. There is also an increase in the return of retired people to their origins, in search of an end of life in the tranquillity of the countryside. This factor has further contributed to the fact that, in addition to the forest entering the alleys, new construction often "enters" the forest in search of tranquillity through contact with nature;
- Strong exposure of vulnerable communities to risk: With the exodus of young people to cities, villages become increasingly aged. The sense of neighbourhood ceased to exist, and it is increasingly common for the elderly to be debilitated in their homes, cared for and often visited by employees of social solidarity institutions. In the face of a fire situation, and in addition to the difficulties associated with age and illness, indirect fire products such as smoke and gases substantially affected these people;
- Understanding the escape process: The lack of preparation and awareness make the population wait for the fire to arrive at the houses. In the face of very intense fire phenomena, combined with poor information and the lack of competent authorities on the ground to guide their exit process, last-minute self-evacuation will increase people's exposure to the fire from which they are fleeing.

5. Conclusions

Forest fires continue to be the source of many fatalities both in Portugal and around the world.

The analysis of fatalities resulting from the 2017 fires in Portugal shows that people still have a poor perception of fire risk, making wrong last-minute decisions that lead to death. The lack of awareness combined with the lack of credible information means that, in the face of a fire, people make decisions based on what they know from their experience on past events. The disrepute in public policies and in action also increase it.

With the analysis of the location and of some characteristics of the mortal victims it is possible to identify risk factors that lead to the death of civilians due to wildfires, such as the increase in demand for rurality, both for permanent and tourist housing, of inhabitants coming from urban areas, which are not familiar with wildfires.

Another problem, very evident in the October fires, is the false sensation of security of elderly population. The habitants in rural areas have a history of peaceful coexistence with fire and consider that they are prepared to face it. However, the abandonment of rural areas, abandonment of the agricultural activities that were developed around the villages, mean that villages are no longer naturally protected and that a fire gets closer to the houses with greater intensity. The strong relationship of belonging to their place of residence means that specially the elderly people want to stay close to their homes, believing that they are naturally protected, something that used to happen in the past. This fact makes these populations even more exposed and vulnerable.

Finally, the lack of preparation and awareness make the population wait for the fire to arrive at their homes. In the face of very intense fire phenomena, combined with poor information and the lack of competent authorities on the ground to guide their exit process, last-minute self-evacuation will increase people's exposure to the fire from which they are fleeing.

The conclusions obtained with this study are intended to be the stepping stone for future work on the creation of methodologies for the protection of civilians in the face of forest fires.

Physics-based simulation, grass fires, quasi-equilibrium spread

Abstract

There are two basic modes of fire spread: buoyancy driven where the fire plume is approximately vertical, and wind driven where the fire plume is attached to the surface. The buoyancy driven mode is usually identified by Byram number Nc>10, and the wind driven mode identified by Nc<2. Grass fires at field scale over a range of Byram numbers are simulated using a physics-based model and the mechanisms of heat transfer to the unburnt fuel are analysed. The wind speed is varied to give different Byram number and different fire behaviour. The current thresholds on Byram number are found to correctly classify the behaviour of the fire plume. Previously it was thought that radiative heating dominates convective heating for buoyancy dominated fires, and convective heating dominates radiative heating for wind dominated fires. However, the radiative boundary heat flux is found to dominate the convective boundary heat flux in all cases. The convective heat flux along the centreline ahead of the main fire front increases with wind speed. The results imply that the heat transfer mechanisms, at least for this fire configuration, is more complicated than previously thought. Further research is required to understand if the convective heat transfer mechanisms are adequately reproduced in the simulations.

1. Introduction

The Byram convective number Nc (Morvan and Frangieh, 2018) is used in various parts of the literature in an attempt to classify fires as wind-driven (wind-dominated, shear force dominated, or sometimes called the boundary layer mode) or buoyancy-driven (buoyancy dominated, plume driven, or plume mode). In wind-driven fires the flame is elongated and at an acute angle to the ground. Radiative and convective heat transfer to unburnt fuel is thought to be enhanced by the flame geometry. In buoyancy-driven fires the flame is roughly vertical and therefore it is hypothesised that the heat transfer to the unburnt fuel is almost exclusively by radiation (Morvan and Frangieh, 2018). The importance of convective structures and convective heating on fuel ignition and fire spread has been studied experimentally (Finney et al., 2015). The equation for Nc is

$$Nc = \frac{2gQ/(\rho\, c_p\, T_a)}{(U_{10} - R)^3}$$

where U_{10} is the wind speed at 10 m, Q is the fire intensity, g is the acceleration due to gravity, R is the rate of spread, ρ (1.2 kg m^{-3}) is the gas density, c_p is the gas specific heat capacity (1.0 kJ kg^{-1} K^{-1}), and T_a is the ambient temperature. Therefore, the Byram number can be thought of as measuring the relative importance of the buoyant or convective force and the shearing force upon a fire. The thresholds proposed for the Byram number are $Nc < 2$ is a wind-driven fire, $Nc > 10$ is a buoyancy-driven fire, and $2 \leq Nc \leq 10$ is some intermediate fire behaviour.

Physics-based simulations are becoming a popular tool for wildfire investigation. Here we use the Wildland-Urban Fire Dynamics Simulator (WFDS, subversion 9977, based upon FDS version 6.0), which has been validated against field scale fires (Mell et al., 2007, Moinuddin et al., 2018).

Four simulations are conducted, with the driving wind speed the only parameter varied across the simulation set. Specifically, we consider the following wind speed: $U = 3$, 4, 6, and 10 ms^{-1}, which are referred to as the

U3, U4, U6, and U10 cases, respectively. The U6 simulation replicates the CO64 experiment conducted during the Annaburoo campaign (Cheney et al., 1993). The rate of spread data for the U3, U6, and U10 cases were presented in (Moinuddin et al., 2018) (averaged quasi-equilibrium value only) and (Sutherland et al., 2020) (values for all time). The Byram number for U3, U6, and U10 at all times was also presented in (Sutherland et al., 2020). All other results, namely the heat transfer and flame shape results, presented here are novel.

2. Methodology

WFDS is a fully physics-based fire spread simulator, that is, the solid fuel degradation, gas-phase combustion, heat transfer and fluid flow are explicitly simulated with as few parameterisations as possible. The simulation methodology for grass fire is also well established and the method used here is identical to (Moinuddin et al., 2018, Sutherland et al., 2020).

Several simplifying assumptions are used to model the fuel bed. The fuel is considered as a thin layer on the ground and heat transfer by conduction between the fuel elements is neglected. The fuel dehydrates at 393 K and pyrolyses between 400 and 500 K following a linear mass loss rate [7].

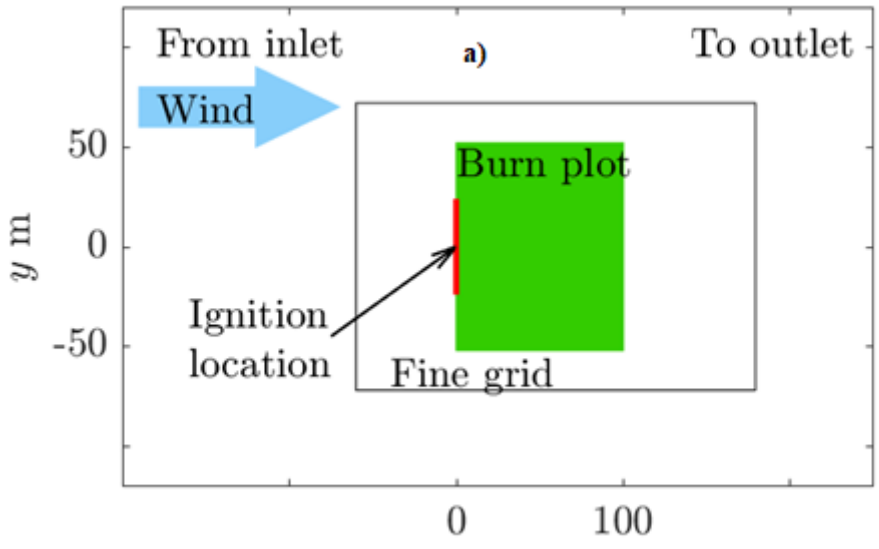
The heat transfer is modelled with several simplifying assumptions. Heat transfer by convection is approximated using an empirical correlation based on approximating the fuels as cylindrical particles. The fuel height and structure are modelled as an aerodynamic drag force term in the fluid momentum equation. The parameters of the convective heat transfer and aerodynamic drag model are deduced from experimental measurements. The flame emits radiation, and the radiation transport equation is solved by the discrete ordinates method. The combustion zone is difficult to resolve using LES, and therefore the gas temperature inside the flame can be underpredicted. Because the emitted radiation depends on the fourth power of gas temperature an underprediction can result in large errors in the radiation term. Therefore, within the flaming zone the source of radiation is a function of local heat release rate per unit volume. Outside the flaming zone, gas temperature is well resolved and the usual fourth power of temperature relation is used. Full details of the WFDS model can be found in (Mell et al., 2007).

3. Results and discussion

3.1. Quasi-equilibrium fire spread

The contours of burning area over time, are extracted from the boundary temperature, T, data. The $T = 400$ K contour at time t represents the extent of the burning region.

The burnable region of the simulation domain and example fire isochrones for the U4 case, are shown in Figure 1.



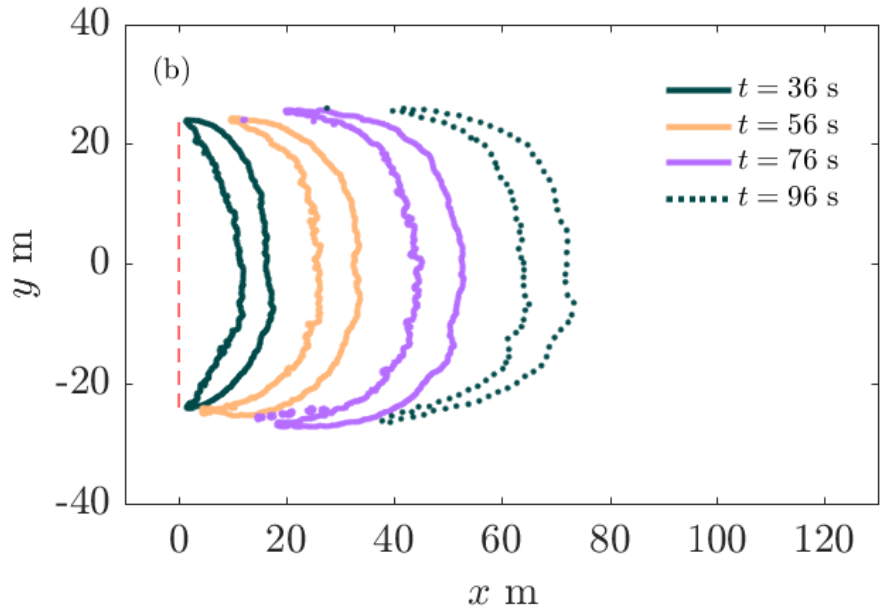


Figure 1- (a) a schematic of the simulation (b) example fire isochrones for the U4 case.

The rate of spread of the fire is estimated from the boundary temperature along the domain centreline. The location of the burning region, x_* is identified from the centre of the interval along $y = 0$ where $T_s > 400$ K. The time dependent rate of spread is then the time derivative of x_*; the derivative is approximated from the simulation data using the standard first-order forward difference scheme:

$$\mathrm{R(t)} = \frac{dx_*}{dt} \approx \frac{\mathrm{x_*(t_{n+1})} - \mathrm{x_*(t_n)}}{t_{n+1} - t_n}$$

The time interval between the data points is 1 s.

Because the data is noisy, the results are smoothed by a 5-point moving average. The quasi-equilibrium rate of spread R_{qe} is then judged manually from the region where $R(x_*)$ is approximately constant. $R(x_*)$ is shown for the quasi-equilibrium regions for all cases in Figure 2(a). Plotting against location stretches $R(t)$ for the higher speed cases to provide a consistent abscissa and allow easier comparison between the different wind speed cases. R_{qe} is achieved at different times for different driving wind speeds. However, the distance from ignition at which a fire can be deemed quasi-equilibrium is approximately the same: 50 m, which is the threshold used here. $R(x_*)$ decreases rapidly from approximately $x_* = 95$ m as the fire reaches the end of the plot, and these data are omitted from the plots and subsequent analysis. Figure 2(b) shows the corresponding Byram numbers.

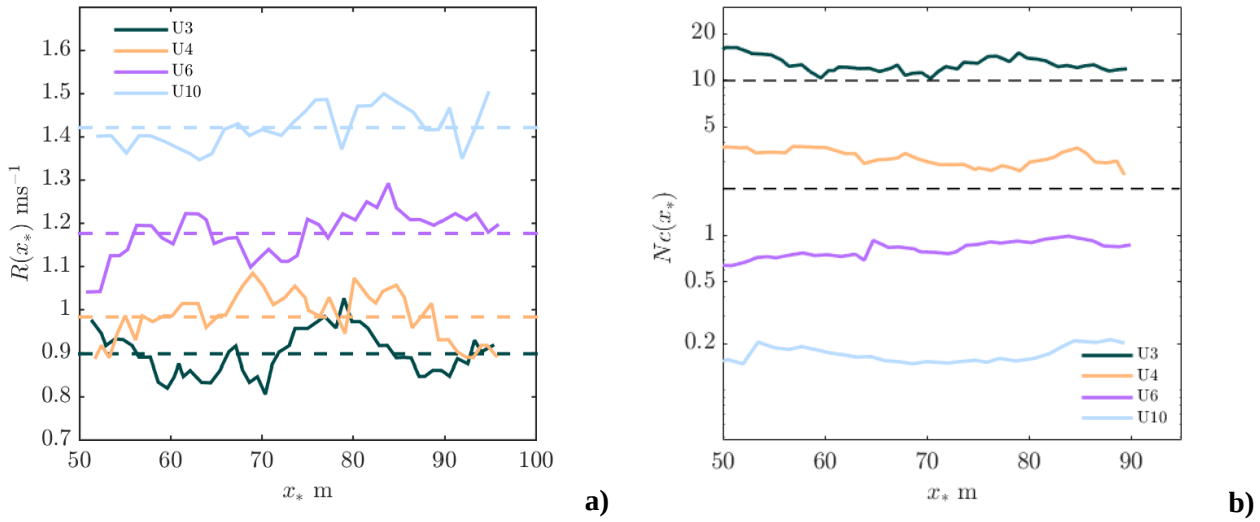

Figure 2- (a) Rate of spread as a function of distance from the ignition line, in the quasi-equilibrium range. (b) the Byram number. The black dashed lines indicate the threshold limits of Nc=2 and Nc=10.

3.2. Quasi-equilibrium flame shape

Because the fires spread at a quasi-equilibrium rate, and the head fire geometry is approximately constant during this phase of spread, ensemble averages of pyrolysis front, boundary radiative heat flux, boundary convective heat flux, centreline heat release rate, and centreline wind velocities can be constructed in a reference frame that moves with the fire. Similar ideas were used by Mueller (2107) to analyse flame geometry.

To construct the ensembles, all data outside of the quasi-equilibrium region were discarded. The trailing edge of the fire was selected as the reference point. At each output step the data was circularly shifted such that the reference point was located at $x = 0$. That dataset was then averaged in time. Errors are introduced by the circular shift; however, these occur far upstream ($x < -100$ m) and far downstream ($x > 100$ m) and can be discarded.

The ensemble averaged u-velocity contours (shaded colours) and the contour of 10% of maximum heat release rate (red) are shown in Figure 3. The red contours were selected as a representation of the flame shape: most of the heat released by the flame is on the inside of this contour. The white arrows in the plot are vector representation of the ensemble averaged u- and v-velocities. In the U3 case, the u-velocity is negative on the downstream side of the flame. To highlight this, the $u = 0$ contour is shown in black. This, and the velocity vector field (white arrows), indicates that the flame and plume entrain fresh air from both sides and is therefore truly a buoyancy dominated fire, consistent with the Byram number prediction. No other cases exhibit two-sided entrainment into the plume. The U4 and U6 cases exhibit roughly vertical flames like the U3 case. The U4 and U6 case exhibit downstream enhancement of the u-velocity, however, this is more prominent in the U6 case. In the U4 case the velocity enhancement decays after approximately 25 m but the enhancement persists for at least 50 m in the U6 case. This suggests that the plume of the U6 case has attached to the ground and this attachment persists for some distance. The plume attachment is consistent with the Byram number prediction of a wind dominated fire. The U4 case has an intermediate Byram number, although with $Nc \approx 3.26$ this fire is notionally closer to wind dominated than buoyancy dominated. The single sided entertainment is consistent with a wind dominated fire, but the u-velocity enhancement does not persist for significant distances, suggesting that the plume has detached close to the flaming region. The U10 case shows an elongated heat release rate contour and significant downstream enhancement of the u-velocity; consistent with a wind dominated fire.

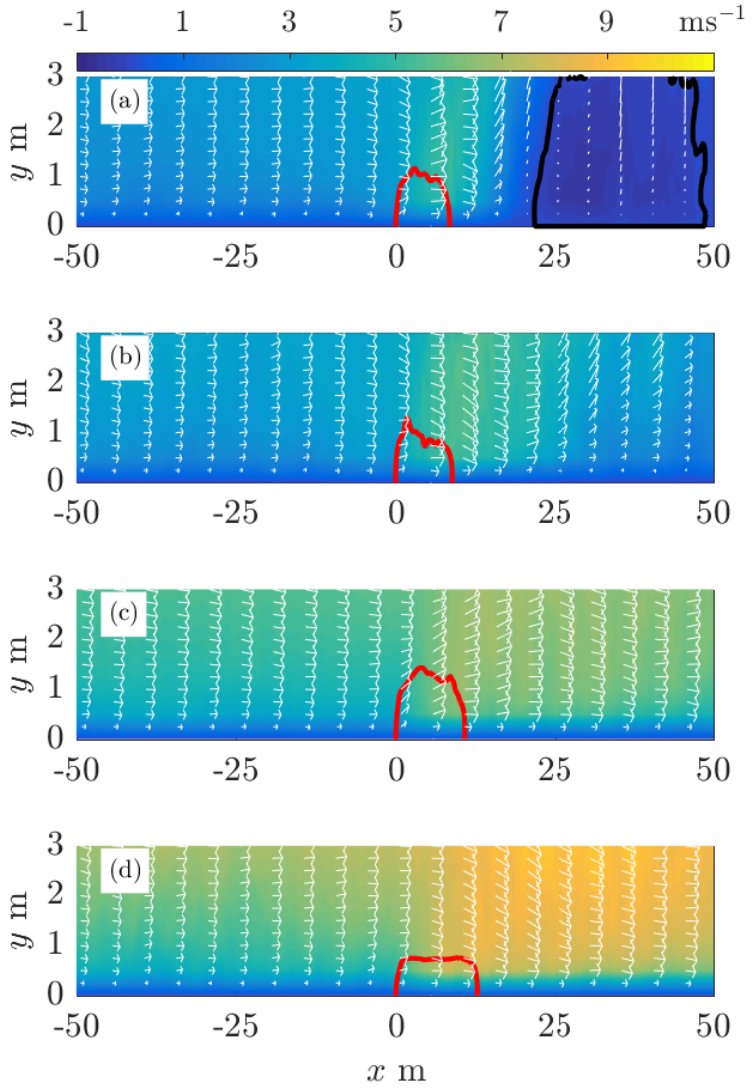

Figure 3- Contours of 10% of maximum heat release rate (red) per unit volume along the line y = 0 averaged in time over the quasi-steady regime superposed on colour contour plot of averaged u−velocity (a) U3 case (b) U4 case (c) U6 case (d) U10 case. To to highlight the region of negative u−velocity in the U3 case, the u = 0 contour is plotted in black. The white arrows show the direction of the ensemble averaged wind field along the centreline

3.3 Analysis of heat transfer

To investigate how the mechanisms of heat transfer change with the mode of fire propagation, the total radiative and convective heat fluxed received by the unburnt fuel is computed. However, the data may still include cooling of the unburnt fuel by radiation and convection, and such cooling is expected at the flanks and trailing edge regions of the fire. To examine the regions of heat transfer, the contours of ensemble-averaged boundary (z=0 m) heat flux are shown in Figure 4 (radiative) and Figure 5 (convective).

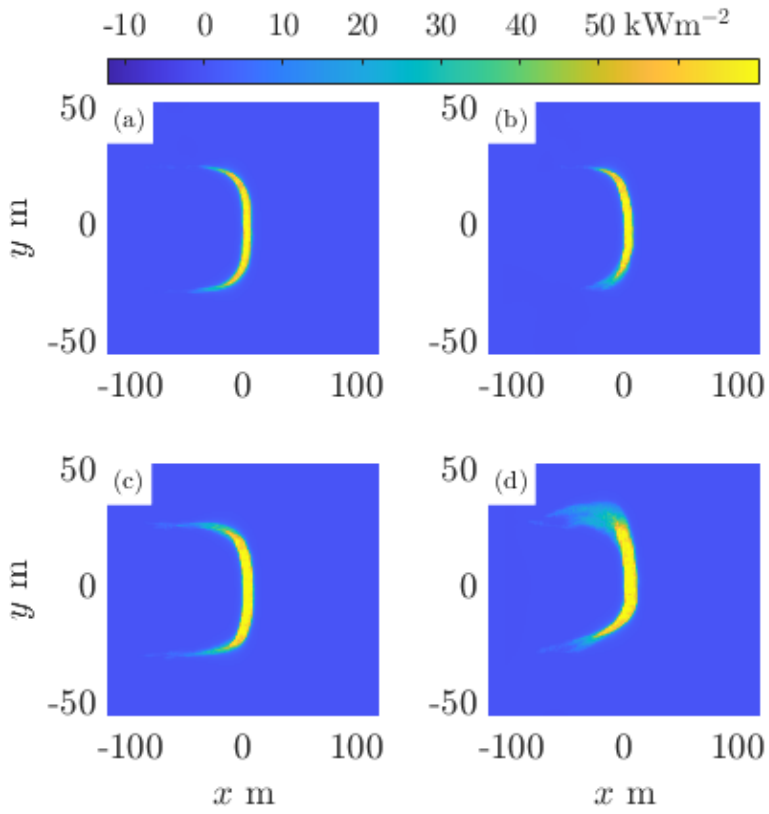

Figure 4- Ensemble averaged radiative heat transfer (a) U3 (b) U4 (c) U6 (d) U10

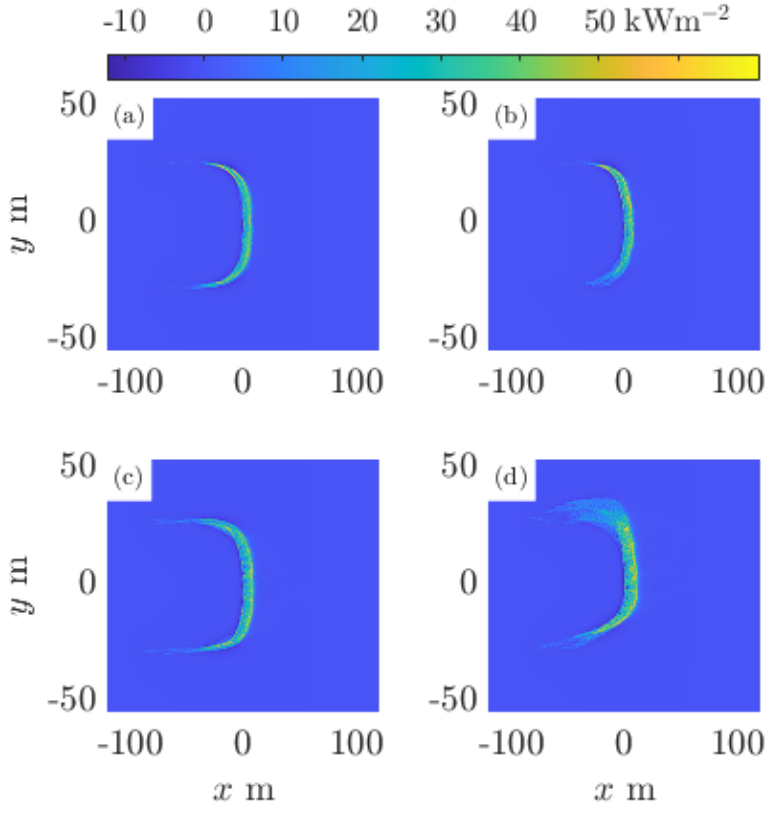

Figure 5 Ensemble averaged convective heat transfer (a) U3 (b) U4 (c) U6 (d) U10

The shape of the contour is like the shape of the pyrolysis zone. The heat fluxes are most intense in the straighter near-centreline head region of the fire. However, at the edges and trailing regions of the fire, the averages appear

indistinct. This phenomenon is strongest around $y = 40$ m in the U10 case. The flanks of the fires, unlike the near centreline behaviour of the fires, are somewhat intermittent and cannot be in a quasi-equilibrium state.

There is little to no radiative cooling, however, there is strong evidence of convective cooling, located at the trailing edge of the fire. The variation in the convective heat flux across the head fire may be associated with the vortex structures identified by Finney et al. (2015). Because these structures appear in the ensemble average, these structures must persist in approximately the same y-location over the quasi-equilibrium propagation.

To identify if there is a dominant mechanism of heat transfer along the centreline, the ensemble averaged boundary heat fluxes are shown upon the centreline in Figure 6. The vertical dotted lines are the locations of the leading edge of the heat release rate contour shown in Figure 3. The centreline radiative heat flux exhibits a single broad peak, which stretches in the positive x-direction as U increases. The centreline convective heat flux has a more complicated shape. There is a region of cooling before the trailing edge, followed by a peak in heating at the trailing edge ($x = 0$ m). The magnitude of the cooling and heating peaks are similar for all wind speeds. There is a region of decreased heat transfer at approximately $x = 2$ m, even extending to a region of cooling in the U10 case. The magnitude of this trough does not appear to follow a systematic trend. It is possible that this region is associated with the previously identified vortex structures that occurs near the centreline in all cases.

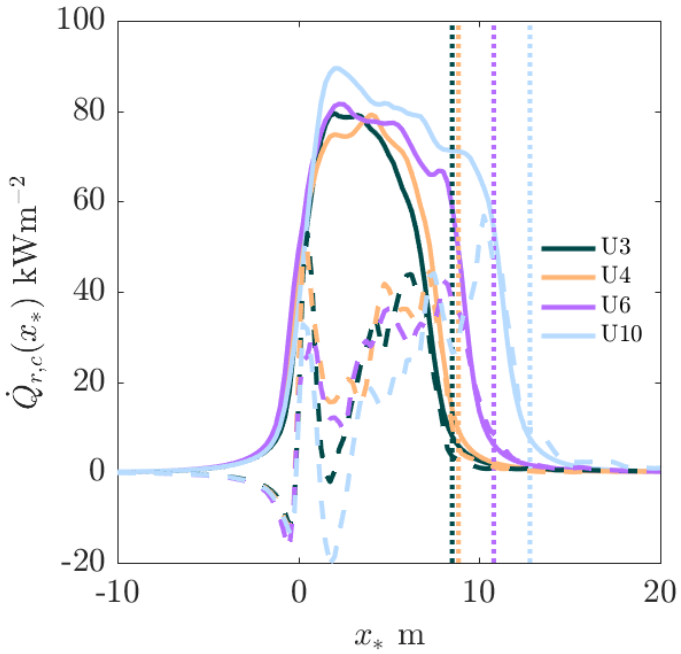

Figure 6- Centreline radiative (solid) and convective (dotted) heat transfer to the unburnt fuel. The vertical dotted lines are the leading edge of the heat release contour shown in Figure 3.

The main peak convective heat flux does increase and stretch in the positive x-direction like the radiative heat flux. The U10 case has a peak of convective heat flux of similar magnitude to the value of radiative heat flux at $x = 10$ m. Similar trends are observable at lower velocities. Therefore, it appears that at the leading edge of the fire, for these cases, both centreline radiative and convective heat fluxes are of approximately equal magnitude. The convective heat flux in the U10 case exceeds the radiative heat flux at $x \approx 15$ m, consistent with the observations of Finney et al. (2015). However, Finney et al. do not look directly at convective heat flux in the flaming region, as we have done. Instead, they observe particle temperature ahead of the main fire front and infer the behaviour of the convective heat flux. The simulated convective heat flux is $\dot{q}'' = h\,(T_w - T_g)$ where h is the convective heat transfer coefficient based upon natural and forced convection empirical correlations. The T with subscripts w and g represent the wall (fuel) and gas temperature respectively. WFDS has been validated by comparing the simulated rate-of-spread to observations (Mell et al. 2007, Moinuddin et al. 2018) however, there is little direct (i.e. measuring and simulating fuel temperature ahead of the front) validation for the convective heat transfer model in surface grass fires and further research is required to investigate the heat transfer further.

4. Conclusions

The Byram number correctly predicts the plume dynamics as expected. Low Nc cases have elongated and attached flames with one-sided entrainment into the plume; whereas higher Nc cases have a more vertical flame with two-sided entrainment.

For these simulations, the dominant heat transfer mechanism was found to be radiation in all cases. The radiative heat transfer was always approximately twice as much as the convective heat transfer, even if the flame was attached in a wind dominated fire. On the centreline, considered representative of the head fire behaviour, convective heating emerges to be of approximately equal magnitude as radiative heating at the leading edge of the fire. This is contrary to the hypothesis that convective heating takes over as the dominant mechanism of heat transfer in wind driven cases. While the results presented here are specific to this fire geometry and represent only a relatively small window of near transitional Nc, the hypothesised behaviour of heat transfer mechanisms are likely more complicated than currently thought and understood.

Wildfire; Downslope; wildland–urban interface; wind–fire interaction; terrain slope; wind structure

Abstract

In the current work, a numerical study is performed to investigate the effect of the downslope field by a wind driven surface fire in the presence of an idealised building structure. Fires burning with different intensity values of 4, and 15 MW/m on inclined terrain with various downslope angles of 0, -10, -20, and -30°, and under two different wind speed of 6, and 12 m/s are simulated using a large eddy simulation (LES) solver, implemented in open-source platform FireFOAM. The results are validated with experimental measurements of a full-scale cubic building model. The presented outcomes highlight the physical effect of sloped terrain on a building in the vicinity of a line-fire. The results show that at high wind velocity values, the buildings at the higher downslope terrains are at higher risk of wildfire damages

1. Introduction

Wildfire is a highly complex phenomenon and while it is an important ecological process, it can also have detrimental effects when it spreads from wildland areas and impacts the wildland-urban interface (Verma, 2019). They are important elements of ecosystem management and functional ecosystems (Menage, Chetehouna, & Mell, 2012).

To mitigate the disastrous impact of wildfire and manage its environmental and economic impacts, people interact with wildfires in different ways. This includes the use of prescribed fires to reduce fire hazard and thereby lessen the associated likelihood of damage to assets, particularly in the Wildland-Urban Interface (WUI) (Canfield, Linn, Sauer, Finney, & Forthofer, 2014). The growing pace of urbanization resulting in increasing encroachment of urban development into forested areas, is considered one of the most significant reasons for landscape transformation in many countries including Australia (Manzello et al., 2018).

Protection of assets (dwellings, associates structures and other infrastructure) in areas likely to be impacted by wildfire requires precise assessment of factors, such as wind and topography, that might affect the many facets of a wildfire and its impact on assets in the WUI (Cruz, Sullivan, & Alexander, 2014; Ghodrat, Shakeriaski, Nelson, & Simeoni, 2021a; Hilton et al., 2017; Mell, Manzello, Maranghides, Butry, & Rehm, 2010).

Terrain slope is generally considered to be a key element impacting the way in which wildfires spread (Abouali, Viegas, & Raposo, 2021; Butler, Anderson, & Catchpole, 2007). It is commonly accepted that fires increase speed up a hill and many deadly incidents have been reported linked with the hilly terrain (Butler et al., 2007; Dupuy, Maréchal, Portier, & Valette, 2011).

Wildfire behaviour reflects a wide range of complex physical and chemical processes (Ghaderi, Ghodrat, & Sharples, 2020; Verma, 2019) that encompasses aerodynamic behaviours, topographic impacts (such as terrain slope) (Edalati-nejad, Ghodrat, & Simeoni, 2021; Verma, 2019), atmospheric conditions (Ghodrat et al., 2021a; Ghodrat, Shakeriaski, Nelson, & Simeoni, 2021b)(wind speed and direction, temperature, and humidity), the rate of fire spread (ROS) (Canfield et al., 2014), and the effects of fuel type and state (Edalati-nejad, Ghodrat, Fanaee, & Simeoni, 2022), including fuel moisture content (FMC) (Morvan, 2013). As such, it is infeasible to

comprehensively account for the myriad effects driving fire behaviour. Instead, researchers have conducted targeted studies that focus on understanding the effects of a small subset of the most significant driving factors, such as Viegas (Viegas, 2004) who carried out an experimental investigation of the combined effect of terrain slope and wind. In this study a plane fuel bed under uniform wind and slope conditions was studied.

These studies provide valuable information about the effect of terrain slope on fire dynamics when fires are spreading upslope. However, there has been considerably less attention paid to scenarios where fires are burning downslope. Sullivan and his co-authors, (Sullivan, Sharples, Matthews, & Plucinski, 2014) developed a rate of spread correction for fires burning downslope, but there is still much to be understood about the dynamics of line fires burning downslope. For example, questions about how negative slopes interact with pyroconvective flows and how they affect the temperature profile downstream of the line-fire source are still relatively unexplored and require further study. Such studies are critical in informing further development of wildfire risk mitigation measures. The outcome of the present study contributes to alleviate the wildfire damages and helps the risk managements, for example, Australian Standard AS 3959 (Debnam, Chow, & England, 2005), the Australian Standard for Building in Bushfire Prone Areas.

In the present investigation, the effect of downslope terrain, at a constant wind speed and fire intensity, on the fire-line dynamics and downstream temperature has been investigated. Moreover, the pattern of heating on an idealised building structure is investigated to better understand the impacts of downslope fires on built assets.

2. Physical model

In the present work, an idealized (cubic) building structure with a size of 6 × 6 × 6 m is located downstream of a fire line. As can be seen in Fig. 1, the size of the computational domain is 50 ×30 × 25 m. The building structure is located 20 m downstream of the fire line.

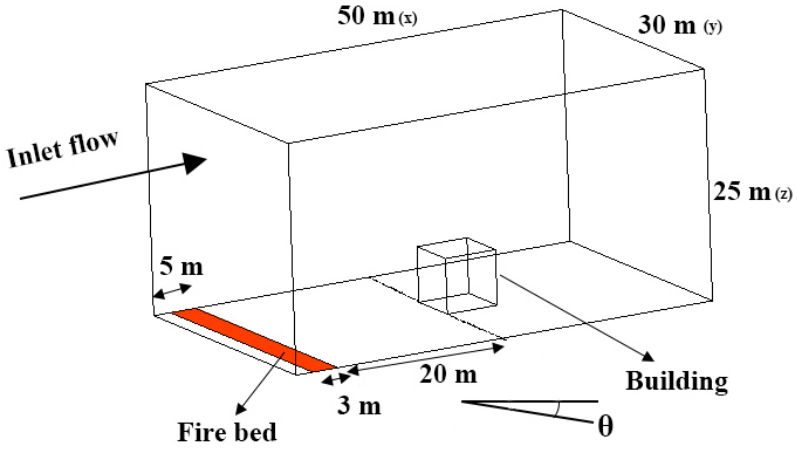

Figure 1- Computational domain and physical model

The fire-line is placed at the edge (near the inlet) of the domain, which is inclined at various downslope angles, with a constant fire intensity and wind velocity to investigate the impact of slope-fire interactions on downstream temperature and air density in the presence of the building structure. In this investigation, a constant fire intensity (Byram, 1959) equal to 15 MW/m is considered, which is equivalent to a forest wildfire (Smith, 2014), and is provided by invoking model parameters in FireFOAM, corresponding to the burning of methane with a heat of combustion equal to 45,435 kJ/kg (Kremer & Schäfer, 1973).

In this model, the boundary layer in the vicinity of the ground has been considered by applying a power-law velocity profile:

$$U(Z) = U_{ref}\left(\frac{Z}{Z_{ref}}\right)^{\alpha} \quad (1)$$

Where U_{ref} is the reference velocity which in this paper is considered 12 m/s, Z_{ref} is the reference height, which is equal to the building's height (6 m), and α is a constant taken equal to 0.16 based on the terrain category of the experimental study (Tominaga et al., 2008).

The angle of inclination of the terrain, θ, is the angle of gravitational acceleration to the z direction, which is defined via:

$$g_x = -g \sin(\theta) \text{ and } g_z = -g \cos(\theta) \tag{2}$$

3. Numerical modelling

To numerically solve the governing equation of the problem, the FireFOAM solver of OpenFOAM, which is an open-source CFD software, is used. FireFOAM is an efficient tool to simulate wildfire behaviour (El Houssami, Lamorlette, Morvan, Hadden, & Simeoni, 2018; Le et al., 2018). To account for the effects of turbulence, the Large Eddy Simulation (LES) (Wang, Chatterjee, & de Ris, 2011) method is utilized. The governing equations for the problem are as follows:

$$\frac{\partial \bar{\rho}}{\partial t} + \frac{\partial(\bar{\rho}\tilde{u}_i)}{\partial x_i} = 0 \tag{3}$$

$$\frac{\partial(\bar{\rho}\tilde{u}_i)}{\partial t} + \frac{\partial(\bar{\rho}\tilde{u}_i\tilde{u}_j)}{\partial x_i} = \frac{\partial}{\partial x_j}\left[\bar{\rho}(\upsilon + \upsilon_t)\left(\frac{\partial(\tilde{u}_i)}{\partial x_j} + \frac{\partial(\tilde{u}_j)}{\partial x_i} - \frac{2}{3}\frac{\partial(\tilde{u}_k)}{\partial x_k}\delta_{ij}\right)\right] - \frac{\partial(\bar{P})}{\partial x_i} + \bar{\rho}\, g_i \tag{4}$$

$$\frac{\partial(\bar{\rho}\tilde{h})}{\partial t} + \frac{\partial(\bar{\rho}\tilde{u}_j\tilde{h})}{\partial x_j} = \frac{D\bar{P}}{Dt} + \frac{\partial}{\partial x_j}\left[\bar{\rho}\left(\alpha_t + \frac{\upsilon_t}{Pr_t}\right)\left(\frac{\partial\tilde{h}}{\partial x_j}\right)\right] + \dot{q}''' - \nabla.\dot{q}_r'' \tag{5}$$

$$\frac{\partial(\bar{\rho}\widetilde{Y_m})}{\partial t} + \frac{\partial(\bar{\rho}\tilde{u}_j\widetilde{Y_m})}{\partial x_j} = \frac{\partial}{\partial x_j}\left[\bar{\rho}\left(D_c + \frac{\upsilon_t}{Sc_t}\right)\frac{\partial(\widetilde{Y_m})}{\partial x_j}\right] + \omega_m \tag{6}$$

$$\bar{P} = \bar{\rho}R\tilde{T} \tag{7}$$

where "¯" and "~" show spatial and Favre filtering, respectively, h is the total enthalpy, Y_m represents the mass fraction of species m, P is the static pressure, and g is the gravitational acceleration. $Sc_t, Pr_t, \upsilon, D_c, \upsilon_t, \rho, \alpha_t, R, \delta$ and ω_m are the turbulent Schmidt number, the turbulent Prandtl number, the laminar viscosity, the laminar diffusion coefficient, the turbulent viscosity, density, thermal diffusion coefficient, gas constant, Kronecker delta, and production/sink rate of species m due to gas reaction, respectively. The PIMPLE algorithm (Jasak, 1996)for pressure-velocity coupling, is applied. The differencing scheme of first order upwind is also used.

In order to validate the simulations, the mean pressure coefficients around the idealized building structure for the current work and an experimental measurement of Richards and Hoxey (Richards & Hoxey, 2012) in the absence of fire were compared as shown in Fig. 2. The pressure along the vertical and horizontal centrelines of the Silsoe cube, at the Silsoe Research Institute, UK, has been measured. In this figure, X-axe corresponds the yellow dashed line shown on the cube, starts from point 0, goes to the point 1, passes point 2, and continues to the point 3.

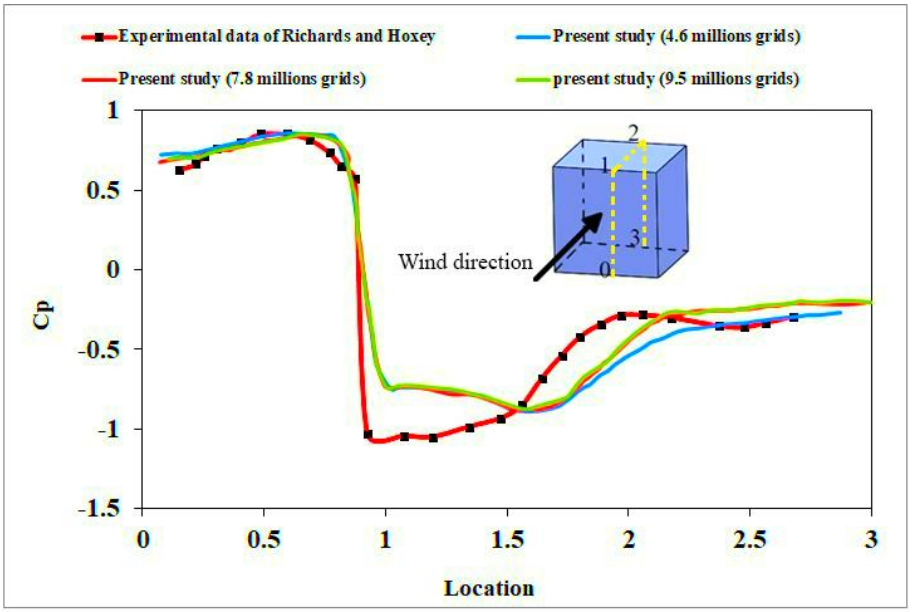

Figure 2- Comparison between the mean pressure coefficient for three different grids number of the current investigation and the experimental measurement (Richards & Hoxey, 2012)

In addition, to study the grid dependency, three different grid numbers of 4,600,000, 7,800,000, and 9,500,000 into the domain have been applied and tested. At the first, increasing the mesh number, changes the mean pressure coefficient, then a further increase will not affect the results. Therefore, the second mesh numbers have been selected for the present study. As can be observed in Fig. 2, there is an acceptable agreement between the present work's results and the experimental measurements.

4. Results

Figure 3 shows the effect of downslope terrain angles on the temperature distribution for the cases at U_{ref} = 6 m/s and fire intensities 4, and 15 MW/m. As can be seen in this figure, at all cases, the wind causes the flames to tilt towards the building. The flame tilt angle is defined as the angle between the centreline of flame and the vertical direction (Li et al., 2021; Li, Wan, Gao, & Ji, 2019). Also, the flame tilt angle decreases as the terrain slope becomes more negative increasing the terrain downslope. This is due to the fact that buoyancy forces cause the flame to rise in the direction opposing gravity, thus reducing the tilt angle. Looking at the figures in more detail, they reflect that in the mentioned cases (U_{ref} = 6 m/s and fire intensities 4, and 15 MW/m), the increasing in the negative downslope, leads to decreasing the risk of being the building in the exposure of high temperature air, caused by the fire.

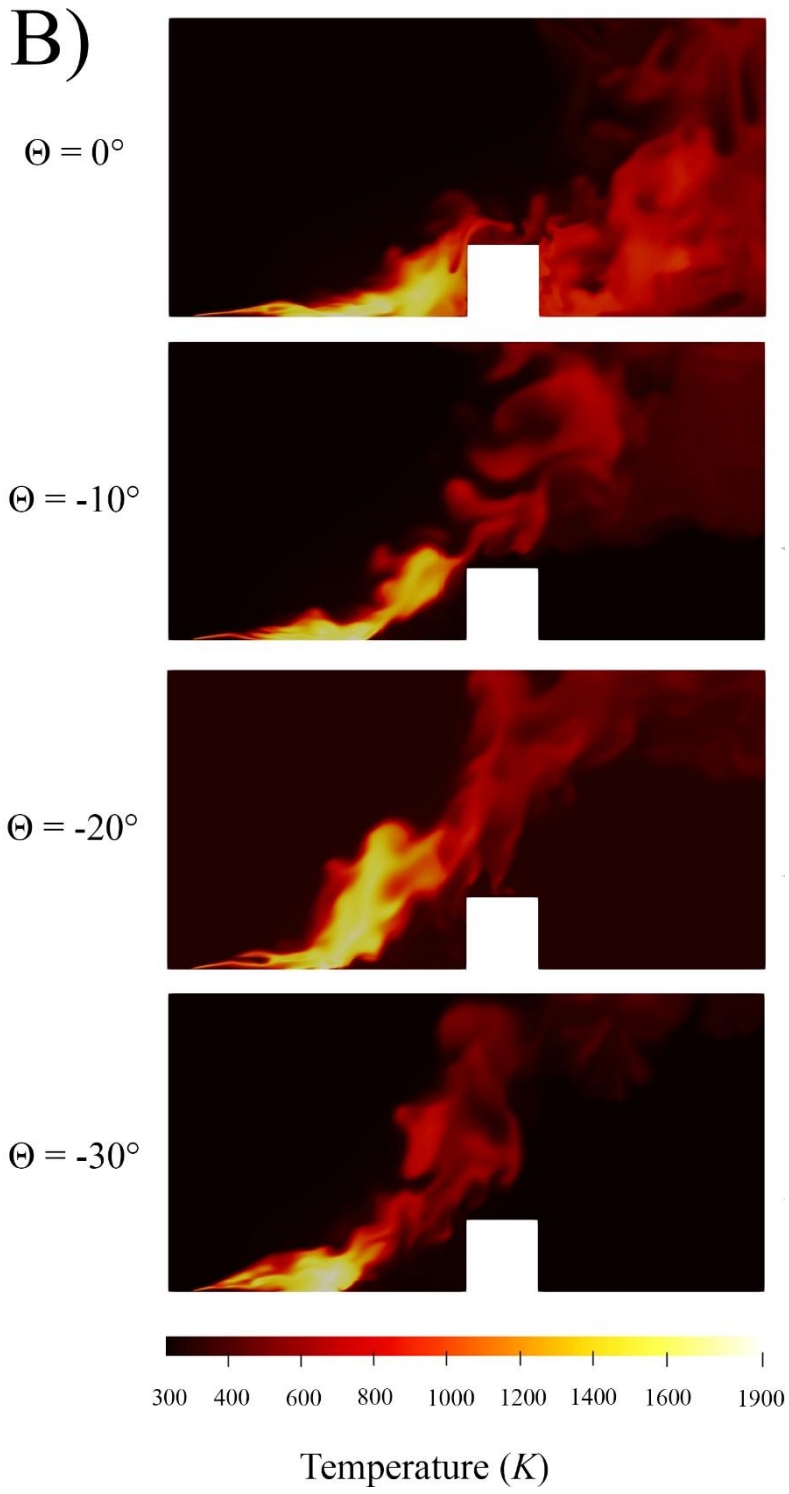

Figure 3- Temperature distribution for the cases at fire intensity (A): 4 MW/m and (B): 15Mw/m and wind velocity 6 m/s for different downslope degrees

Figure 4 shows how the average temperature downstream of the fire-line and the building surface varies with the downslope terrain angle. Considering the effect of wind, the fire plume is directed in the downstream direction so that in the case with no slope, the fire plume is close to the ground. This is due to the effect of wind on enhancing the tilt angle toward to the building. Increasing the downslope angle, decreases the flame tilt angle and the takes the plume closer to the higher altitude surfaces of the building structure. So, for the cases with U_{ref} = 12m/s, an increase in the downslope inclination leads to an increase in the higher temperature region downstream of the fire, which can be seen in Fig. 6. It can also be observed that by increasing the downslope terrain angle, the building temperature increases, for the mentioned cases. This is also due to the combination

of the wind speed and the downslope terrain, which have contrary effects on the flame tilt angle in the current cases. For the cases with U_{ref} = 12 m/s (I = 4, and 15 MW/m), increasing the downslope angles from 0˚ to -30˚, increases the average temperature of the building surface by 14%, and 30%, and increases the temperature of the zone downstream of the fire by 3%, and 9%, respectively.

On the other hand, the effect of increasing in the downslope angles, on the temperature of the building surface and downstream, for the cases with U_{ref} = 6m/s, is in the contrast with the cases with U_{ref} = 12 m/s. Because the wind velocity is lower and the fire plume is not that close to the ground, compared to the cases with U_{ref} = 12 m/s. Accordingly, for the cases with U_{ref} = 6 m/s (I = 4, and 15 MW/m), increasing the downslope angles from 0˚ to -30˚, decreases the average temperature of the building surface by 15%, and 30%, and decreases the temperature of the zone downstream of the fire by 3%, and 17%, respectively.

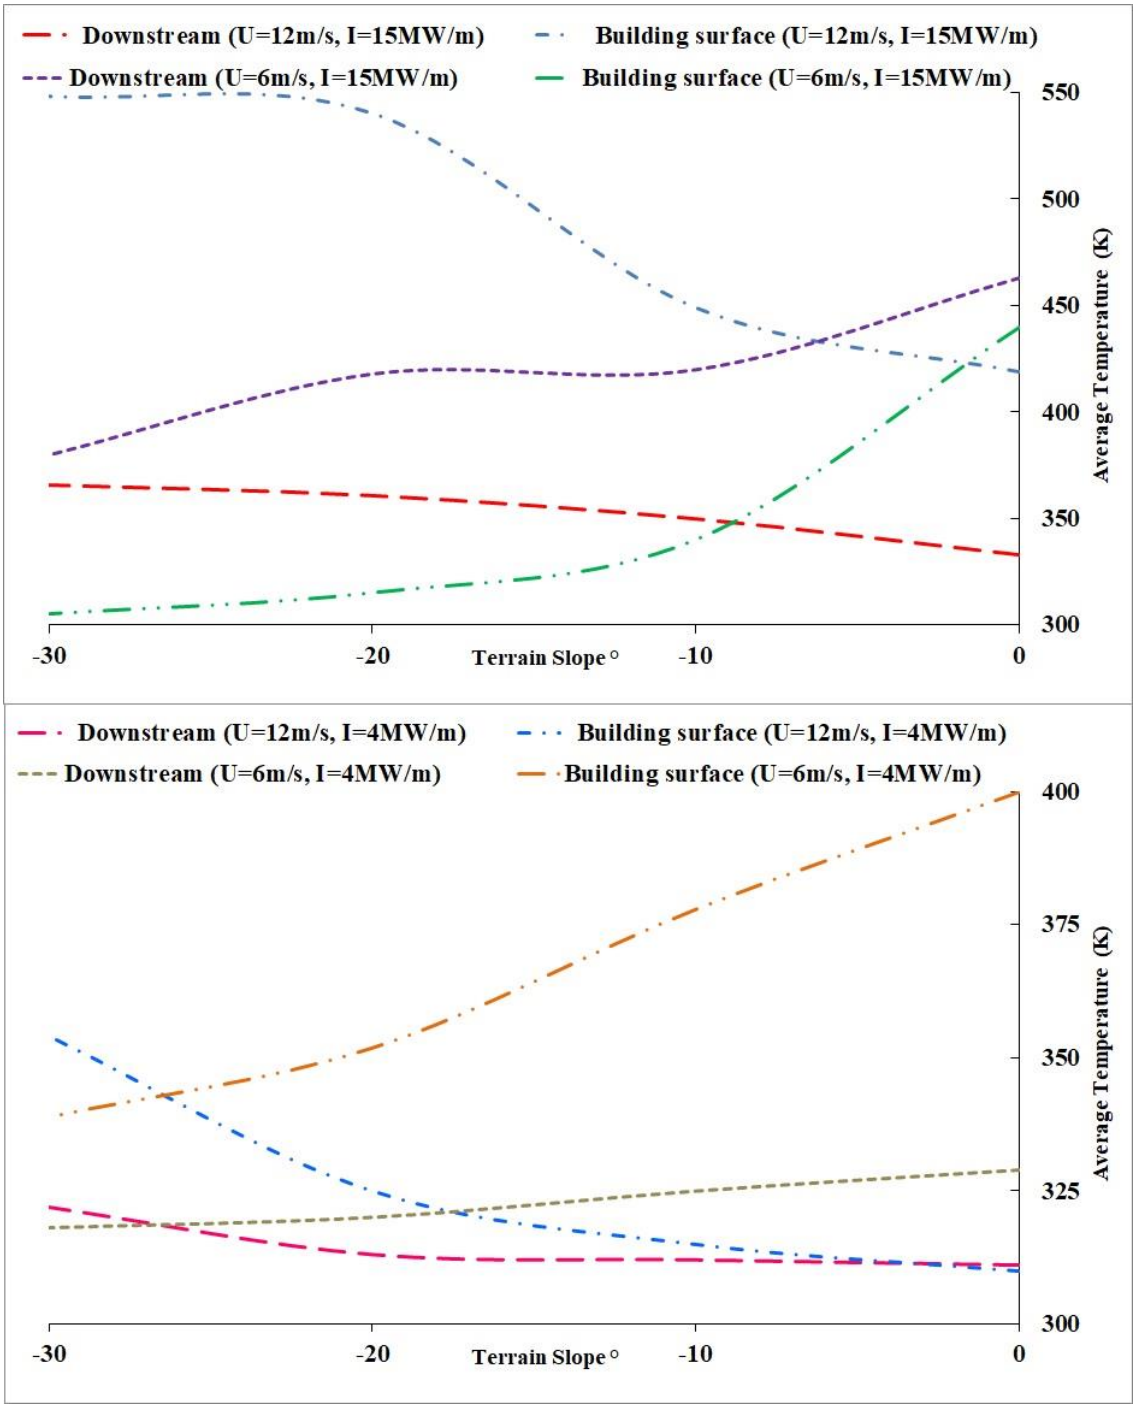

Figure 4- Average temperature of the downstream of the domain and the building surface versus the terrain slope for the cases with U_{ref} = 6, and 12 m/s and fire intensities 4, and 15 MW/m.

5. Conclusion

In the present work, the effect of downslope terrain on fire-line dynamics and downstream temperature, at a constant wind and fire intensity, in the presence of an idealized building structure has been numerically studied. The downslope angles varied from 0˚ to -30° and a wind-field with reference velocity of 6, and 12 m/s and fire intensity 4, and 15 MW/m are considered. The main results of the present investigation are summarized as follows:

- The calculated results show an acceptable agreement with the empirical measurements in the absence of fire.
- At constant wind velocity of 12 m/s, the buildings at the higher downslope terrains are at higher risk of wildfire damages, in contrast, at constant wind velocity of 6 m/s, the buildings at the higher downslope terrains are at lower risk of wildfire damages.
- For the cases with U_{ref} = 12 m/s, increasing the downslope angles from 0˚ to -30˚, increases the average temperature of the building surface by 14%, and 30%, and for the cases with U_{ref} = 6 m/s, increasing the downslope angles, decreases the average building temperature by 15%, and 30%, respectively.

Abstract

The replacement of grasslands by woody plants represents one of the main threats to the biodiversity conservation in open landscapes around the world. This transformation occurs when ecological processes that are essential to avoid the canopy closure are prevented, such as fire. We sampled trees and shrubs and evaluated the effects of fire in an old-growth grassland remnant released from fire for 18 years in Southern Brazil. Our main objective was to analyze whether woody encroachment promotes a biome shift of the grassland ecosystem. We hypothesized if woody encroachment is deterministically structured towards a dominance of forest species and a significant decrease in fire intensity and severity along the encroachment gradient occurs. Then, the woody encroachment does not represent a simple process of woody densification, but a biome shift towards an alternative forest state, that change the ecology of the system in a positive feedback loop and get stability as the woody community expands. We found clear evidences that woody encroachment promotes a biome shift from an open grassland state to an alternative forest state. In this process, our results indicated that woody encroachment was structured deterministically in the multivariate space with the occurrence of indicator species in the early and late stages. Throughout the entire encroachment gradient analyzed, a significant dominance of forest species was found, indicating that Southern Brazilian grasslands have the potential to be converted into forests more rapidly than savannas in the absence of fire. A significant decrease in fire intensity was found as the process of woody encroachment increased, indicating a change in the system behaviour that favoured the occurrence of a positive feedback loop between the canopy cover and the recruitment of shade-tolerant forest species. Simultaneously to fire intensity decrease, we observed that the reversion of the woody encroachment process was significantly reduced as the woody dominance increased. Thus, the woody encroachment mediated by fire suppression can be considered a degradation factor in our study area, since it can shift the system balance to another alternative stable state. By elucidating the ecological consequences behind woody encroachment, we recommend the use of prescribed fires to the conservation of the grasslands landscapes in Southern Brazil.

1. Introduction

Temporal analyses based on satellite images indicated that Araucaria Forest areas are expanding in Soutern Brazil, specially in forest-grasslands ecotones where fire has been avoided (OLIVEIRA; PILLAR, 2004). However, its is still unclear whether woody encroachment represent only a process of woody densification or a general biome shift towards a generation of a new alternative forest state. Furthermore, if woody encroachment actually results in a change in the fundamental state of the ecosystem, we still don't know the level of stability of this new state.

To address these issues, we studied an old-growth grassland remnant that was encroached by woody species due to fire suppression for a period of 18 years (from 1999 to 2017). In 2017, this same area was hit by a wildfire, then we analyzed the fire effects over the woody plants community with the objective of to evaluate the fire intensity and severity along the woody encroachment gradient. We hypothesized if woody encroachment is deterministically structured towards a dominance of forest species and a significant decrease in fire intensity and severity along the encroachment gradient occur. Then, the woody encroachment does not represent only a simple process of woody densification, but a biome shift towards an alternative forest state, that change the ecology of the system in a positive feedback loop and get stability as the woody community expands.

2. Material and Methods

2.1. Study area

This study was conducted in Vila Velha State Park (VVSP) located in the municipality of Ponta Grossa, Paraná State, Brazil (latitude: 25º 13' 30" S, longitude: 50º 0' 0" W) (Table 1). The VVSP was created in 1953 (PARANÁ, 1953), in an area of 3,122 ha considered as a remnant of the original vegetation of Campos Gerais region (INSTITUTO AMBIENTAL DO PARANÁ, 2004). The Campos Gerais region comprises areas of old-growth grassland vegetation associated with Araucaria Forest fragments forming mosaics (MAACK, 2012).

2.2. Data collection

2.2.1. Vegetation sampling

We sampled trees and shrubs in five permanent transects measuring 50 m wide per 100 m long (subdivided in 20 plots of 250 m² - 10 x 25 m). The plots were randomly distributed over an area mapped in the VVSP management plan as steppe-savanna transition vegetation (INSTITUTO AMBIENTAL DO PARANÁ, 2004). In this place, we previously assumed that there is a natural tendency of forest expansion over grasslands and that the current vegetation pattern is associated with fire suppression policies, which guided the park management during the past decades. In each plot, tree and shrub data were collected according to the inclusion criterion of DBH equal to or greater than 3 cm.

2.2.2. Assessment of fire intensity and severity

We inferred the intensity of fire by measuring the height of bark-char left on the tree boles after the fire passage. We adopted as standard measure the highest stem-bark char height.

We determined fire severity by calculating the proportion of basal area lost as a result of fire in each plot. For this, one year after fire, trees and shrubs were reassessed according to survival and complete mortality or topkill. Then, the basal area obtained in each plot were compared with the basal area obtained in the first survey. The fire severity ranged from 0 to 1, with 1 being noted for complete mortality or topkill of all woody individuals present in the plot and 0 for complete absence of mortality or topkill of all woody individuals present in the plot.

2.3. Data analyses

2.3.1. Community structure and dominance of forest specialist species along the encroachment gradient

To verify if the woody encroachment was deterministically structured towards a dominance of forest species, we firstly evaluated the floristic-structural relationship among the plots by the construction of a hierarchical cluster dendrogram. Then, the occurrence of multivariate structure among the plots was analyzed by similarity profile test (SIMPROF) (CLARK; SOMERFIELD; GORLEY, 2008). Later, the multivariate structure captured by SIMPROF test was analyzed by a Principal Coordinate Analysis (PCoA) with the adjustment of generalized additive model (GAM) *a posteori*.

In each cluster identified in the SIMPROF test, we verified the occurrence of indicators woody species through the IndVal analysis (DUFRÊNE; LEGENDRE, 1997). In addition, the species were classified into three distinct functional groups according to the habitat preference: savanna specialists, generalists and forest specialists. To verify the existence of significant associations between the number of individuals in each functional group and the stages of woody encroachment, a chi-square test was applied to a contingency table.

To verify the patterns of change in species richness of each functional group along the woody encroachment gradient, we used a generalized linear model (GLM), in which the absolute and relative species richness was adjusted as a function of the density of woody plants per plot.

2.3.2. Effect of woody encroachment in fire intensity and severity

We analyzed the effect of woody encroachment in fire intensity by a Kruskal-Wallis variance analysis and beta regression models with logit link was applied to model the fire severity as a function of the sum of the basal in each plot.

3. Results

The SIMPROF analysis rejected the null hypothesis ($p < 0.01$) of absence of community structuring associated with the woody encroachment process, indicating the formation of six significantly different floristic-structural groups (Figure 1).

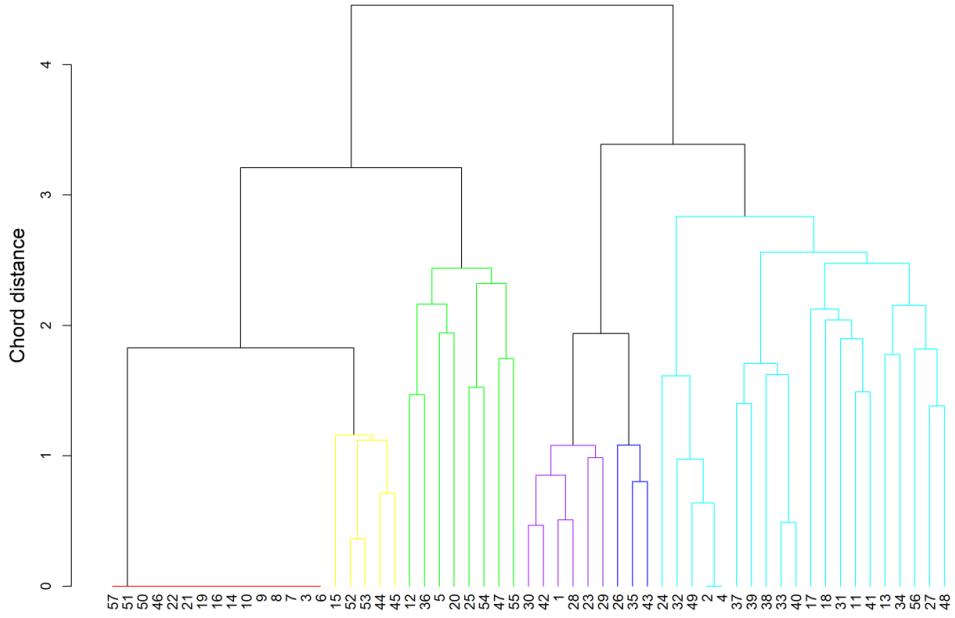

Figure 1 - Similarity profile analysis (SIMPROF)

The ordination produced with the smoothed surface adjusted *a posteriori* by GAM indicated that 55.4% of the floristic-structural variation was explained by the density of woody individuals ($R^2 = 0.502$; $p \leq 0.05$) (Figure 2). Thus, the floristic-structural groups established by the SIMPROF analysis were significantly associated in the multivariate space in response to woody encroachment gradient.

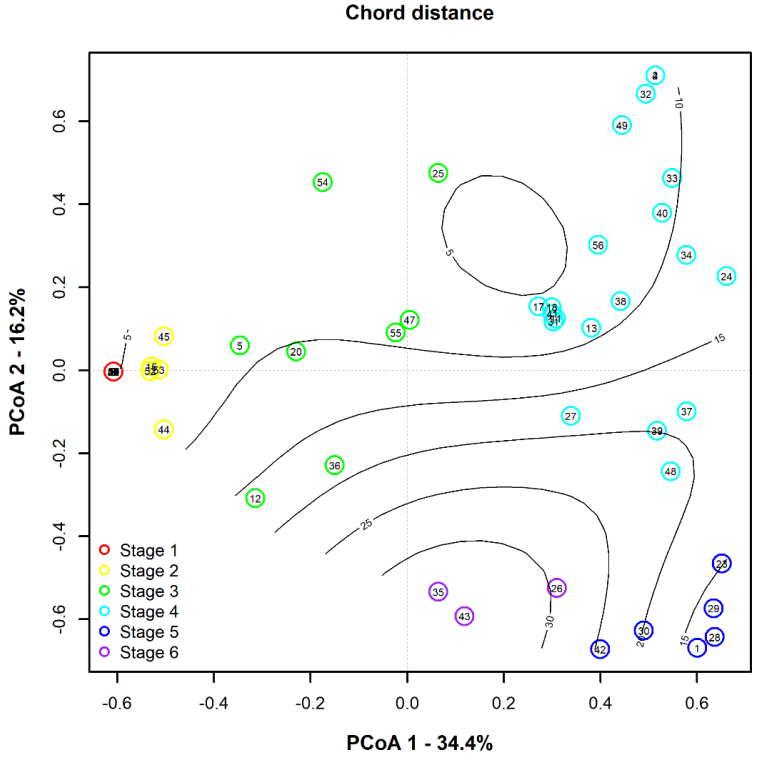

Figure 2 - Principal coordinate analysis with smoothed surface lines of woody abundance per plot adjusted a posteriori by GAM

The IndVal analysis recognized the occurrence of typical species in the initial (1 and 2) and advanced (5 and 6) stages of woody encroachment. In early stages 1 and 2, *Clethra scabra* Pers. (IndVal = 38.85%; p = 0.015) and *Myrcia splendens* (Sw.) DC. (IndVal = 46.74%; p = 0.014) were recognized as indicator species, respectively. In late stages 5 and 6, the indicator species were: *Myrsine umbellata* Mart. (IndVal = 51.84%; p = 0.010) and *Miconia sellowiana* Naudin (IndVal = 29.95%; p = 0.034), respectively.

We observed significant associations among functional groups and the stages of woody encroachment according to the chi-square test (χ^2 = 51.098; p = 0.01; Cramer's V = 0.2072). The analysis of the standardized residuals of chi-square test showed that forest specialist individuals were positively associated with initial and advanced stages of woody encroachment (Figure 3).

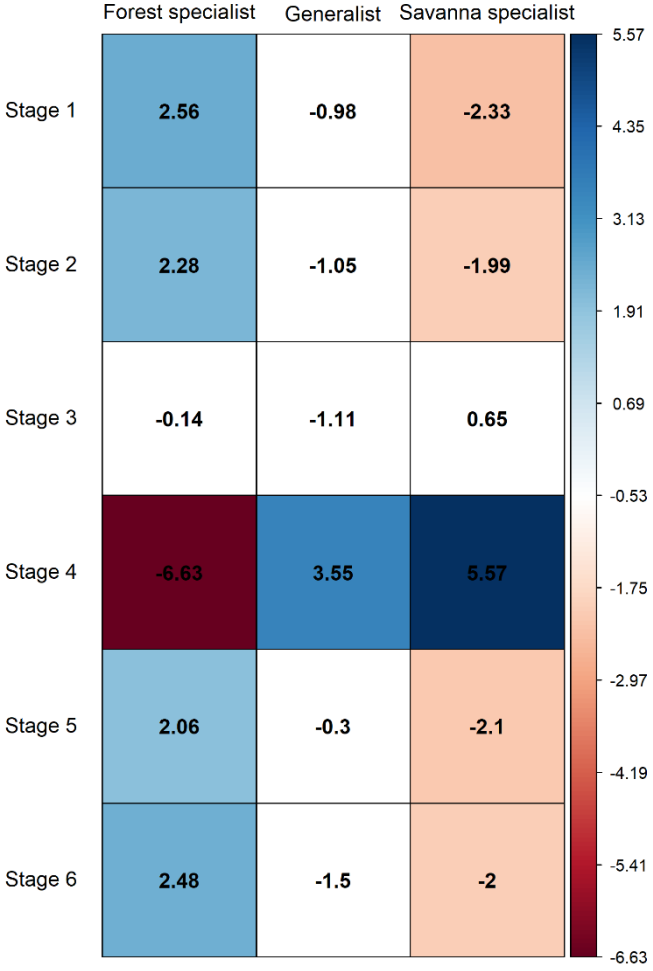

Figure 3 – Pearson's chi-square test (χ^2) between functional groups and stages of woody encroachment

The increase of woody encroachment process resulted in a significant increase in the absolute richness of savanna specialist (F = 5.45; R^2 = 0.23; p < 0.01; Deviance explained = 12.74%) and forest specialist species (F = 33.72; R^2 = 0.34; p < 0.01; Deviance explained = 40.84%). The same pattern was not observed for generalist species (F = 0.21; R^2 = 0.002; p = 0.65; Deviance explained = 0.86%), which showed constant species richness along the woody encroachment gradient (Figure 4A). Proportionally, the species richness of all functional groups maintained constant along the woody encroachment gradient, with forest specialist species being responsible for leading the encroachment process from early to advanced stages (Figure 4B).

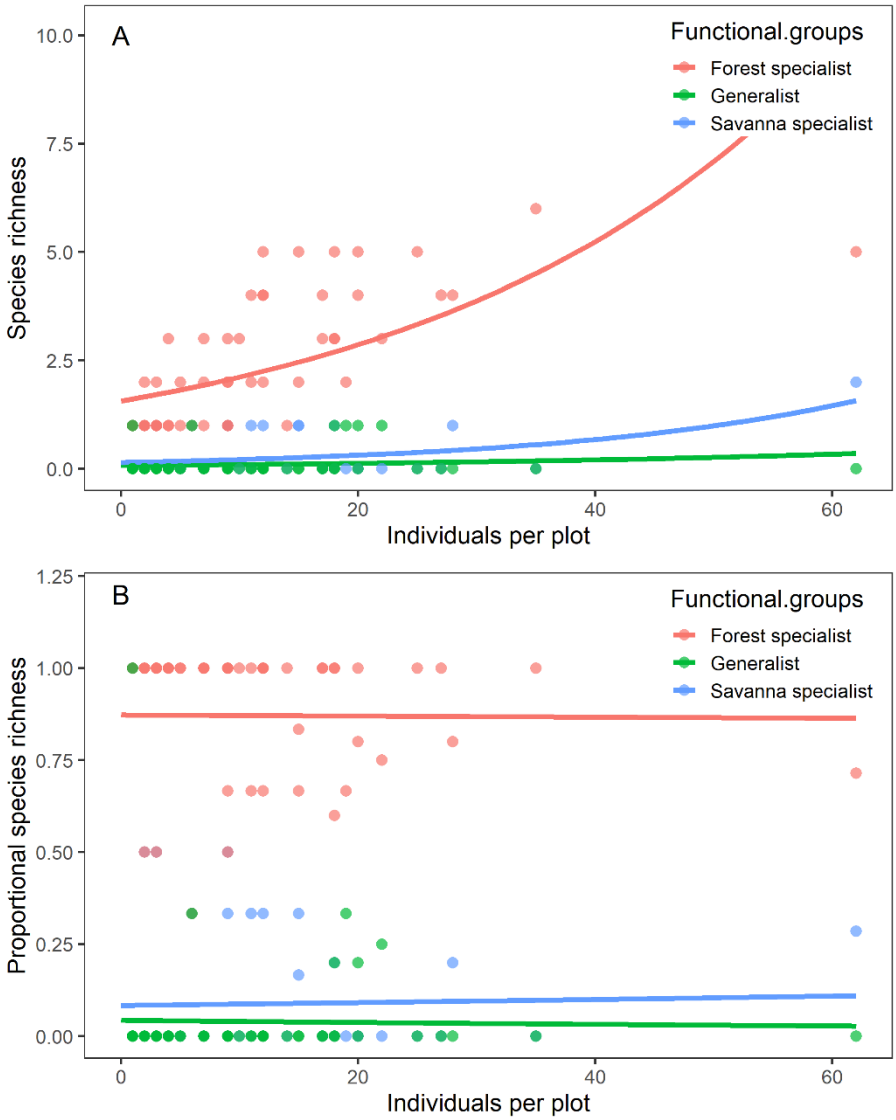

Figure 4 - Changes in absolute (a) and relative (b) species richness of the functional groups along the gradient of woody encroachment

The fireline intensity showed a significant reduction along the woody encroachment gradient (Kruskal-Wallis χ^2= 18.37; df = 5; p = 0.0002). The Dunn *post-hoc* test of multiple comparison showed that stage 6 (0.81 ± 0.79 m) had a significantly lower carbonization height than the other stages of encroachment, with the exception of stage 5 (0.93 ± 0.73 m). Stage 5, in turn, showed a significantly lower carbonization height than stages 1 (1.12 ± 0.74 m) and 2 (1.20 ± 0.85 m). The other stages of invasion did not show significant differences among them in relation to the stem-bark char height (Figure 5).

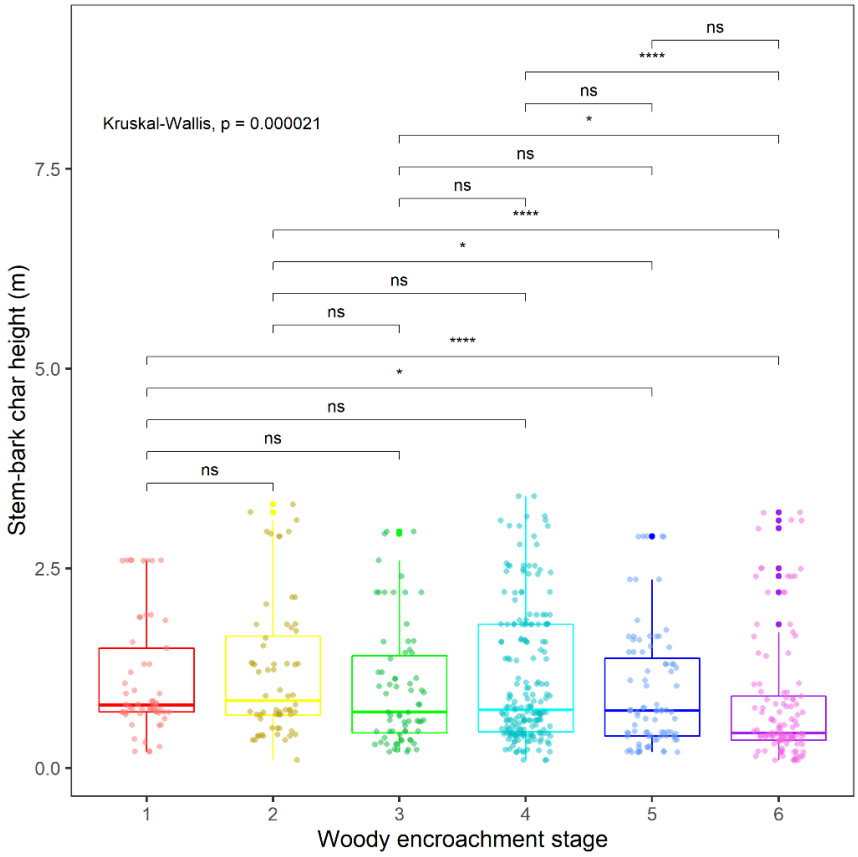

Figure 5 – Kruskal-Wallis's test and Dunn post-hoc test of multiple comparison of the height of stem-bark char and woody encroachment stages

Fire severity significantly decreased as the woody encroachment process advanced (p = 0.0001). The fitted GLM model showed that 39% of the variability in fire severity was explained by the increase in basal area per hectare (Figure 6). The value of basal area per hectare needed to reach the fire severity threshold corresponding to 0, i.e., complete absence of mortality and/or topkill, was estimated at 32.3 $m^2.ha^{-1}$.

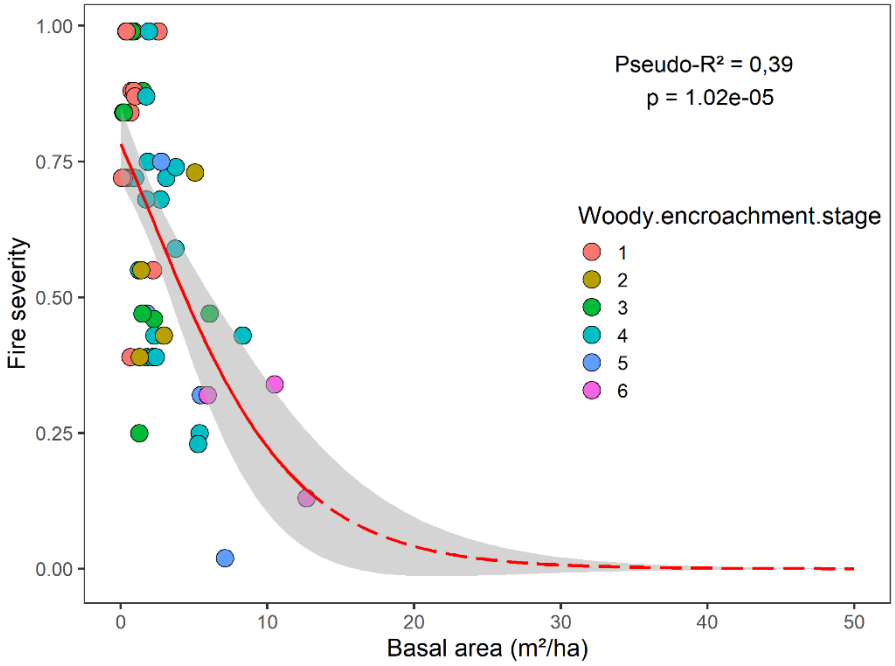

Figure 6 – Beta regression between fire severity and basal area of plots

4. Discussion and concluding remarks

Our results support the assumption that subtropical highland grasslands of the Atlantic Forest Biome are ecosystems that depend of fire for their maintenance (OVERBECK et al., 2018). Studies carried out in the region have shown that in the absence of fire, the remnants of grassland vegetation are likely to be invaded and replaced by woody species (*e.g.* OLIVEIRA; PILLAR, 2004; SÜHS; GIEHL; PERONI, 2020).

Although the woody encroachment has been extensively documented worldwide, few studies explored if this phenomenon exclusively represents a process of woody densification that does not interfere in the flammability of the system, or if it is associated with a change in the fundamental state of the ecosystem towards an alternative forest state. Specifically, the flammability of Southern Brazilian grassland ecosystems is of particular interest for their conservation, because it allows the occurrence of periodic fires, which are capable of sustaining vegetation in an open state, since the climate could otherwise way, promote the forest (BEHLING; PILLAR, 2007). On the other hand, the shading provided by canopy closing of woody species is a critical factor for the survival of light-demanding grassland vegetation (PARR; GRAY; BOND, 2012). Here, we observed that the flammability was negatively affected by the progress of woody encroachment, indicating a change in the behavior of the system.

In the process of state transition between grassland and forest ecosystems, the increase in canopy cover, provided by the woody encroachment, results not only in the reduction of herbaceous biomass, but also in lower air temperature, higher relative humidity, lower wind speed and higher moisture content of the combustible material (HOFFMANN et al., 2012b). Furthermore, as the density of trees and shrubs increases, the fuel bed becomes increasingly dominated by leaf litter, which is less flammable than grasses (PRIOR et al., 2017). Thus, grass loss in response to canopy closure indicates the transition from a fire-maintained state to a fire-independent state (HOFFMANN et al., 2012a). Identifying the transition from one state to another provides a basis for understanding how fire governs the distribution of different types of vegetation under the same climatic conditions. Hoffmann et al. (2012a) indicated that when an ecosystem reaches sufficient canopy cover to suppress fire and exclude grasses, a fire suppression threshold is reached. In order to find an analogous threshold for our study system, we analyzed fire severity along a gradient of basal area per hectare and found that the ability of fire to reverse the invasion process is significantly reduced as the woody encroachment progresses until reaching the threshold of 32.3 $m^2.ha^{-1}$, which is when the forest state reaches stability and becomes independent from fire.

Understanding the consequences of woody encroachment is important because grassland ecosystems are undergoing widespread degradation worldwide (HOEKSTRA et al., 2005). In Southern Brazil, the practice of cattle grazing and the preservation of the endemic biodiversity of the highland grasslands fundamentally depend on the maintenance of the ecosystem in an open state, which makes woody encroachment a prominent concern for both the local economy and biodiversity conservation (OVERBECK et al. al., 2007; SÜHS; GIEHL; PERONI, 2018, 2020). In this way, the integration of the woody invasion process into a coherent strategy for the management of natural resources can help the management and restoration of grassland ecosystems. Therefore, we recommend the use of prescribed fires to the conservation of the grasslands landscapes in Southern Brazil.

Fire use, Tradtional fire, Wildfire, Fatalities, Rural population

Abstract

In Portugal, there are countless historic and legislative references about fire use in rural areas. This popular use of fire to manage the huddled of agricultural and forestry leftovers and small burns to clean the farmed lands continues nowadays, to be used in rural environments. However, these environments are becoming depopulated, with aged populations which are often isolated.

Every year, in the social media, there are news about fatalities or injuries from elder people when using fire in the landscape. In 2018 the number of incidents were much higher than usual. For that, the objective of this work was to identify which were the factors that could explain this anomaly.

To obtain a systematic data of the incidents, a thorough analysis of the regional and national newspapers, both in paper and online, was performed from 2008 to 2020. Variables like date, place, sex, age and other were gathered. All the incidents variables were complemented with meteorological data associated with wildfire risk, sociodemographic variables and the legislative context.

From 2008 to 2020 there were 50 incidents, with 78% of fatalities. The anomaly of incidents in 2018 corresponded to 42% of cases. Most of the incidents occurred with elder (75%) and male (82%) people. The predominant months of occurrence were April and October particularly in the year 2018. The majority of fatalities (69%) occurred when the victim was burning alone. Legislative, social and meteorological analysis showed that the most probable factor that lead to the incidents anomaly of 2018 was the extreme pressure to manage the vegetation, held by police forces, legislation and fines value if you didn't comply.

1. Introduction

In Portugal, there are countless historic and legislative references about fire use in rural areas (OTI, 2021). This popular use of fire to manage the huddled of agricultural and forestry leftovers and small burns to clean the farmed lands continues nowadays, to be used in rural territories. However, these areas are becoming depopulated, with aged populations remaining, and often isolated.

If in the 50´s of the XX century, the territory had a network of patches with agriculture and woodlands, maintained by the local farmers, at the present, this no longer occurs. Consequently, there is an increase of the biomass accumulated in unused areas creating fuel-loads prone to wildfires. The remaining population continues to use fire for the management of the land, however not always with the strength to control it (Colaço, 2019). As mentioned in the report of WWF (2019), "under these circumstances, the traditional use of fire in the maintenance of pasture and agricultural land can have disastrous effects when the flames spread onto abandoned plots and turn into uncontrollable wildfires".

Not only wildfires can start by these traditional burns, but this practice can lead to injuries or even fatalities. Every year, all over Europe, in the social media, there are news about fatalities or injuries from elder people when using fire in the landscape. In 2018 the number of incidents in Portugal was much higher than the usual

yearly three or four records. Thus, the objective of this work was to identify all the injuries and fatalities that occurred by the use of fire, analysing which were the factors that could explain 2018 increase of numbers.

2. Methodology

To obtain a systematic data of the incidents, a thorough analysis of the regional and national newspapers, both in paper and online, was performed from the years 2008 to 2020. For the search online the terms used were "incidents, death, fatalities, injury" cross over with "agricultural burns, traditional burn, stubble burn, farmer, elder population". Variables like date, place, sex, age and other information considered relevant were gathered from the newspapers. All the incidents variables were complemented with meteorological data associated with wildfire risk provided by the Information Management System of Wildfire (ICNF, 2021), sociodemographic variables obtained from the National Statistical Institute (INE, 2020) and the legislative context. A statistical analysis was performed crossing over the incidents with meteorological data (FWI indices), sociodemographic data and to the legislation context.

3. Results and discussion

From 2008 to 2020 there were 50 incidents, with 78% of fatalities. The anomaly of incidents in 2018 corresponded to 42% of cases (figure 1).

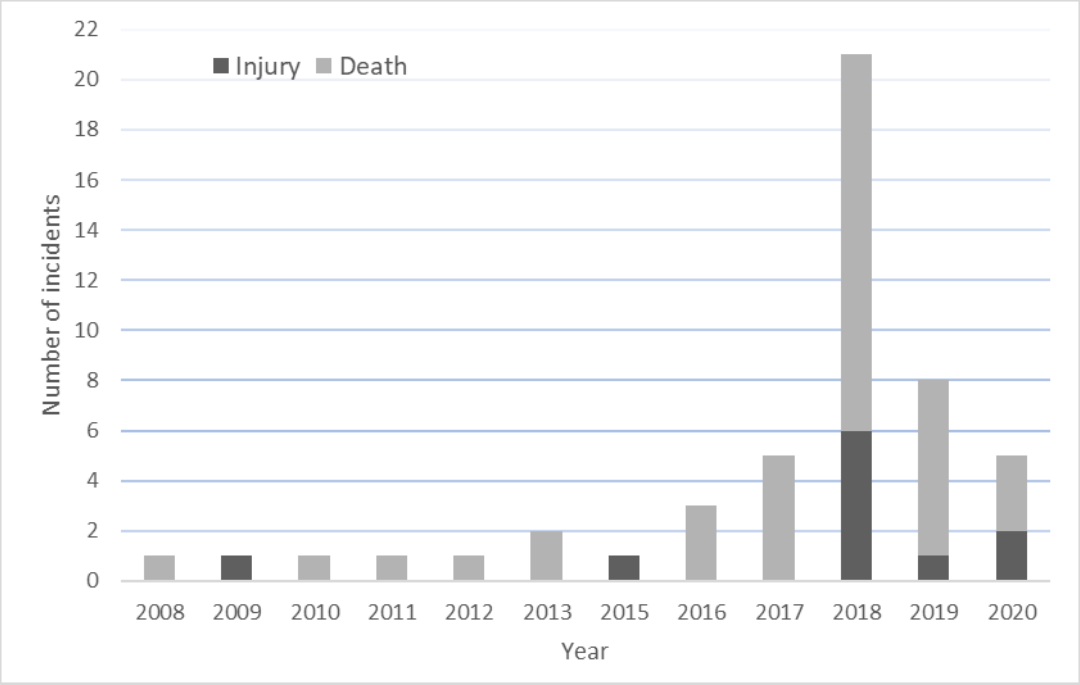

Figure 1- Number of incidents (injury and death) during the 2008-2020 period in Portugal.

The predominant months of incident occurrence were March/April and October particularly in the year 2018. While the first period of the year coincides with the deadline for the fuel management mandatory by law before the fire season, the second period in October coincides with the preparation of the fields to plant new agricultural cultures.

Between the months of December until April, the incidents only occurred after the year 2015 with a greater predominance on the years of 2018 and 2019. Instead, the incidents occurring in October and November ranged most of the study period (2008-2020).

3.1. Sociodemographic characteristics

Age can be considered a critical factor. Most of the incidents (from 2008 to 2020) happened with people above 66 years old (72%) and male (84%). All the incidents occurred with women above 70 years old. Traditionally in southern Europe, field work that uses fire is a gender issue, with predominance for men to perform it (Proxecto

Batefogo, 2019). Most of the incident with women are related with burnings that the couple were performing together. However, the majority of fatalities (69%) occurred when the victim was burning alone and only 10% burned with company, usually with their wives. The information for all the incidents is incomplete since the newspapers in 21% of the news didn't mentioned how was this context (alone vs. with company).

In what relates to the sociodemographic context, most of the incidents (64%) occur in regions with high ageing index (people above 65 years / people bellow 15 years x 100) and 41% in areas with very low population density (values bellow 50 inhab/km^2).

These factors could roughly explain the risk associated with the use of fire by an elder population, isolated and conditioned by the lack of renewal of the population that allows maintaining traditional practices safely, where the use of fire as a rural tool is included. However, these factors don't explain the increase in 2018.

3.2. Meteorology analysis

Meteorology is a factor that influence greatly fire behaviour and its control. Among other meteorological data, and analysis of the Daily Severity Rating (DSR) of the day and area where the incident occurred was performed. This index indicates the difficulty in fire extinguishing operations reflecting the effort required to its deletion (Rego & Colaço, 2013). So, the higher the value of DSR, the most complex and difficult will be fire control and extinction. The analysis showed that 75% of the incidents occurred on days with very low values, so it did not indicate a relationship with the difficulty of burning and consequent incidents.

Once more the meteorology does not explain the increase of 2018.

3.3. Legislation context

Immediately after the extreme wildfires that affected Portugal in 2017, prevention and the responsibility to do fuel management was considered a priority. In particular, around houses and roads, with a bigger demand from the government and from the authorities that control it. Although the legislation already existed (DL 124/2006), in 2018 the authorities increased public announces, doubled the fines if the citizen don't comply, and the police forces were more present doing inspection. These impositions, led to a real race to comply with the law, leading to the speculation of the prices, which were very high for the majority of the population, particularly the elderly without resources (in many cases with very low retirement pensions).

The pressure about fuel management around the houses felt by the citizens it is well expressed in figure 2, where google trends shows the interest on this subject on google searches.

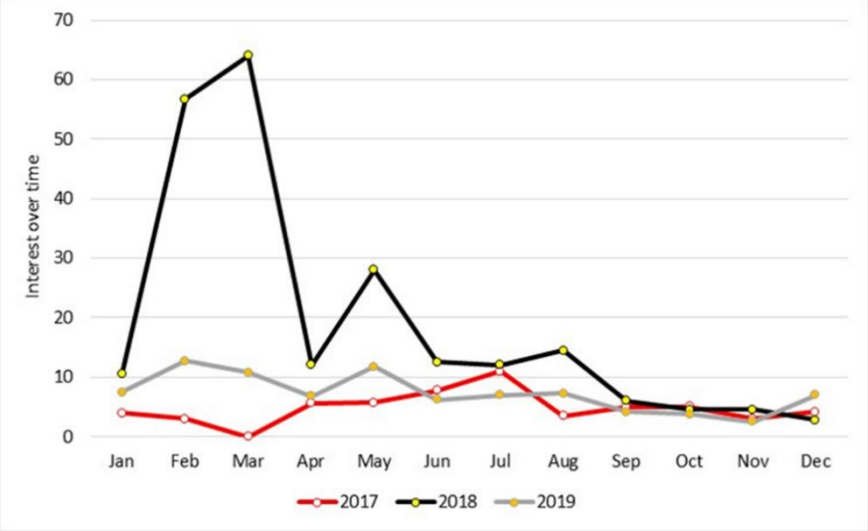

Figure 2- Internet search interest on the topic "Fuel clearing around the houses" on google trends

4. Final remarks

Since 2019, in Portugal, to burn agricultural debris it is necessary to ask permission on an Mobile app. The numbers for 2020 and 2021 reach more than one million permits (personal communication Oliveira, E.).

Although 50 incidents on a universe of millions can be considered very low, we should consider that our goal is to have zero fatalities performing these actions in the field.

Legislative, social and meteorological analysis showed that the most probable factor that lead to the incidents anomaly was the extreme pressure to manage the vegetation, held by police forces, legislation and fines value if you didn't comply.

Several actions from the forest authorities to support and to monitor the traditional burns and to know who is going to perform it have been taken. Considering the results above, it is important that the burns done with elder people who are alone and on a high or very high structural fire risk zone, should be supported by fire teams in the field.

Also, in here there are evidences that a mandatory law with high pressure from the authorities, should always be complemented with pedagogical and support actions. When that doesn't happen, it can lead to unsecure actions leading to injuries or fatalities.

Fire-atmosphere interaction, rate-of-spread, ember wash, spotting, dynamics

Abstract

We implement an ember spotting and ember wash model within an idealized 2D coupled fire-atmosphere model. To do this, we add a stochastic transport to the background or total coupled wind field. An exponentially distributed or a normally distributed velocity anomaly added to the total wind vector represents a turbulent transport of the probability of ignition near ground by intermittent processes. These bed load transport processes may include including gusts, tumbling, and near-front small-scale coherent wind eddies that trap embers and transport them forward, hence carrying the fire along the near-surface total wind field.

1. Introduction

Short range spotting can be difficult to distinguish from fire front movement in higher winds, typical of strong spotting conditions. Some of this short range spotting is due to firebrands that did not rise in the fire's plume but rather spread nearly horizontally in the surface boundary layer. These and the heavier embers and burning debris that emerge from the main fire frontal region carried by strong winds are responsible for rapid movement and widening of the front. We use the phrase "*ember wash*" to denote this part of the fire.

Models have demonstrated the important role of plume intensity and turbulence in the degree and range of spotting, and suggested an exponential-like distribution of spotting downwind of the fire (Martin and Hillen, 2016; Bhutia et al., 2016). Data analyses confirm some aspects of this short-range behavior (Page et al., 2019; Storey et al., 2021). A possible example of this behavior appears in the "Northwest Oklahoma Fire Complex" of three large wildfires that burned about 800,000 acres in Oklahoma and Kansas (Figs. 1 and 2).

Our objective is to represent in an idealized fashion some of the most important processes for surface wind-driven fire in a turbulent flow. We show below how complex fire fronts and effects emerge from the interaction of background wind, fire-induced flow, and a new ember wash effect near intense fires.

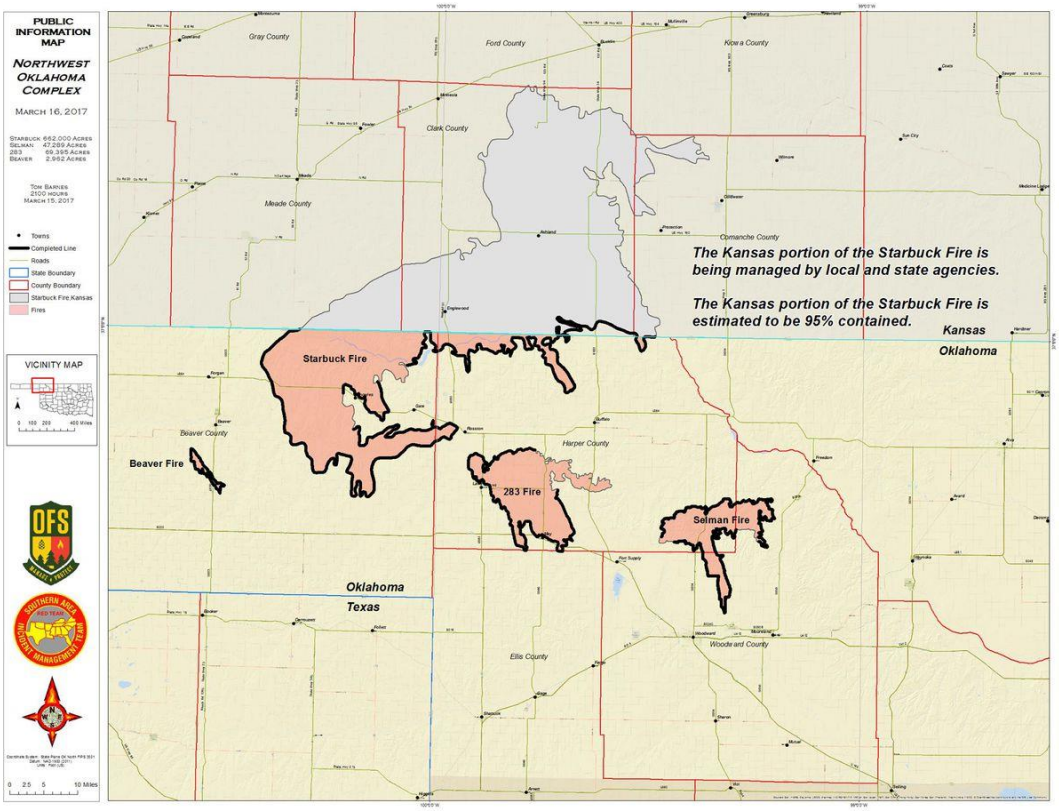

Figure 1- The 2017 NW Oklahoma Complex Fire consisted of several major fires and burned over 834,000 acres. Wind speeds were over 30 mph (15 m/s) with gusts up to 50 mph (25 m/s) in places. Source: Public Information Map of the OK Forest Service.

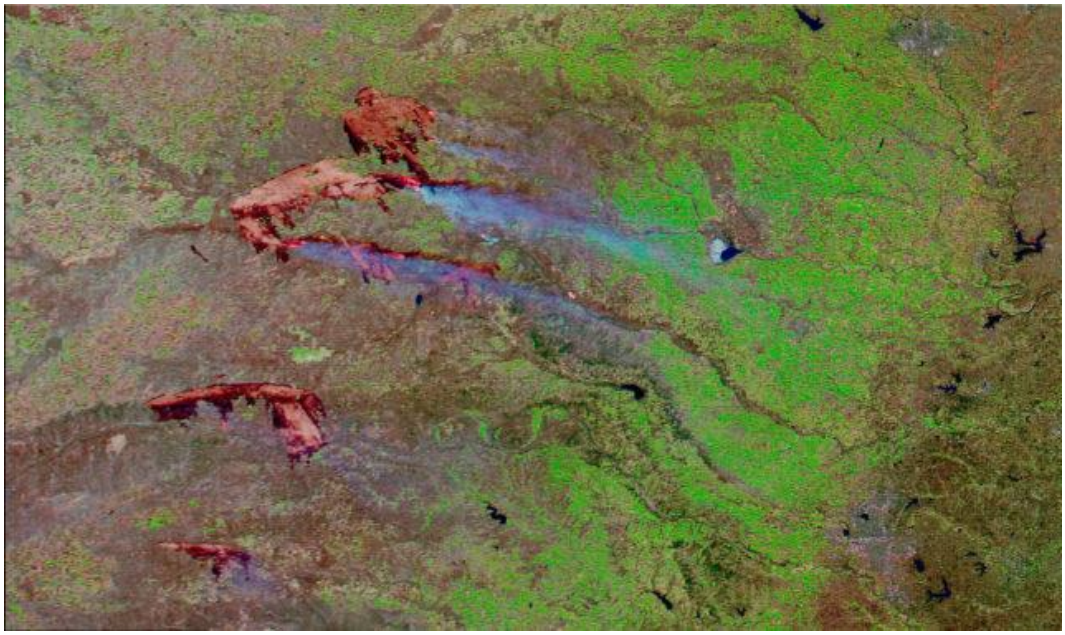

Figure 2- Infrared imagery of the 2017 NW OK Complex Fire near Woodward showing the intense fingering and complex spread behavior, some associated with wind and fuel variations and river drainage slopes. Flame heights were reported in places at over 40 ft.

2. Idealized Surface Wind Model

We use an idealized 2D model for near-surface wind in the presence of fire to investigate ember-enhanced spread in the presence of fire-atmosphere interaction (Quaife and Speer, 2021). The divergent flow is induced

by the rising buoyant fire plume that entrains surrounding air, and the rotational flow at the surface is induced by the lifting of horizontal background vorticity by the buoyant plume. Turbulent diffusion is incorporated into fire spread to represent the fluctuations in hot gases and flames at the near-surface boundary due to small-scale horizontal turbulent motion of the wind within and above the fuel. QS2021 provided a suite of runs that demonstrate various effects of fire-atmosphere interactions on spread rate and geometry of the fire. Standard phenomena such as a parabolic fire front shape, accelerated merging of flank fires, fingering, and other effects are well represented in the idealized model. In QS2021 the *first arrival time* or *time-of-arrival* heat map was emphasized as well as the rigorous relationship between this map and the rate-of-spread in any direction.

We solve for the flow generated by each burning elemental cell in a cellular automata (CA) model of combustion. A simple combustion term with fixed burn time is used. In the CA framework, we specify small-scale divergence and vorticity sources to the flow around individual fire elements which sum to produce the total wind on the fire front.

2.1. Solution Method

The model CA domain is defined by a two-dimensional rasterized grid and solved by decomposing the velocity into the sum of an irrotational and a solenoidal velocity field (Quaife and Speer, 2021). The first component is a background velocity that we take to be the uniform velocity U_{BG}. The other two velocity components are fire-induced, arising from flow convergence into the fire plume and from specified vorticity sources. Hilton et al 2018 call the divergent component the *pyrogenic potential*. At the flanks of the fire, we impose a vorticity source that, depending on the intensity of the fire, may be clockwise or counterclockwise on the fire flank. The model and velocity fields with and without the vorticity model are illustrated in Fig. 2.

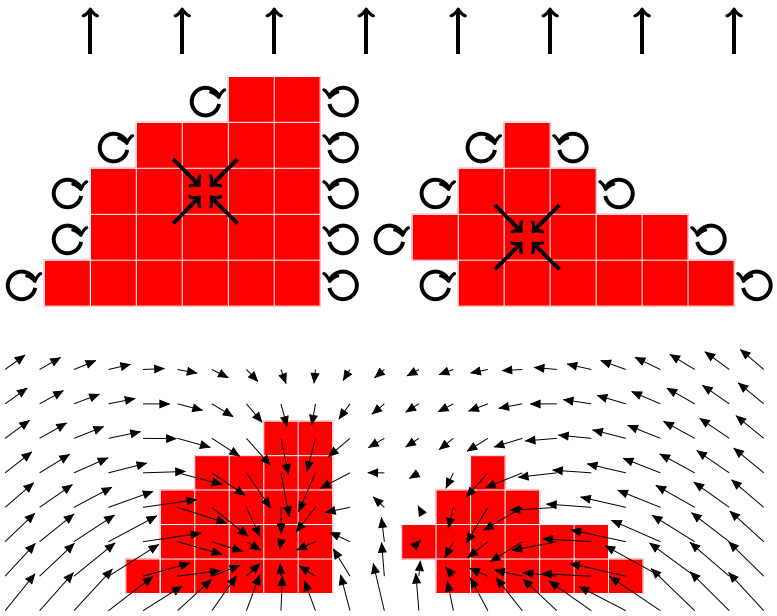

Figure 3- Wind around combusting elements (indicated by red cells). The atmospheric velocity is the sum of three components: a background flow, a pyrogenic potential or divergent term, and vorticity along the flanks.

Computing the flow field requires solving the two-dimensional Poisson equation with a known (and evolving) forcing function. We use the standard second-order central difference formula to discretize the Laplacian, and we impose a constant Neumann boundary condition. The resulting sparse linear system is solved with Matlab's backslash operator. With the total velocity field in hand, new cells must be ignited downwind. We use Bresenham's line algorithm to carry the fire downwind. This algorithm is a line drawing algorithm that determines cells of a rasterized geometry that are between a start and end point. We modify the algorithm since we only have a starting point at a burning cell and wind speed and direction. In addition, we stop igniting cells along the line if it reaches a cell that is either combusting or has no remaining fuel.

2.2. Model Configuration

Here, the cell size is 1m on a side, and the time evolution occurs over minutes to hours. The full model domain is rectangular, flat, and 200 m on a side. The only fuel parameter in the model is a constant burn time. This

parameter depends on the fuel and combustion process and is regarded here as an observed parameter, estimated from observations (Currie et al., 2018). While the range of this quantity can be large, mean values of a few seconds to minutes are typical in light to moderate fuels. The strength of the pyrogenic source is related to fire intensity by standard plume scaling.

We introduce a stochastic term that allows cells to ignite neighboring cells the time step before the original cells extinguish, with a probability of 0.4. This diffusion-based ignition occurs independently of the convection-based ignition due to wind. The rate of spread under diffusion is simply related to the burn time and probability of ignition since the model waits for the cell to burnout before igniting a neighboring cell.

The wind in our CA model is kinematic, and satisfies mass conservation but not a full set of momentum equations. Its role is to act as a "convective agent" for the probability of fire in a cell, and the added stochastic terms are designed to reflect the statistics of a multitude of processes and interactions in the surface boundary layer ahead of the fire front. In this implementation we relax this assumption and carry the fire stochastically down the local wind direction to simulate short-range spotting and ember wash.

3. Extension to Ember Spotting Effects

We extend this model with simple spotting and ember wash representations. We first consider an idealized spotting model to illustrate how embers may be distributed down the ambient wind when they are lofted, and the resulting flow complexity induced by the fire. Next we introduce *ember wash* that is induced by ember transport down the local near-surface wind. Representation of the latter is substantially different from spotting since the embers may roll or bounce along the ground as well as be carried by the wind hence their transport is more complicated, but also more localized to the fire front.

Spot fires are introduced based on a Gaussian-distributed lifetime (Tohidi and Kaye, 2017) with mean 20s and standard deviation 5s downwind *using the background flow* (not the total wind which include fire-induced flow). The reason for this is that aloft the main influence on trajectories is the background wind, with the plume effects secondary once the embers have been released by the plume into the surrounding environment. The ignition probability of the spot is given by a Poisson process with Bernoulli distribution and probability p=0.01. Higher probabilities produce too much fire with new fronts emerging rapidly mirroring the initial front; lower probabilities produce infrequent spotting. This is a useful idealization of the overall spotting process that reflects actual physical processes in an idealized manner. The subsequent spread of the fire is strongly influenced by the presence of spotting, which draws air in toward the new fire and dramatically changes the local flow (Fig. 4).

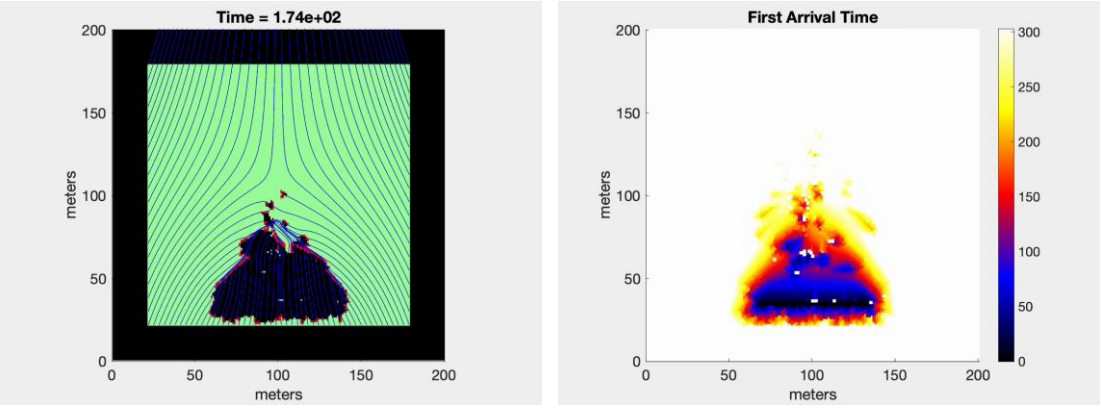

Figure 4- Idealized example of fire spread due to spotting. Fire progression map at 174s after ignition (left) and first arrival time heat map (right; seconds in color, with darker colors showing earlier arrival times). The addition of spot fires produces a complex fire-induced surface wind that affects subsequent spread. Streamlines of the wind (solid curves) indicate the interaction of a constant background wind of 1 m/s from the south (bottom) with the fire-induced wind; combusting elements are shown as red cells. The atmospheric velocity is the sum of three components: a background flow, a pyrogenic potential or divergent term, and vorticity along the flanks.

4. Extension to Ember Wash Effects

In contrast to spotting, *ember wash* or *ember blizzards* show a tendency for embers to spread near the surface rather than aloft. Much of this may occur in a tumbling or *bed load* mode of transport with embers bouncing, rolling, and being re-suspended and carried rapidly forward again in wind gusts. Thus we represent this process by a highly localized probability of ignition with an exponential decay away from the fire front. Such a shape may be justified as a subset of the observed close-range, exponential, spotting distributions in observations of spotting distance (Storey et al, 2021; Page et al, 2019) and sediment transport (Furbish and Schmeeckle, 2020).

A dot-fire ignition pattern is used to generate a fire and illustrate the ember wash effect on spread (Fig. 5). To model the ember wash, the magnitude of the velocity of each burning cell is increased with a probability of p=0.2. The increase in magnitude is sampled from an exponential random variable with a mean of 1 m/s. Streamlines show the very different effect of fire-atmosphere interactions in the case of ember wash that produces a much stronger perturbation to the ambient wind due to the larger area on fire at any given time compared to a simpler continuous, front with a relatively narrow width. The combination of ember wash and fire-induced wind generates a spread geometry not well described by exponential alone from a single well-defined front. Intense fingering due to dynamics with ember wash can also enhance total spread rates. Interactions with structures will be described in our presentation.

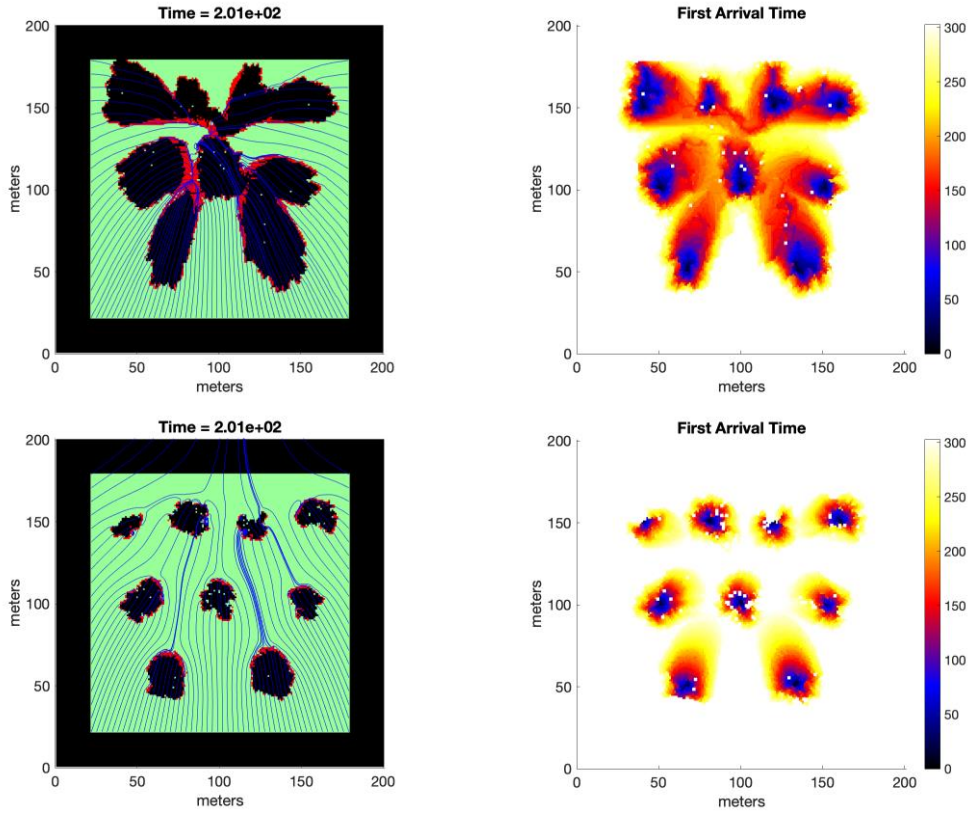

Figure 5- Fire spread with ember wash (top) and without ember wash (bottom). Fire progression map at 201s after ignition (*left****) and first arrival time heat map (****right****); seconds in color, with darker colors showing earlier arrival times. The ignition pattern is nine isolated spots. With ember wash a large region of ignition appears following the direction of the coupled fire-induced wind field. Streamlines of the wind (solid curves) indicate the interaction of a constant background wind from the south (bottom) with the fire-induced wind; combusting elements are shown as red cells. The atmospheric velocity is the sum of three components: a background flow, a pyrogenic potential or divergent term, and vorticity along the flanks.***

Fire risk awareness, homeowners, probability of failure, fuel management, experts' poll

Abstract

WUI fires are posing great challenges to firefighting services, which are overwhelmed by the need to not only suppress the fire, but also protect the community. The need for self-protection is therefore growing, as is the need for the creation of fire-adapted communities. A tool that can aid homeowners and residents of the WUI is therefore created, so that they can identify the vulnerabilities present on their properties and consequently reduce them in order to diminish the risk of damage due to a wildfire. This Vulnerability Assessment Tool is based on a fault tree analysis that includes possible structural vulnerabilities as well as the different ways a fire could spread on a property to finally enter and damage the building. The identification of the probabilities of the different events in the fault tree is obtained through the use of fuzzy logic, for which inputs, outputs and rules are identified. A questionnaire targeted to homeowners and based on the fault tree and linked to the probability identified with fuzzy logic is then developed. By filling in this questionnaire, homeowners at the WUI will be able to know what the probability of a fire entering their house is. The result of the questionnaire also indicates which are the issues on the property that need to be addressed in order to lower this probability. Finally, the tool is validated with a case study of several houses affected by a fire in Spain.

1. Introduction

Fires at the Wildland-Urban Interface (WUI) are annually expanding in frequency and severity, resulting in catastrophic events that take a heavy toll in human life and structure losses (Ganteaume et al. 2021). These events often overwhelm firefighters' capacities due to the need of a simultaneous response to wildfire suppression, community evacuation and structure protection, therefore highlighting the need of the creation of fire-adapted communities, which can safely co-exist with fire (Vacca et al. 2020). Risk reduction strategies which include preventive actions not only at the community scale, but also at the residents' scale (i.e., the WUI microscale) are needed to reach this goal, as case studies indicate that a home's structural characteristics and its immediate surroundings determine a home's ignition potential in a WUI fire, thus influencing its chances of survival (Cohen 2000), (Hakes et al. 2017).

The analysis of past fire events all over the world has resulted in the identification of the different pathways leading to building ignition, which have been summarized by Hakes et al. (2017). Consequently, some countries that have historically been affected by wildfires at the WUI have created standards and guidelines for new and/or existing buildings that include WUI microscale risk reduction strategies related to both building and property characteristics. These are mainly general rules based on experience, but frequently poorly supported by scientific evidence and studies, thus without taking into account the appropriate parameters and processes that explain fire behaviour and effects on assets at the relevant scale (Pastor et al. 2019). In the Mediterranean region, standards and guidelines do not always include building construction or maintenance, or it is not analysed with the appropriate detail.The focus of this work lies in creating a Vulnerability Assessment Tool (VAT) specific for Mediterranean WUI microscale settings, directed to WUI homeowners and residents that is supported by scientific evidence and studies and can give quantitative information on the vulnerability of a property to an incoming wildfire, and can thus identify the main issues that need to be addressed. The tool is presented in form of a checklist that can be easily filled in by the homeowners or residents themselves.

2. Methodology

In order to reduce the risk of home loss at the WUI, a coupled approach that reduces the vulnerability of a home to fire along with the probability of its exposure conditions is necessary (Calkin et al. 2014), (Caton et al. 2017). The causes of fire entrance inside a building located at the WUI can be summarized therefore in two intermediate events of a fault tree, as shown in Figure 1: one involving the exposure conditions and the other involving structural vulnerabilities typical of Mediterranean constructions. For the fire to enter a building, both of these events should occur. The different paths that lead to these two intermediate events in a Mediterranean environment, identified through a literature review of past events (Vacca et al. 2020), are further explored to develop the sketch model in Figure 2.

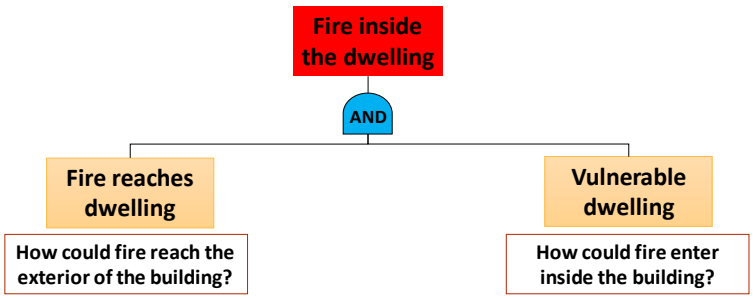

Figure 1: Events that lead to fire enetring a buidling at the WUI

When it comes to the ways the fire can reach the building, two areas around the dwelling have been identified: zone 1 includes the area within a radius of 10 m from the dwelling, while zone 2 consists of a 10 m to 30 m ring around the dwelling. In both zones, three types of fuels are considered: ornamental vegetation, artificial fuels (e.g., LPG tanks, garden furniture, sheds, etc.) and wildland vegetation. A set of fuel management guidelines (based on a review of existing guidelines as well as from observations from past fires and fire tests) has been established for each type of fuel. Failure occurs when compliance to these guidelines is not met.

The same method is applied to elicit the structural vulnerability of the dwelling according to the different paths through which fire could enter. According to Vacca et al. (2020), there are four main paths: glazing systems, roof, vents and structural damage to the dwelling's envelope due to heat accumulation in semi-confined spaces. The failure sequence for each one of these elements is identified as shown in Figure 2. For example, the failure of a glazing system depends on the thickness of the glass pane and the type of shutters, with different degrees of protection depending on the material.

Quantification of the probability of failure of each of these events has proven to be difficult, as information on paths that lead to ignition during past fires is not always available or reliable, as it is mostly collected without the possibility of thorough investigation due to lack of information or resources. To deal with this difficulty, a model that combines fuzzy logic with classical logic has been developed, that uses fuzzy sets that provide means to model the uncertainties associated with lack of information (Sivanandam et al. 2007).

2.1. Model Description

The structure of the developed model is given in Figure 2. Note that, according to Figures 1 and 2, two system variables lead to the final output of the model (i.e., fire inside the dwelling) through a classical logical AND gate, these are: (i) Probability of fire reaching the dwelling (POF_1) and (ii) Probability of failure of the dwelling due to its vulnerabilities to fire (POF of the dwelling). In the same way, this last variable (ii) is obtained through a classical logical OR gate according to the values obtained for the probabilities of failure of the four elements that constitute pathways for the fire into the house, i.e. glazing systems, roof, vents and semi-confined spaces that can suffer structural damage due to heat accumulation. The probability (i) (POF_1) depends on the compliance to different rules set for fuels located in the two considered zones previously described. All the probabilities of failure are obtained through the use of fuzzy logic. Seven fuzzy inference systems (FIS) are defined, as shown in Figure 2.

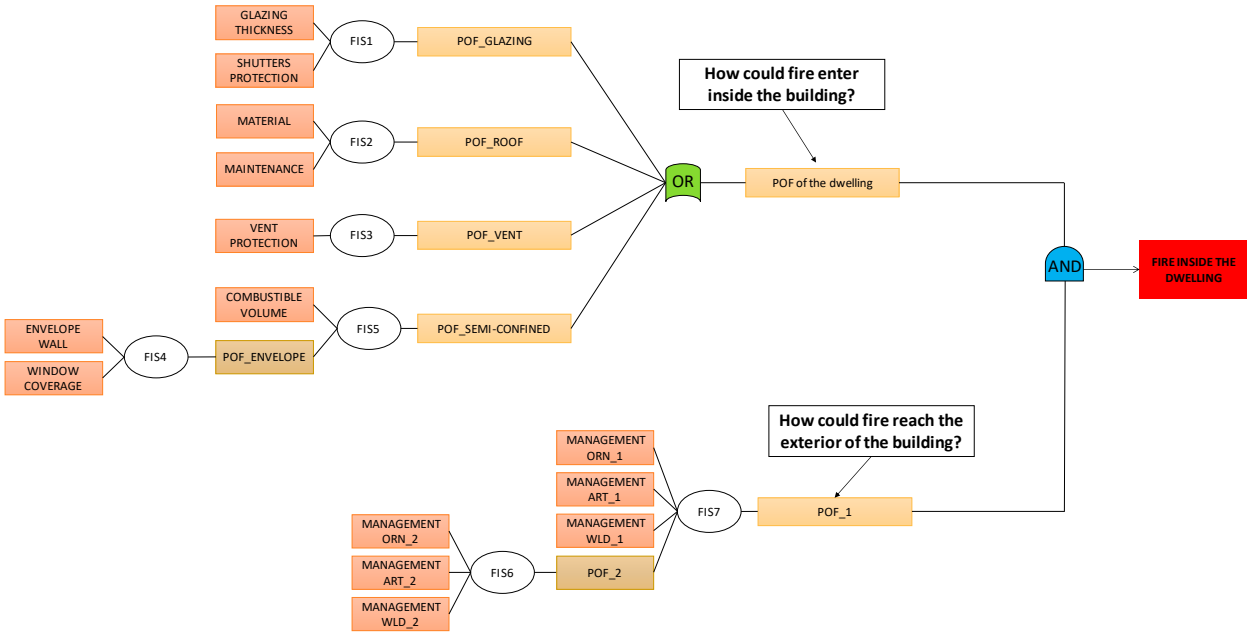

Figure 2: Scheme for vulnerability assessment to wildland fires for dwellings at the WUI. FIS: Fuzzy Inference System; POF: Probability Of Failure; ORN: Ornamental; ART: Artificial; WLD: Wildland; _1: Refers to zone 1; _2: Refers to zone 2.

When a FIS is defined, the generic process shown in Figure 3 must be followed. Initially, the variables that are relevant in the system must be identified (inputs and outputs). These variables must then be fuzzified, meaning that they need to be defined as fuzzy sets by identifying their universe of discourse and selecting a set of linguistic terms (i.e., fuzzy subsets) that accurately describes them. Subsequently, a membership function for each fuzzy subset must be defined to quantify the degree of belonging of any value in the universe of discourse to each fuzzy subset (Sivanandam et al. 2007). Then the inferring process is performed by using a set of rules that connect antecedents (input variables) with the consequent (output variable). These rules usually have a structure such as: "IF …, THEN …". An aggregation process is required to take into account the different rules that activate according to the inputs. Then, since the output is also defined as a fuzzy set, a defuzzification process is necessary in order to transform the fuzzy results into a precise output.

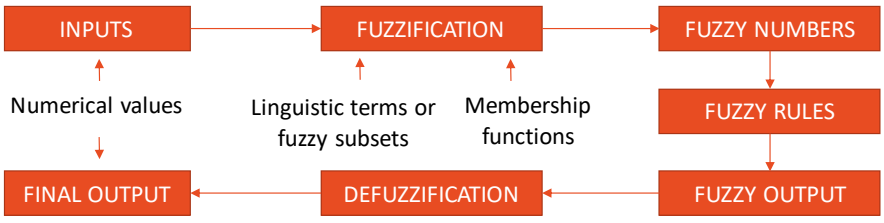

Figure 3: Generic Fuzzy Inference Process - bas ed on (Darbra et al. 2008)

2.2. Poll for experts

A poll for experts on WUI fires and vulnerabilities was prepared to calibrate this fuzzy model. It was filled in by 13 experts. Their expertise helped to determine membership functions, as the poll consisted in giving the most characteristic value (or range of values) for the fuzzy subsets that defined each set present in the model. Additionally, the poll included the fuzzy rules, for which the experts could choose the linguistic value of the output variable. When more than one input variable was combined, the logical operator AND was used. An example of the selection for the rules' consequent is shown in Figure 4.

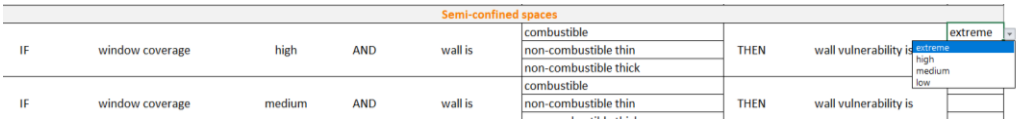

Figure 4: Example of rules present in the questionnaire prepared to synthetize experts' knowledge

2.3. Homeowners questionnaire

The previously presented model has to be used together with a questionnaire that homeowners can fill in autonomously. Questions can be answered mainly with YES or NO and they include all information needed to run the vulnerability model for a specific property. An example of the type of questions is shown in Figure 5.

	Building characteristics	
	Shutters	
1	Do you have protection for all your windows/glazing systems (i.e. shutters)? made of non-combustible materials (solid core wood fire-resistant, metal like aluminium)?	◻ Yes ◻ No
2	What material are the shutters made of?	◻ Wood ◻ Aluminium ◻ PVC ◻ Fire resistant materials
	Glazing panes	
3	What is the thickness of the glazing systems (in mm)?	
	Roof material	
4	Is your roof covering or your roof assembly made of fire-rated material (e.g. clay tiles, concrete tiles, asphalt glass fibre composition singles, slate, etc.)?	◻ Yes ◻ No
	Roof maintenance	
5	Are there missing, displaced or broken tiles?	◻ Yes ◻ No
6	Is the underlying roof sheeting exposed?	◻ Yes ◻ No
7	Are there unsealed spaces between the roof and the external walls or between the roof covering and the roof decking?	◻ Yes ◻ No
8	Do you perform regular cleaning of debris piling up on roof or gutters?	◻ Yes ◻ No

Figure 5: Example of questions included in the homeowners questionnaire.

Once the questionnaire is completed, the replies are introduced into the fuzzy model to calculate the probabilities of failure of the different considered elements, which are then used to calculate the probability of a fire entering a building.

3. Case study

This vulnerability model was tested using information gathered from five homeowners affected by a WUI fire that took place in July 2021 in Lloret de Mar, Spain. These homeowners replied to the questionnaire and we used their answers to quantify the probability of fire entrance in their dwelling (Table 1). They got our feedback and could identify the different issues (fuel management, structural constraints, etc.) that needed to be addressed in order to reduce this probability.

The WUI fire under study prompted evacuation orders and several homes were threatened, various elements present outdoors were burned (e.g. vehicles, fences and garden furniture), and one house was severely damaged (H02) due to the fire entering the building as a result of the breakage of a window pane.

Table 1. Probability of fire entrance in the dwellings according to the elements identified in the scheme for vulnerability assessment to wildland fires presented in Figure 2. FIS: Fuzzy Inference System; POF: Probability Of Failure; _1: Zone 1 (10-m around the dwelling); _2: Zone 2 (10-m to 30-m ring around the dwelling).

FIS / Classical logic results (%)	**Dwellings**				
	H01	**H02**	**H03**	**H04**	**H05**
POF_GLAZING	39	48 (70*)	65	16	16
POF_ROOF	14	14	65	14	14
POF_VENT	0	0	88	0	0
POF_ENVELOPE	0	14	39	39	39
POF_CONFINED	0	41	32	21	21
POF_2	71	71	88	65	88
POF_1	55	87	83	63	66
POF of the dwelling	47	74 (85*)	99	42	42
Probability of fire entrance	26	64 (74*)	82	27	28

* Values obtained considering no-shutters, since PVC shutters were not pulled down during the fire.

According to Table 1 the dwellings with the highest probability of fire entrance were H03 (82%) and H02 (74% considering no-shutters). H03 presented the highest probability of failure of the dwelling itself (99%). Vulnerable elements in H03 structure were the shutters' material, glazing thickness and vents design. Moreover, regarding the probability of fire reaching the dwelling (POF_1), H03 had a value of 83%. This value was not the highest one from the set of dwellings monitored, since H02 reached a slightly higher value (87%), but it was quite high nonetheless. The dwelling H02 had the highest probability of fire reaching the building (POF_1 = 87%), because compliance with fuel management rules was low in both zones.

4. Conclusions

The tool we have developed (i.e. VAT) considers the complex nature of the WUI microscale fire risk problem through the use of fuzzy logic. The end users of this tool are intended to be not only fire safety practitioners, but also the homeowners and residents of the WUI. The use of this VAT will lead to the improvement of fire safety practices at the microscale; i.e. it will increase WUI fire risk awareness of homeowners by identifying systematically major problematic conditions present on their property and in its surroundings. While the building of the tool is complex, the final product that is presented to the user is straightforward and easy to use. Moreover, a planned use of this tool at a local level would be key to improving fire protection at the community level.

Structural vulnerability, social vulnerability, ecosystem vulnerability, Barcelona wildfire risk.

Abstract

Wildfires pose a growing threat to populated areas around the world and especially in the Mediterranean Basin. Numerous Mediterranean cities have typically developed neighbourhoods that expand into forest land in which basic aspects for an efficient WUI fire management have not been considered. In this paper, we present a holistic approach to analyse threats to metropolitan areas due to WUI fires, accounting for infrastructural, societal and ecosystems vulnerability at settlement scale. Based on design fires and the key parameters responsible of fire impact and percolation through communities of most probable WUI fire events, we define key indicators to describe how vulnerable structures are in WUI metropolitan areas. Following, urban and societal indicators are selected to account for population's vulnerability and, finally, ecosystems potential losses are accounted by ecosystem vulnerability indicators such as ecosystem sensitivity and adaptability. We have implemented this methodology to analyse vulnerability in Barcelona WUI areas and identified those that can be more threatened in case of wildfire. Results of this study will be key to inform risk-reduction public policies, as they provide particular insights on those WUI areas within Barcelona municipality that should be prioritized along with the specific issues that should be tackled.

1. Introduction

Wildfires pose a growing threat to populated areas around the world and especially in the Mediterranean Basin. In 2018, the residential area of Mati, Greece, suffered a fire that killed 102 people and reduced more than 600 buildings to ashes. In the summer of 2021, numerous fires ravaged southern Turkey, killing 9 people and destroying hundreds of homes. Algeria also suffered several fires, with 65 deaths, and Greece, southern France, southern Italy, Cyprus and Sardinia had also severe outbreaks with multiple affected towns and resorts (Figure 1).

Climate change is affecting the synoptic weather patterns in the Mediterranean, with episodes of more intense and lasting Saharan air advections involving high temperatures and very low relative humidity, as well as extreme weather events with episodes of strong winds and hurricanes (medicanes). Although the number of ignitions has not risen significantly, the consequences are observed to be more and more severe.

Figure 1- Left: fires in Athens – Greece, 2021 (source: Aggelos Barai); Right: fires in Marmaris – Turkey, 2021 (source: Yetkin Report)

Built-up areas located in the wildland-urban interface (WUI) are increasingly threatened. Buildings, facilities and infrastructure are in direct touch with or very close to vegetation, which, in the event of a fire, suffer the direct consequences of flame contact, radiation and smoke exposure. Numerous Mediterranean cities have typically developed neighbourhoods that expand into forest land. Those wild areas, which provide basic ecosystem services (e.g. biodiversity conservation, water availability, air quality improvement, recreation, etc.), are usually on high slopes and are frequently visited by non-residents and tourists. In the development of such districts, the basic aspects for an efficient WUI fire management have not been considered, such as access roads, fire-resilient urban planning, fuel-reduced fringes, water points, etc.

In addition, evacuation processes in WUI fires are often very complex and, in some cases, end in disaster. Education, awareness, and training are critical issues for building resilient communities, as well as trust, engagement and interaction between experts, managers, and communities (McCaffrey et al., 2013). Giving all parties the opportunity to express their opinions, exchange knowledge and clear up misunderstandings, are central to meet social needs and improve community preparedness, response, and recovery (Mort et al. 2020).

In this paper, we present a holistic approach to analyse threats to metropolitan areas due to WUI fires, accounting for infrastructural, social and ecosystems vulnerability indicators at settlement scale. Our method is applied to Barcelona WUI area as a case study showing great potential to be replicated to other vulnerable metropolitan WUI areas.

2. Methodology

WUI fire vulnerability can be defined by the characteristics and circumstances of a WUI area that make it susceptible to the damaging effects of a wildfire (Gaunteaume et al., 2021). The magnitude of wildfire effects (i.e. heat from flames and toxic dose of smoke components) depend on the spread and intensity of the fire, driven by environmental parameters such as weather, topography and fuel. In turn, wildfire effects can lead to tremendous consequences in urbanized areas, ruining assets and infrastructures, killing and injuring people, and destroying basic ecosystem services.

In line with this definition, our methodology to analyse vulnerability to fires in WUI metropolitan areas is based on two main grounds (Figure 2). On the one hand, WUI fire vulnerability is intimately linked to the type of wildfire that can potentially threat a WUI zone, which may be different depending on the synoptic weather conditions. Fires generally follow particular behaviour patterns according to weather and topography, which have led to the definition of the so-called design fires in many Mediterranean regions (e.g. Costa et al., 2011). Design fires are thus the basis to infer fire impact and effects in WUI zones, and have to be well understood and parametrized for a comprehensive vulnerability analysis. On the other hand, vulnerability of WUI areas has to be explored covering three main axes to account for all possible damages: vulnerability of structures and infrastructures, social vulnerability and ecosystem vulnerability.

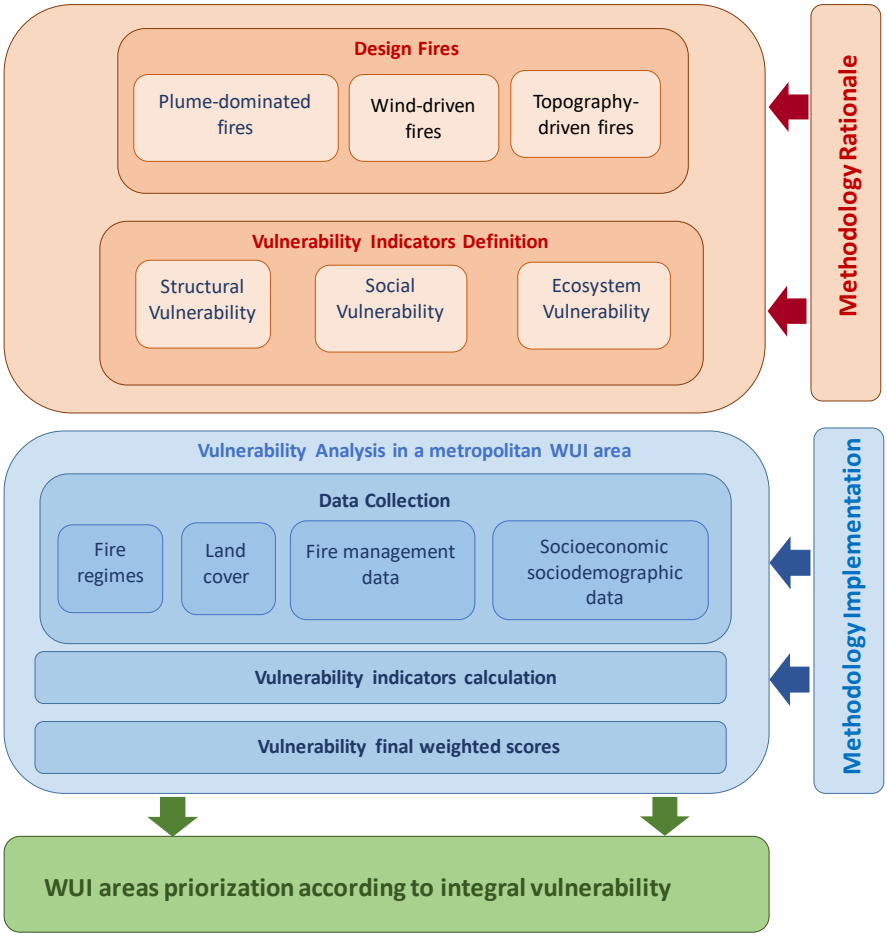

Figure 2- WUI fire vulnerability analysis. Methodology rationale

We have defined key indicators for structural vulnerability (Table 1) in line with the different fire exposure phases – pre-impact, impact and fire transfer (Vacca et al., 2020) that a WUI settlement faces in a fire incident. During the pre-impact phase, it is likely that firebrands will reach the settlement and initiate a spot fire within. This probability can be associated to the area of flash fuels (i.e. grasses and other fine fuels that ignite readily) present in the settlement, which will favour spot fire development. During the impact phase, the magnitude of the consequences in a WUI settlement due to direct flames/smoke exposure of the main fire perimeter will depend on the type of design fire and on the fire propagation mode (head, flank or back fire propagation). Fire permeability within the settlement (i.e. the easiness at which the fire propagates through the community) will largely depend on the type of WUI (e.g. interface, intermix or occluded, as defined by Mell et al, 2010) and is mainly driven by the vegetation continuity and channelling effects due to complex topography. Following, we have identified several severity-escalating factors that may increase fire risk, to account for *i)* the spatial arrangement of the structures with the surrounding vegetation (e.g. length of friction between structures-vegetation or roads-vegetation), *ii)* the presence of critical infrastructure that in case of fire impact may result in the escalation of the fire consequences; *iii)* the operation response (both regarding firefighting response and population response) and *iv)* the degree implementation of preventive measures. Finally, the last component of infrastructural vulnerability deals with the likelihood of a settlement to become itself a fire source term to consolidated adjacent wildlands.

Regarding social vulnerability, it is well known that socio-economic and socio-demographic variables closely correlate with levels of risk, vulnerability, and disaster within and between communities. Wildfires may be especially harmful to people who suffer from exclusion or discrimination on economic grounds, age (particularly the elderly, children, and young people), gender, origin, functional diversity, among others (Eriksen, 2014). According to this, we use these indicators to identify and further understand, in a more nuanced and qualitative examination, the social dimensions and intersections mediating and influencing WUI fire vulnerability

Table 1 – Infrastructural vulnerability components and indicators. (Qn) stands for quantitative indicator. (Ql) stands for qualitative indicator

Vulnerability component	**Indicators**
Pre-impact (firebrands exposure)	Area with flash fuels within the settlement (Qn)
Impact of the main fire perimeter (flames and smoke exposure)	Type of design fire (Ql)
	Propagation mode (Ql)
Fire transfer	Type of WUI (Ql)
	Degree of vegetation continuity (Qn)
	Presence of canyons within the settlement (Ql)
Severity escalating factors	Structure-vegetation and road-vegetation friction (Qn)
	Presence of critical infrastructure potentially exposed (Ql)
	Firefighting arrival time (Qn)
	Population response time (notification, decision and action) (Ql)
	Compliance with water network provisions (Ql)
	Compliance with fuel-reduced fringes provisions (Ql)
Fire source term potential	Perimeter length with flash fuels around the settlement adjacent to consolidated wildlands (Qn)

As for ecosystem vulnerability analysis within the wildfire context, it has to be highlighted that it has been receiving increasing attention during these last years. Several methods can be found in the literature (e.g. Chuvieco et al., 2010; Duguy et al., 2012; Tedim et al., 2013; Aretano et al., 2015) which basically differ on the components that make up ecosystem vulnerabilty and on the type of key issues under study, wether they mainly focus on habitats of greatest ecological value, on socioeconomic aspects or on a wider range of paramaters. In an holostic approach, ecosystem vulnerability analysis in WUI areas must integrate biodiversity indicators as well as other significant landscape and ecosystem values relevant for metropolitan areas, like residential areas, areas with historical-artistic heritage elements, and leisure equipment or infrastructure. In order to consider all these different aspects with a good trade-off between scope and computational cost, in our methodology we consider ecosystem vulnerability to be fairly represented by two basic indicators: sensitivity and adaptability. Ecosystem sensitivity represents the degree to which exposed elements may be affected by fire disturbances, while ecosystem adaptability considers the socioecological adaptive capacities of both ecosystems and communitties that allow to generate recovery and regeneration strategies when facing fire disturbance. Sensitivity and adaptabiltiy are usually infered by considering parameters such as types of habitat, forest cover and community facilities (Aleksandrova et al., 2021; Birkmann et al. 2013).

3. Case study: analysing vulnerability of WUI fires in Barcelona

Barcelona is a large metropolis with a WUI area of remarkable extension, coinciding with the urbanized perimeter within the Collserola Natural Park (NP). Inserted within or in contact with a continuous forest mass, buildings, streets and highways, facilities and infrastructure could be potentially threatened by large forest fires. WUI areas of Barcelona are densely inhabited with population with diverse socio-demographic and socio-economic characteristics. They are also frequently visited for recreational and sports purposes. It has to be highlighted that Collserola NP ecosystem has a direct impact on the health of the millions of people living around it, supplying key ecosystem services to the metropolitan area of Barcelona. The many functions that Collserola generates are air quality (through the absorption of CO_2 and the release of O_2), the regulation of water resources through uptake and evapotranspiration, and the regulation of the urban climate. In addition, Collserola provides habitat for valuable biodiversity.

3.1. Design wildfires

According to Ballart and Pagès (2021), the WUI area of Barcelona can be affected by two different types of wildfires: *A)* a plume-dominated fire, under a synoptic weather pattern of southern heat wave, involving synoptic westerly hot winds from the Iberian Peninsula; and *B)* wind-driven fires (sea winds) with upslope propagation which may occur under southern heat waves or anticyclones. The scenario involving higher risk corresponds to type A fires, as those would involve larger burnt areas with high intensity (Figure 3).

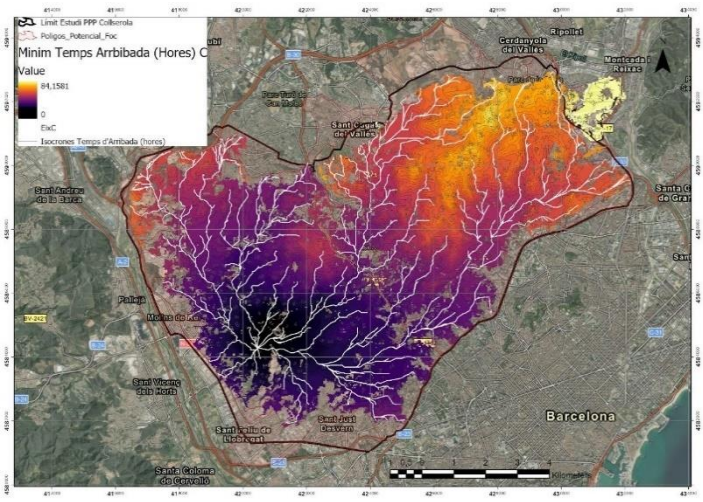

Figure 3- FlamMap simulation of a fire initiated in the metropolitan area of Barcelona (Molins de Rei) including all potential fire runs. The enormous destructive potential of the fire can be observed, as almost the overall Collserola NP area would be affected (Collserola NP perimeter is drawn with a brown solid line).

3.2. Vulnerability analysis

Vulnerability has been analysed in nine 1x1 km-areas of interest (AoI) within the WUI area of Barcelona (Figure 4) in which a preliminary screening of structural, social and ecosystems indicators has been done.

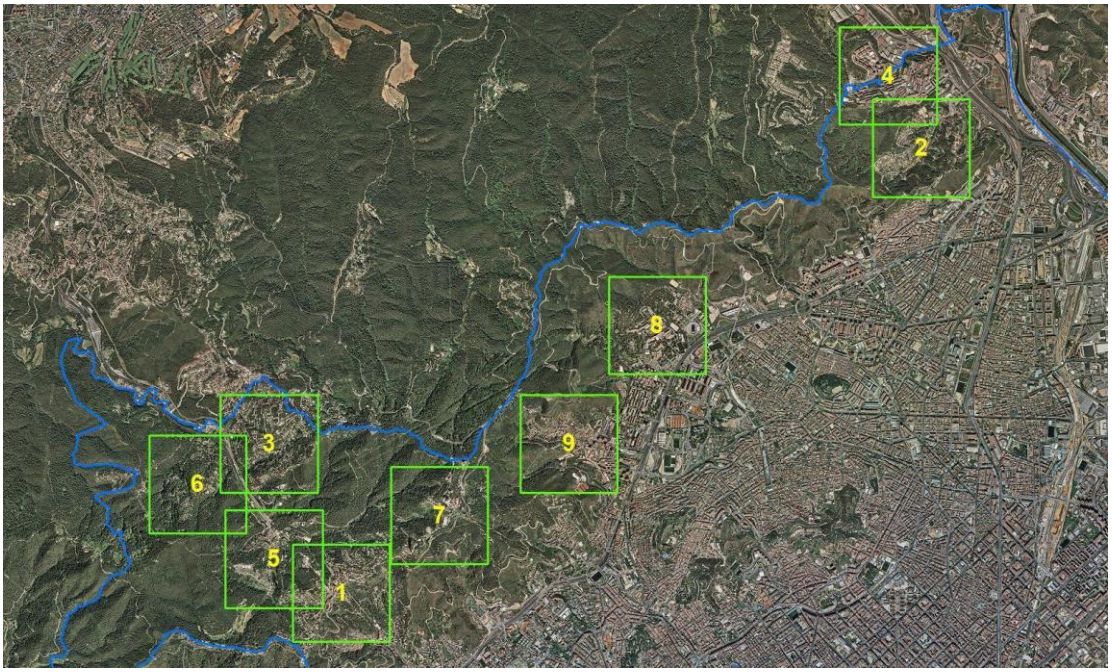

Figure 4- Location of the areas of interest within the WUI area of Barcelona. 1) Vallvidrera, 2) Torre Baró, 3) Can Rectoret, 4) Ciutat Meridiana, 5) Mas Sauró, 6) Mas Guimbau, 7) el Tibidabo, 8) Universitat de Barcelona Campus Mundet, 9) Sant Genís dels Agudells.

Regarding structural vulnerability, the indicators of the different components (i.e. firebrands exposure, fire and smoke impact, permeability, severity escalating factors and fire source potential) have been analysed and weighted across the nine AoIs. As for fire and smoke impact, the two design fires have been considered (i.e. plume-dominated fire with W-E direction and sea wind-driven fire with SE-NW direction) examining both potential head and flank impact. Permeability has been qualitatively analysed by classifying all AoIs in the study area in the two different types of WUI present in Barcelona (i.e. intermix and interface). Moreover, a quantitative analysis of vegetation continuity has been undertaken by using the WUIX algorithm (Caballero, 2019). The same software has also been used to compute the section of the WUI perimeter adjacent to consolidated grasslands or other wildlands with flash fuels, to obtain the potentiality of the AoI to become a wildfire source

term egressing from the main fire perimeter. Firebrands' exposure has been inferred by computing the area of flash fuels in all AoIs. The main severity escalating factors have been investigated with data provided by the Barcelona fire agency (Bombers de Barcelona), and Barcelona city and provincial councils. As for structure-vegetation and road-vegetation friction length, again the WUIX algorithm has been used. The three AoIs with higher structural vulnerability have appeared to be Vallvidrera, Torre Baró and Can Rectoret.

In terms of social vulnerability, the main indicators of social and urban vulnerability most used to inform public policies at municipal and metropolitan level in Barcelona have been identified. These are indicators that are essentially based on socio-demographic and economic variables at neighbourhood level. In particular, we should mention the Social Vulnerability Index (SVI), based on three basic variables such as aging, migrant status and income (Ruiz et al, 2020) and the Urban Vulnerability Index (UVI, Antón-Alonso et al., 2021) that integrates information on social and residential exclusion. Mean normalized values of SVI and UVI have been calculated for the nine AoIs. Torre Baró, Ciutat Meridiana, UB Mundet and Sant Genís dels Agudells, have appeared to be the WUI areas with higher social vulnerability.

As for ecosystem vulnerability, Barcelona WUI area has been analysed both in terms of ecosystem sensitivity and adaptability according to the methodology developed in Moran (2020). Both parameters have been combined to obtain a final value of ecosystem vulnerability. The maximum ecosystem vulnerability corresponds to those elements of maximum sensitivity and minimum adaptability. In our case study, maximum values have been found in areas of scattered intermix or settlements surrounded by dense forest coverage. According to these criteria, Vallvidrera, Can Rectoret, and Torre Baró have appeared to be the WUI areas with higher ecosystem vulnerability.

4. Conclusions

A holistic methodology to analyse vulnerability to wildfires in metropolitan areas has been designed and implemented for the case study of the WUI areas of Barcelona. It considers three main vulnerability components: infrastructural, social and ecosystem vulnerability. Relying on different types of indicators, this integrated vulnerability analysis is key to inform risk-reduction public policies, as it provides particular insights on those WUI areas within a municipality that should be prioritized along with the specific issues that should be tackled.

Wildfire, Fire spread simulation, Evacuation modeling, Wildland-urban interface

Abstract

Wildfires have been growing dramatically over the past decades due to climate changes, global warming, droughts and forest-landscape, and vegetation changes. Increasing losses due to wildfires have been a significant concern; therefore, wildfires have become an important field of study and research. This paper assesses and reviews the wildfire simulation approaches to predict the fire spread characteristics. These simulations are essential to analyze the potential risks and impacts of wildfire, predict the fire rate of spread (RoS), fireline intensity, and flame length, which are the most crucial parameters for fire management and first responders, and determine the evacuation necessity or requirement. The assessment of evacuation triggers is investigated according to the available literature, and studies on wildfire and fire spread simulation based on different approaches such as physical, numerical, or computational fluid dynamic (CFD) modeling and empirical are reviewed. All mentioned simulations are modeled on different scales, i. e. microscale, mesoscale, and macroscale, based on the desired criteria assessment of each case study. These approaches are distinguished basically by their ability to model an area of a certain extent or scale, and their accuracy in attaining the desired analysis, data, and prediction, and selecting one approach over the others is always a trade-off between these two criteria.

1. Introduction

Wildland fires have been recognized as a crucial field for research by the International Association for Fire Safety Science (IAFSS) agenda 2030 for a fire-safe world (McNamee *et al., 2019*). Wildland-urban interface (WUI) communities are defined as places "where humans and their development meet or intermix with wildland fuel" (Us Department of Agriculture, 2001), which are the most vulnerable to wildfires given their proximity. Moreover, other risks usually exist in WUI communities, such as insufficient transportation systems that fall behind in comparison to urban development and an increase in population; for instance, many WUI communities have only one road in and out of them, which can cause difficulties during evacuation (Cova, 2005). Multiple fatalities have been reported as the consequence of a wildfire or occurred during evacuations due to the inadequacy of the rural road. The inadequacy of the rural roads can cause congestion and trap the evacuees (e.g., Pedrogão Grande). Moreover, delayed evacuation triggers alarm or delays in evacuation advice implementation are other problems, which can cause locals to stay until the last minute and face hazardous situations (Haynes *et al. 2010*).

Wildfire modelings play a crucial role in fire management, determining the fire risk exposure, mitigating fire risk, evacuation management, and evacuation planning. The ability to forecast the wildfire behavior accurately will ensure the safety and effectiveness of wildfire control and fire management (Countryman, 1972). Different aspects of fire in the wildland context, such as intensity of the fire, direction of spread, and the rate of fire spread in the wildland, are the main desired quantities, which are modeled in accordance to conditions that affect the wildfire, e.g., weather, topography, vegetation, etc. (Dhall, 2020). A flow diagram is presented in Fig. 1 to grasp an idea of different factors of uncertainty that would affect the characteristics of fire.

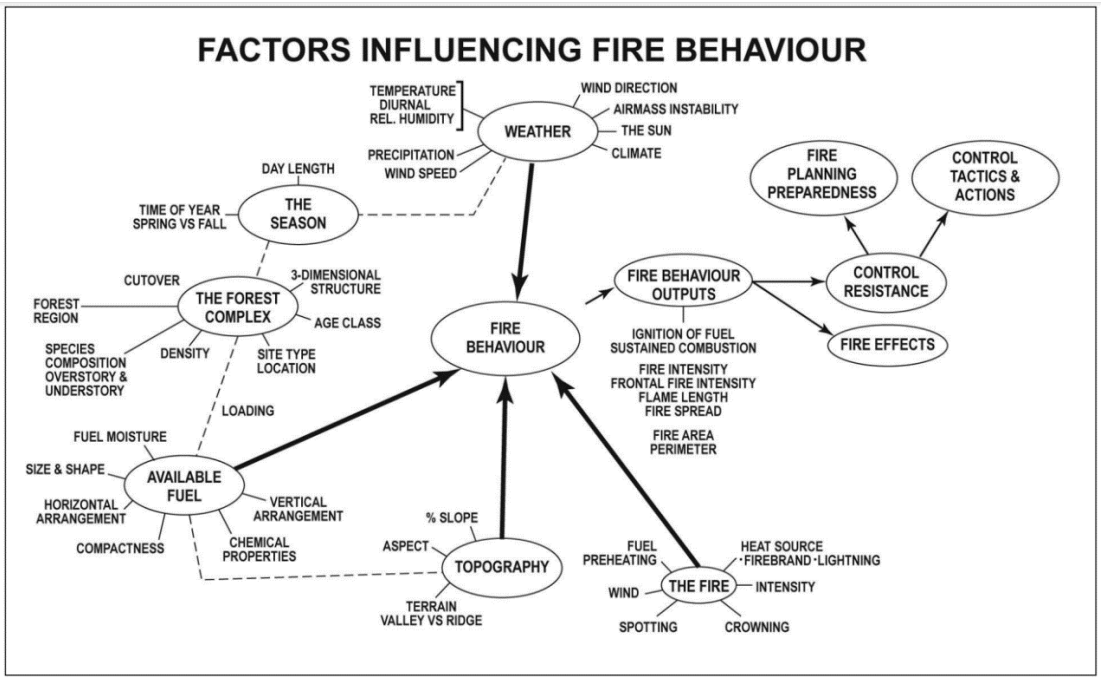

Fig. 1. Factors influencing wildland fire behavior and in turn, the complexities involved in its prediction (Santoni et al. 2011).

Wildfires, especially at the wildland-urban interface, raise various challenges for the residential population and the governing authorities in terms of producing a safe and effective plan to preserve the society, protect the infrastructure and residents' assets, and, if necessary, evacuation. To ensure life safety and evacuation effectiveness, various social and environmental characteristics of WUI communities, which pose different challenges, need to be addressed (Cohn *et al.* 2006). Heterogeneity of the household density over the WUI, layout and the positioning of the roads, insufficiency of the roads due to the WUI community growth, and the topography and geography of the surrounding environment are the physical factors that need to be considered to produce an effective and safe evacuation (Cova, 2005), in addition to social factors, e.g., age, sex, income, race, and culture of the residents (Folk *et al. 2019,* McCaffrey *et al.* 2018, McLennan *et al.* 2019, Vaiciulyte *et al.* 2018). Even though it is not yet the standard protocol, evacuation simulation models are increasingly used to develop better evacuation strategies for WUI communities (Pel *et al.* 2012, Alsnih *et al.* 2004). These simulation models enable the authorities to manage and plan an effective evacuation by deciding the evacuation trigger or start time, evacuation roads and routes, and traffic management for different wildfire scenarios. This is achieved by forecasting evacuation-affecting factors, i.e., departure time and pattern, travel duration, the mean speed of the evacuees, the traffic length, and flow rate (Pel *et al.* 2012).

2. Wildfire modeling

Wildfire simulation models are distinguished into two basic categories regarding their fundamental approach: physical models and empirical or semi-empirical models. The actual development of the combustion process is not the aim of empirical or semi-empirical simulations but rather be used in the management and decision-making process (Papadopoulos and Fotini-Niovi 2011). Many identified a coupling of both approaches as the best solution to better simulate the characteristics of wildfire and fire behavior (Cruz and Gould 2009).

Richard Rothermel (1972) published a detailed mathematical model of wildfire to predict the fire rate of spread in wildland fuels, which is the basis of many other models and simulations. This model could not be used to incorporate the crown fires, while it could only predict the fire's intensity and its spread rate in a continuous fuel bed on the ground. Finally, with the development of such models and programs, computer calculations started their use for operational and research purposes in the field of wildfires in the 1970s (Frandsen 1973, Burgan 1979).

The cellular automata (CA) model was used by Karafyllidis and Thanailakis (1997) for the very first time to predict the fire spread in homogenous and heterogeneous forests (also referred to as the KT model). The most outstanding advantage of this model was the ability to incorporate weather conditions and land topography. Later on, in an attempt to create software to simulate small-scale fires in the Mediterranean regions, with the scope of fire management and deployment of firefighters, Giorgio and Baracani (2002) combined the mathematical model introduced by Rothemermel for the simulation of fire spread with the CA theory.

In the following years, various research was carried out to improve the KT model to get more accurate results. Hernandez Encinas *et al.* (2007) improved the former developed KT models with two different approaches. First, the wildfire spread in homogenous and heterogeneous environments was modeled by changing the square cellular into a hexagonal cellular automaton. Second, a more realistic simulation was achieved by improving the KT model, which was modeling the circular fire front spread coming from the diagonal cell over linear spreading.

Tiziano *et al*. (2015) presented a CA approach that can mitigate the problem of distorted fire shapes thanks to a redefinition of the spread velocity. With the same method, the Spatio-temporal evolution of fire bands simulation with more simulated fire properties was carried out by Yuxuan *et al*. (2018). Fire shape distortion simulation was improved without any mathematical correction.

Onur Satir *et al*. (2016) manipulated the artificial neural network method to map forest fire probability in Mediterranean forestland using multiple data assessments. A new method called Evolutionary Statistical System (ESS) was developed by Bianchini *et al.* (2015) to simulate forest fire spread. This method addressed the challenges raised by the input parameters' uncertainty.

The cellular automata theory was then combined with a data-driven parallel fuzzy theory approach to simulate the wildfire spread by Ntinas *et al.* (2017). The introduced fuzzy cellular automata (FCA) model enables data incorporation from real wildfires to improve its accuracy due to a data-driven approach based on evolutionary optimization. Nevertheless, the application of this method for real-time wildfire scenarios would be restricted due to its computational complexity. Zhong Zheng *et al.* (2017) applied extreme machine learning (EML) to the traditional wildfire prediction CA method and validated the newly introduced model with five fires in the western United States. Significant improvement in the simulation accuracy was observed as a result of the method implementation.

In recent years, extensive studies have been conducted concerning wildland-urban interface fire spread modeling. Jiang *et al*. (2021) proposed a fire spread model based on the heterogeneous Cellular Automata model for large-scale complex wildland-urban interface (WUI) areas using thermal principles and empirical statistics. Valero *et al.* (2021) enabled uncertainty quantification in wildfire CFD models using multi-fidelity strategies. Attempting to overcome the wildfire modeling uncertainties, which are mainly due to the computing constraints, these authors improved the classic Monte Carlo method and achieved simulation speedups of up to 100 times; this improvement was used to quantify uncertainties and assess the sensitivity of the fire rate spread (RoS) to weather and fuel parameters. Agranat and Perminov (2020) developed a physics-based multiphase Computational Fluid Dynamics (CFD) model of wildfire initiation and spread to create a user-friendly computational tool for analyzing wildland fire behavior and its effect on urban and other structures.

3. Evacuation modeling

On the other side of this field of research stands the evacuation simulations. Wildfires necessitate the evacuation of large groups of people from large locations, often across long distances. The increasing frequency of these catastrophes shows that suitable evacuation strategies for wildfire-prone areas are required.

There is a scarcity of household data on wildfire evacuation behavior to support and design evacuation models. Most wildfire research has focused on forecasting who would flee, and how to anticipate traffic needs, however, they are still restricted in scope. Evacuation models also require information on decisions and behaviors made during the evacuation process, such as which and how many cars will be utilized, which routes evacuees will take to reach safety, which destinations will be chosen as safe spots, and many other aspects (Alsnih and Stopher 2004). In the absence of such data, most models default to ideal household behaviors, such as Leon and March (2017), and/or only consider one method of transportation (e.g. on foot (Veeraswamy *et al.* 2018) or vehicles

(Shahparvari *et al.* 2019)). Because evacuation data from WUI fires is scarce, models that integrate behavioral features frequently rely on users' judgment or defaults, which are not always anchored in fire evacuation data (Carole and Gaudo 2017, Cova and Johnson 2002).

Traditional evacuation simulation models have been demonstrated to be too optimistic regarding clearance timeframes and other results (Murray-Tuite and Mahmassani 2003). According to a study by Wu *et al.* (2012), evacuees are unlikely to organize themselves optimally along major corridors during hurricanes. When compared to models using ideal assumptions, simulating actual behavior (e.g., individuals delaying evacuation and/or choosing regular routes) (Bulumulla *et al.* 2017) can considerably reduce evacuation "effectiveness" (Chiu and Mirchandani 2008). Incorrect assumptions regarding evacuation behavior in WUI fires might jeopardize the safety of a WUI community. Models that incorrectly account for evacuee decision-making and behavior might understate evacuation results (e.g., clearance time), leading to emergency officials using ineffective traffic management measures or delaying warnings until it is too late.

Multiple time periods are involved in the household evacuation procedure. Ronchi et al. (2019) describe a generic WUI fire evacuation timetable, which lists emergency officials' and households'/evacuees' activities chronologically. After being alerted and deciding to leave, a household's evacuation timetable may include time to finish preparations, time to go on foot, time to travel by car, and time to board at a safe location. Trip generation (which predicts the number of people who will evacuate and when they will leave), trip distribution (which predicts where [the destination] people travel to reach safety), modal split (which predicts the types of transportation chosen for evacuation), and traffic assignment (which predicts the routes chosen to reach the destination) are the four steps traditionally followed by traffic models to simulate households' evacuation timelines. Driving parameters (such as speeds and flows) are included in the traffic assignment (Koligowski 2021).

The type and structure of data required for each phase vary depending on the modeling approach. Macroscale, microscale, and mesoscale modeling methodologies are employed to simulate household behavior and mobility in evacuation models. To detect larger patterns in evacuation behavior, macro models describe households/traffic behavior at the aggregate level, needing data on traffic speed and flows, capacity, and densities. Individuals (agents or vehicles) can be simulated using microscale models, which require data about household decisions, behaviors, and/or movements within the broader evacuation community. Mesoscale models offer a middle ground between the two approaches, representing traffic entities in greater depth and their interactions at a lower resolution (Murray-Tuite and Wolsohn 2013). All modeling methods require data on WUI fire evacuation decision-making and behavior. Data on evacuation decisions and timing are required to give models and users information on the number of individuals, homes, and cars entering the traffic system at various points throughout the evacuation. To offer the models/users an evacuation endpoint, data on the destinations or zones to which evacuees would be moving is also required. Following that, data on mode choice reveals how evacuees are distributed across various modes of transportation of various sizes and capabilities. Finally, data on traffic assignment is required to inform models and consumers about how various modes are dispersed and move along the road network (Murray-Tuite and Wolsohn 2013).

Cova *et al*. (2005) developed a new method for delimiting wildfire evacuation trigger points using fire spread modeling and geographic information system (GIS). It was suggested that using data on wind, topography, and fuel in conjunction with estimated evacuation time, a trigger buffer can be computed for a community whereby an evacuation is recommended if a fire crosses the edge of the buffer. Additionally, in an attempt to couple the fire simulation, pedestrian evacuation, and traffic, Wahlqvist *et al*. (2021) developed the WUI-NITY platform, which simultaneously models fire and evacuation to enhance situational awareness in evacuation scenarios.

Ronchi *et al*. (2019) focused their study on the modeling of wildland-urban interface fire evacuations. Since the most important "layers" of a WUI wildfire, including wildfire, pedestrians, and traffic, were mainly modeled in isolation, this research presented a framework for evacuation simulation, including all the layers.

An agent-based simulation model (ABM) was developed by Grajdura *et al*. (2022), to study the behavior of evacuees in case of a fast-moving wildfire toward a community. A "Post-disaster Survey" and decision tree methods were used to model agent movements and decisions. Another study modeled awareness of the residents, departure, and preparation time in case of a no-notice wildfire evacuation (Grajdura *et al*. 2021). The effects of age, race, income and other characteristics of a resident at the time of being alerted to a wildfire were

assessed. It was shown that smartphones and community evacuation plans have a large and positive effect on no-notice fire awareness time (Grajdura *et al*. 2021).

4. Gaps, challenges, and conclusions

As discussed above, in the field of wildfires and evacuation caused by wildfires simulation and modeling, there is always a challenge: the trade-off between computation power or availability and the accuracy of the results obtained by models. As a result, studies made step-by-step improvements, including considering more factors that influence the actual case to attain a more accurate result and changing the whole simulation model or the approach toward the problem. With advances in computer hardware and sophisticated processing resources, the "fully physical" models had exponential growth over the past two decades. Many factors which were considered for modeling by empirical correction coefficients are now modeled physically, and almost the exact phenomenon is implemented into the model. The distinction between radiation heat transfer and convection heat transfer, the existence of two different fire propagation regimens (wind-driven and plume-dominated), identification of surface fire and crown fire, and the transition of surface to crown fire, ignition by firebrands, fire whirlwinds, along with many other physical phenomena. Yet still, many other issues remain a challenge. Empirical factors that are used in the models need to be corrected and updated constantly; the weather data available for the fire propagation simulation are not completely exact and are based on forecasting, in which the intervals of forecasts are from hour to hour, the fuel models i. e., fuel types and fuel moisture content, vary from time to time in each location, and many other issues that need to be addressed to be able to make a more exact prediction on wildfire behavior.

As for the evacuation simulation models, none of the models that were overviewed are specially designed for WUI wildfire evacuation scenarios. But as discussed, they can be modified to provide useful data for evacuation planning and management regardless of their original mission. These models either focus on vehicle transport through the road systems as a mass concept or on individual cars through an urban area or even pedestrians. Usually, the integration between vehicles and pedestrian are not considered, which can cause serious challenges during a wildfire evacuation. The models usually lack detailed features which take the interaction between wildfire behavior and WUI residents' evacuation behavior. Different factors like age, sex, culture, race, and income affect each evacuee's decision-making process. Even the proximity to wildfire hazards has a great deal of influence on the behavior of evacuees.

Nevertheless, these models can be of great use in identifying critical points in a transportation system and roads that might cause problems during evacuations. The evacuee decisions can be estimated by a professional analyst and implemented into the model. In order to have a complete and effective evacuation simulation software, a model should be provided that integrates the wildfire characteristics, and smoke spread with the evacuee behaviors and the transportation and network system.

Abstract

Concentrated sunlight is a potential ignition source of wildfires, but its ignition mechanism is still poorly understood. Herein, we study the smoldering ignition of tissue paper (a common fuel that was abandoned by human in wildland) by a concentrated sunlight spot with heat fluxes up to 780 kW/m2, which is focused by a transparent glass sphere. The diameter of the sunlight spot on the paper sample ranges from 1.5 to 20.0 mm by varying the paper position within the focal length, where a smaller spot has a larger intensity of sunlight irradiation. We found that the concentrated sunlight can easily ignite the tissue paper. The measured minimum spot irradiation for smoldering ignition is not a constant but is much higher than 11 kW/m2 measured in a traditional cone-calorimeter test. As the diameter of the irradiation spot decreases from 20 to 1.5 mm, the minimum irradiation for smoldering ignition increases from 17.5 to 205 kW/m2. A 2-D computational model was successfully applied to reproduce the experimental observations and validate the results. This work ultimately quantifies the potential fire risk from concentrated sunlight spots and helps elucidate the underlying mechanisms leading to smoldering ignition.

1. Introduction

The ignition of wildland fuels defines the initiation of devastating fire events. Many ignition events leading to wildland fires occur remotely by a point heating source (Caton et al. 2017), such as the deposition of lofted firebrands, lightning strikes, and concentrated sunlights (Fernandez-Pello 2017a; Wang et al. 2022). Significant studies have focused on spotting ignition by lofted firebrands (Fernandez-Pello 2017b). Comparatively, a lesser-studied source of ignition is a concentrated sunlight spot, which can be focused by a dew droplet, curved glass window and decorations, transparent fish bowls, or cylindrical bottles filled with water (Fig. 1a). In 2018, sunlight concentrated by shards of broken glass had burned roughly 80 acres near Reardan, Washington (Fig. 1b). However, our understanding on this potential ignition source is still limited.

Once an intense irradiation spot is applied, a recipient fuel may first be heated, dried, decompose, and then begin to smolder (Drysdale 2011). Smoldering can be easily initiated by a weaker ignition source or even self-ignited, providing a shortcut to severe fire events through the smoldering-to-flaming transition (Rein 2014; Santoso et al. 2019). Therefore, it is of vital significance to fully understand smoldering ignition. So far, little research has studied the smoldering ignition by concentrated irradation spots, and the ignition criteria are still poorly understood.

This work investigates the smoldering ignition of multiple-layered tissue paper samples by sunlight spots concentrated by a spherical glass ball. Within the focus length, the diameter of the heating spot was varied from 1.5 mm to 20 mm, and the intensity of irradiation was varied up to 780 kW/m2. The ignition delay time, critical heat flux of smoldering by the irradiation spot were quantified. Eventually, a 2-D model will be established to vlidate the experimental results.

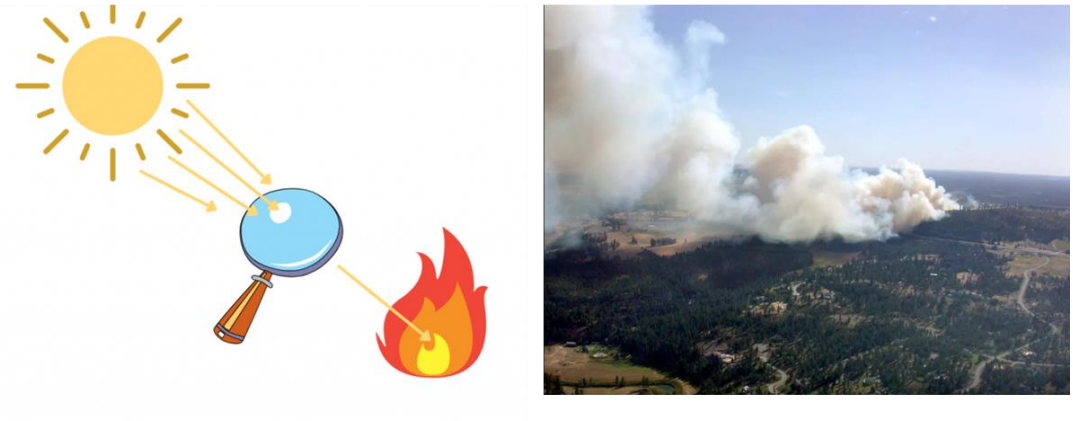

Figure 1- (a) schematic diagram of ignition by concentrated sunlight (copyright: Survival Guide), (b) a wildfire triggered by sunlight concentrated in US (copyright: The Spokesman-Review).

2. Experimental Method

2.1. Materials and setups

Thin tissue paper was used in the experiment, as it was a typical thin fuel abondoned by humans in wildlands. Before the test, the tissue paper was first oven-dried at 75 ℃ for 48 h, and its dried bulk density was measured to be 98 ± 5 kg/m^3. For the test, the tissue was first cut into a size of 60 mm × 60 mm, and six layers of tissue were packed into a sample with an overall thickness (δ) of about 2 mm (see Fig. 2a).

In the experiment, natural sunlight was concentrated by a 150-mm K9 crown glass sphere with a refractive index (n_c) around 1.53. The focal length and back focal length of the crown glass sphere were theoretically calculated to be 108 mm and 33 mm, as illustrated in Fig. 2b.

A solar power meter was fixed at the front towards the sunlight direction to record real-time solar irradiation ($\dot{q}_s''$). The sample frame was a hollow box that was inserted into the sample holder. The sample holder was installed on a slide that can adjust its distance between the tissue sample and the glass sphere with a precision of 0.5 mm.

2.2. Quantification of solar irradiaiton heat flux

To quantify the high irradiation of concentrated sunlight spot, an optical simulation performed in *TracePro* (TracePro) was first used to c orrelate the size of the light spot and theoretical irradiation ($\dot{q}_c''$) concentrated by a 150-mm crown glass sphere.

In the optical simulation, the overall concentration factor (C) is a ratio of irradiation level after and before concentrating which could be used to quantify the concentrated irradiation flux in this study. Fig. 2b shows the overall concentration factor (C) vs. light spot diameter (D) of a 150-mm glass sphere based on an optical simulation performed in *TracePro* (TracePro).

With the instant solar irradiation ($\dot{q}_s''$) and the overall concentration factor (C) for different light spots determined, the actual concentrated solar irradiant heat flux to the fuel sample can be calculated as

$$\dot{q}_c'' = C\dot{q}_s'' \qquad (1)$$

Four different positions (x) of 3 mm, 13 mm, 19 mm, and 33 mm within the glass sphere's back focal length were tested, with respect to four heating diameters (D) of 20.0 mm, 9.0 mm, 5.5 mm, and 1.5 mm.

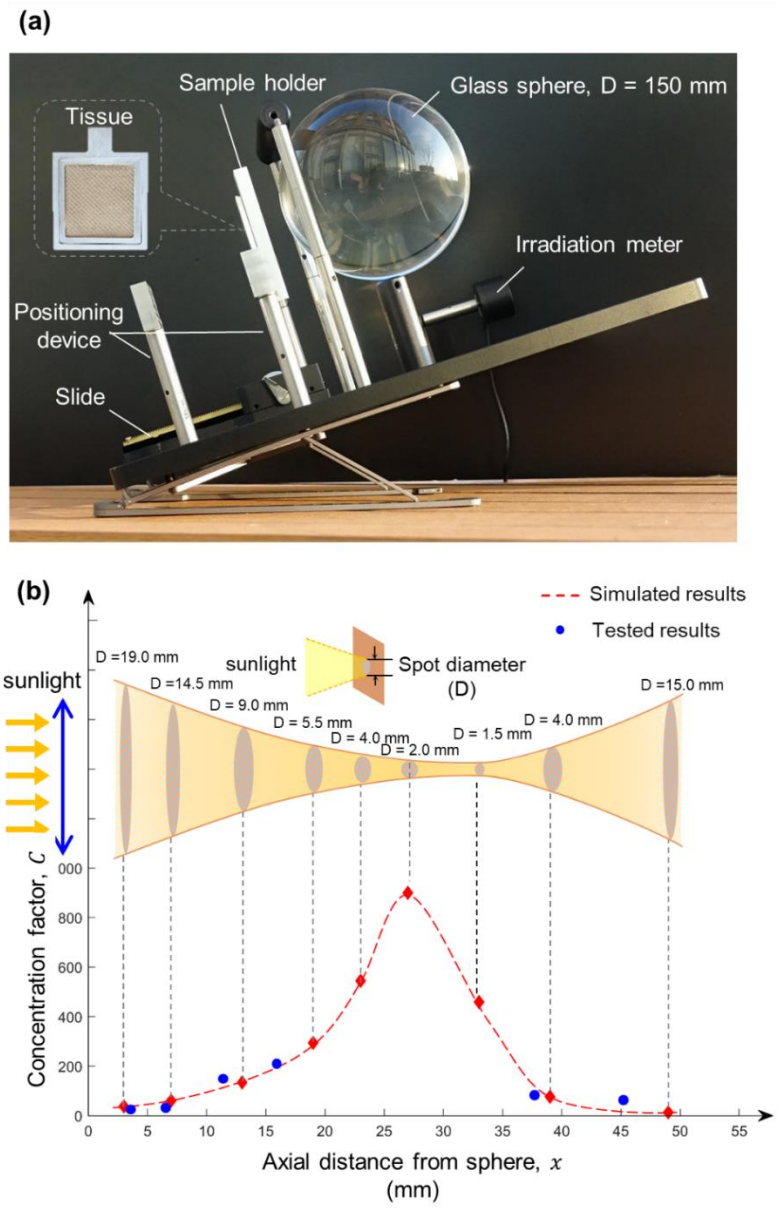

Figure 2- (a) Photos the experiment apparatus, and (b) overall concentration factor at different axial distance from sphere.

3. Experimental results

3.1. Smoldering ignition phenomena

Fig. 3a shows an example of a successful smoldering ignition process by a concentrated irradiation spot with a diameter of 1.5 mm and a resultant irradiation heat flux of 560 kW/m^2. Once the irradiation spot was applied on the sample surface, some smoke was released (Lin et al. 2019). Continuing the heating, the surface layer within the light spot turned black (or charred) and cracked, allowing the light beam to heat the lower layers directly. After heating for about 8 s, the sample detached from the apparatus but remained in the controlled environment (without wind) for another 5 min. As a result, the black spot expanded outwards evenly, expanding at a stable rate, and eventually burned out the sample. Fig. 3b shows an example of a failed smoldering ignition process by the concentrated irradiation spot with a diameter of 1.5 mm and a resultant radiant heat flux of 300 kW/m^2. Initially, smoke and a charring tendency were also observed. However, after heating for 8 s, no smoldering propagation phenomenon was observed, indicating a failed ignition.

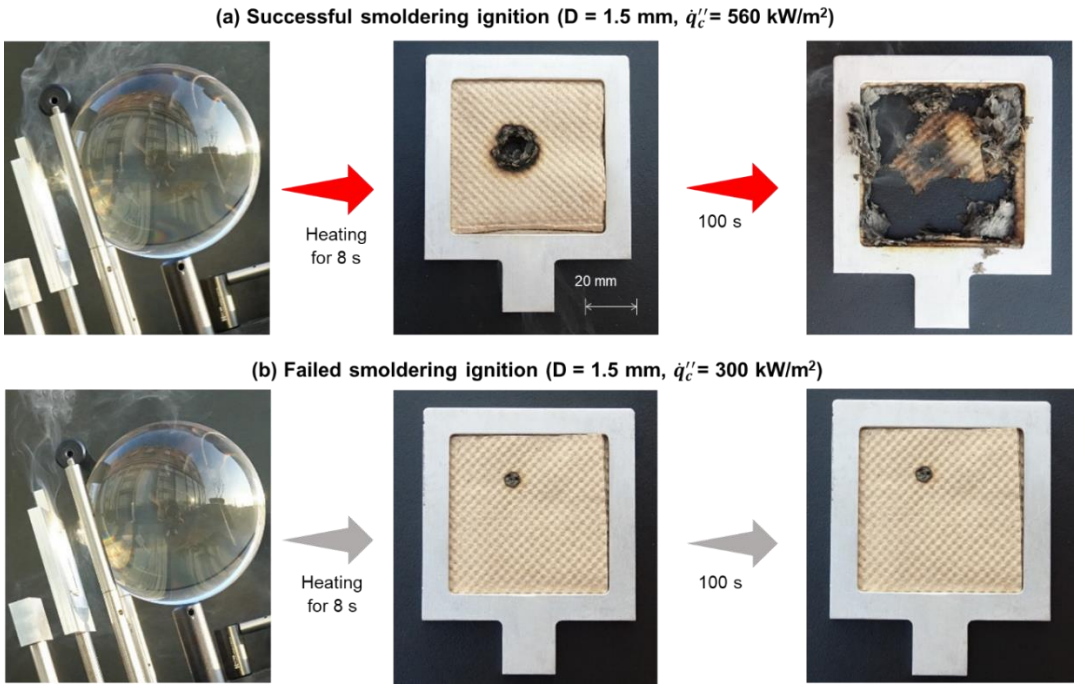

Figure 3- Smoldering ignition of dried tissue samples by concentrated irradiation spot with a diameter of 1.5 mm for 8 s, (a) successful ignition under irradiation of 560 kW/m², and (b) failed ignition under irradiation of 300 kW/m².

3.2. Critical heat flux

Fig. 4a plots the critical irradiation heat fluxes for smoldering ignition vs. the spot diameters. Interestingly, as the diameter of concentrated irradiation spot decreases from 20 mm to 1.5 mm, the critical heat flux increases dramatically from 18 kW/m^2 to 205 kW/m^2. Moreover, as the diameter of the irradiation spot increases, eventually, the critical heat flux for smoldering ignition approaches a near-minimum value obtained from the cone calorimeter (about 11 kW/m^2).

To scientifically understand the effect of the small irradiation spot on the critical heat flux of smoldering ignition, a simplified 2-D heat transfer analysis was applied. To achieve ignition, the critical irradiation heat flux ($\dot{q}''_{crt}$) should balance the environmental heat losses from the top and back sides ($\dot{q}''_{\infty}$) and the radial conductive heat loss to the virgin fuel ($\dot{q}''_{cond}$) (Lin et al. 2019; Huang and Gao 2020) a t the smoldering temperature (T_{sm}) as

$$\dot{q}''_{crt}\left(\frac{\pi D^2}{4}\right) = \dot{q}''_{\infty}\left(\frac{\pi D^2}{4}\right) \times 2 + \dot{q}''_{cond}(\pi D\delta) \qquad (2)$$

which can be further expressed and simplified as

$$\dot{q}''_{crt} = 2\dot{q}''_{\infty} + \frac{4\delta\dot{q}''_{cond}}{D} \quad \text{(small spot)} \qquad (3)$$

Therefore, as the diameter of the irradiation spot increases, the critical heat flux for smoldering ignition decreases, agreeing with the trend in Fig. 4a.

As the diameter of the irradiation spot (D) increases, the effect of conduction in Eq. (3) gradually approaches zero. Thus, for a larger irradiation spot, heat transfer can be approximated as a conventional 1-D process. The critical heat flux for smoldering ignition then approaches 11 kW/m^2, which approximately equals the environmental heat losses from the top and back surfaces as

$$\dot{q}''_{crt} = 2\dot{q}''_{\infty} = 2[\varepsilon\sigma(T_{sm}^4 - T_{\infty}^4) + h(T_{sm} - T_{\infty})] \quad \text{(large spot)} \qquad (4)$$

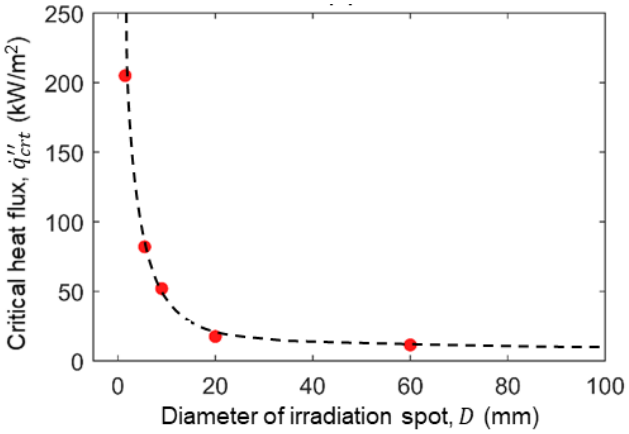

Figure 4-The relationship between diameters of irradiation spots (D) and critical ignition heat fluxes ($\dot{q}''_{crt}$).

4. Numerical modelling

To simulate the experimental observation, a 2-D numerical model is developed using Gpyro v0.8 (Lautenberger 2016). The governing conservation equations include the conservation of mass (Eq. 5), species (Eq. 6) and energy (Eq. 7) in the condensed phase as well as the mass (Eq. 8), species (Eq. 9), and momentum (Darcy's law) (Eq. 10) in the gas phase (see details in (Lautenberger 2016)). The schematic diagram of the computational domain has the same sample thickness (2 mm) and length (60 mm) as experiments. To save computational cost, the domain can be half of the actual sample owing to geometrical symmetry (Lin et al. 2022), as illustrated in Fig. 5.

$$\frac{\partial \bar{\rho}}{\partial t} = -\dot{\omega}'''_{fg} \quad (5)$$

$$\boldsymbol{\frac{\partial(\bar{\rho} Y_i)}{\partial t} = \dot{\omega}'''_{fi} - \dot{\omega}'''_{di}} \quad (6)$$

$$\boldsymbol{\frac{\partial(\bar{\rho}\bar{h})}{\partial t} = k\frac{\partial}{\partial x}\left(\frac{\partial T}{\partial x}\right) + k\frac{\partial}{\partial z}\left(\frac{\partial T}{\partial z}\right) + \dot{\omega}'''_{di}(-\Delta H_i)} \quad (7)$$

$$\frac{\partial}{\partial t}\left(\rho_g \overline{\psi}\right) + \frac{\partial \dot{m}''_x}{\partial x} + \frac{\partial \dot{m}''_z}{\partial z} = \dot{\omega}'''_{fg} \quad (8)$$

$$\frac{\partial}{\partial t}\left(\rho_g \overline{\psi} Y_j\right) + \frac{\partial}{\partial x}\left(\dot{m}''_x Y_j\right) + \frac{\partial}{\partial z}\left(\dot{m}''_z Y_j\right) = -\frac{\partial}{\partial x}\left(\overline{\psi}\rho_g D_{eff}\frac{\partial Y_j}{\partial x}\right) - \frac{\partial}{\partial z}\left(\overline{\psi}\rho_g D_{eff}\frac{\partial Y_j}{\partial z}\right) + \dot{\omega}'''_{fj} - \dot{\omega}'''_{aj} \quad (9)$$

$$\dot{m}''_z = -\frac{\kappa}{\nu}\frac{\partial p}{\partial z}\ \dot{m}''_x = -\frac{\kappa}{\nu}\frac{\partial p}{\partial x}\ \left(\rho_g = \frac{P\overline{M}}{RT}\right) \quad (10)$$

For the symmetrical plane ($x = 0$), adiabatic and impermeable boundary conditions are applied. At the top free surface ($z = 0$), initially ($t \le t_h$), irradiation ($\dot{q}''_{ir}$) with a heating diameter of $D/2$ is applied for a prescribed duration (t_h), and both convective ($h_{c,z=0} = 10\ \mathrm{W/m^2 \cdot K}$) and radiative heat losses are considered. Afterwards ($t > t_h$), the irradiation spot is removed. The mass transfer of gas species on the top free surface is considered. Based on the heat-mass transfer analogy, the mass transfer coefficient can be approximated as $h_{m,z=0} = h_{c,z=0}/C_g = 9.09\ \mathrm{g/m^2 \cdot s}$ (Lautenberger 2016). At the right and bottom boundary ($z = \delta$ and $x = L/2$), similar to the top free surface, both convective ($h_{c,z=0} = 10\ \mathrm{W/m^2 \cdot K}$) and radiative heat loss are considered, and the same mass transfer of gas species as the top surface is applied on the bottom surface. TThe whole computational domain has the same initial gas composition as the ambient air ($Y_{O_2} = 0.232$ and $Y_{N_2} = 0.768$). The solution starts to converge at $\Delta z = \Delta x = 0.1$ mm and $\Delta t = 0.01$ s.

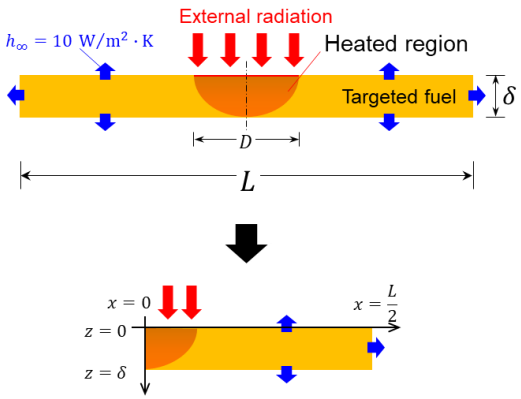

Figure 5- Schematic diagram of the 2-D computational domain for smoldering ignition using solar irradiation spots.

A previously developed 5-step kinetic scheme of typical biomass was applied here (Eq. 11-15) (Li et al. 2014; Yang et al. 2016; Huang et al. 2017). The kinetic parameters for the smoldering of biomass are obtained by optimizing the TG data in both inert and oxidative atmospheres using the Kissinger-Genetic Algorithm method ((Li et al. 2014)) and are listed in Table 1. The detailed species thermophysical properties can be found in (Huang et al. 2017).

5. Modelling results

Fig. 6(a) summarizes the modeled ignition time and compares it with the experimental data (uncertainty shown by shadowed area). Considering the complex nature of the smoldering process, a good agreement can be observed between predictions and experiments. Also, the effect of irradiation level ($\dot{q}''_{ir}$) on the ignition time is well predicted by the model; that is, the ignition time decreases as the irradiation level increases. For example, given an irradiation spot of 5 mm, as the radiant heat flux increases from 60 kW/m^2 to 150 kW/m^2, the predicted ignition time decreases from 85 s to 8 s.

Fig. 6(b) further summarizes the predicted minimum heat fluxes of smoldering ignition for different irradiation spots and compares them with the experimental data. For example, as the diameter of the irradiation spot increases from 2 mm to 10 mm, the predicted minimum heat flux for smoldering ignition decreases from

85 kW/m^2 to 43 kW/m^2. In general, simulations show an excellent agreement with experimental measurements with a relative error of less than 10%.

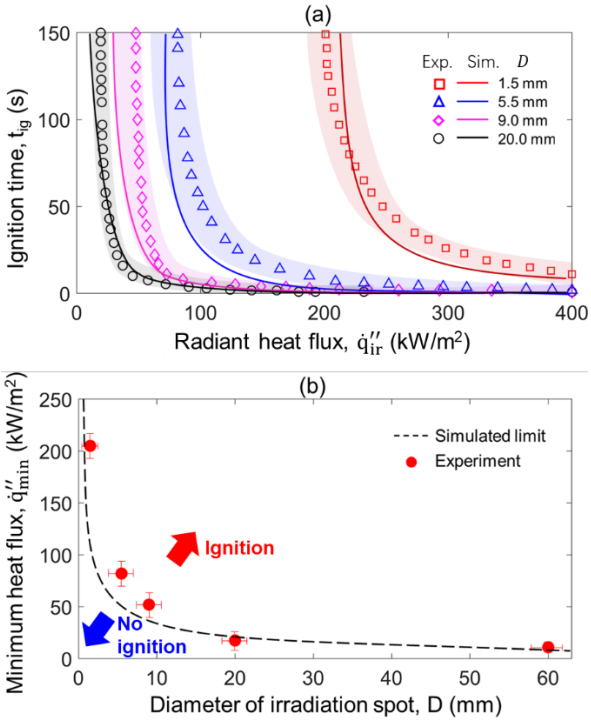

Figure 6- (a) Comparison between the experimental and modelled ignition time under different irradiation spots, (b) predicted minimum heat flux of smoldering ignition vs. test data.

6. Conclusion

In this work, we investigated the smoldering ignition of multi-layered thin tissue paper (common fuels in wildland abandoned by humans) by small irradiation spots. We found that the measured minimum spot irradiation for smoldering ignition is not constant but remains much higher than the 11 kW/m^2 measured from cone-calorimeter tests. As the diameter of irradiation spots decreases from 20.0 mm to 1.5 mm, the minimum irradiation necessary for smoldering ignition increases from 17.5 kW/m^2 to 205 kW/m^2. A simplified heat transfer analysis was proposed, which explains the critical smoldering ignition heat flux for solar irradiation spots by including two-dimensional cooling effects.

Afterwards, a 2-D computational model was successfully established to reproduce the experimental observations and validate the results. Future numerical simulations are needed to further reveal the underlying physical and chemical process of smoldering spot ignition for other fuels.

Chapter 3:
Risk Adaptation

After an off-season fire: the behavior of exotic *Eucalyptus globulus* and invasive *Acacia longifolia* in Portugal

Sapling establishment; Pre-fire management; Nodulation; *Bradyrhizobium* spp.

Abstract

The introduction of species into exotic areas results in serious transformations on introduced areas. In Portugal, Eucalyptus globulus (exotic species) and Acacia longifolia (exotic invasive species) occupy a vast forested area. Eucalyptus globulus was extensively planted due to its role in pulpwood industries and, while the majority of plantations are managed, some are poorly managed along with isolated trees dispersed in the landscape (seed-trees) that are very huge and old, potentially increasing the risk of dispersal. Acacia longifolia was introduced for dune stabilization, but quickly expanded, becoming invasive without human intervention. As a leguminous species, the ability to establish symbiosis with nitrogen-fixing bacteria seems to be crucial to potentiate this invasiveness; however, these mutualistic interactions will interfere with soil microbiota, altering plant communities and affecting local biodiversity. Being two species adapted to post-fire regeneration, their behavior changes after fire occurrence, however after off-season fires, there is a gap in knowledge about their establishment dynamics. Eucalyptus globulus plantations and surrounding areas of seed-trees affected by June and October 2017 fire events were sampled, as well as unburnt areas. Acacia longifolia root-nodules were collected from unburnt and burnt areas affected by 2017 October fire and bacterial community was isolated and identified. Our results showed that the fire date and pre-fire management restrained E. globulus natural regeneration, with greater establishment in unmanaged plantations affected by the October fire. The presence of seed-trees seems to be less influenced by these factors (fire date and management), and can be considered an important seed source. Also, A. longifolia bacteriome has lower diversity after fire, but the main symbionts seem to be nitrogen-fixing bacteria, indicating a more specialized symbiosis that could enhance post-fire invasion. Bradyrhizobium spp. were the main partners in both studied zones, revealing its role as a facilitating microorganism. Off-season fires specific conditions seem to create more favourable conditions for E. globulus establishment, while A. longifolia seems to be able to establish promiscuous symbioses, but simultaneously adapt to a disturbed environment, managing to outcompete effectively with other plant species.

1. Introduction

Globally, the introduction of plant exotic species has increased due to economic interests and with ecosystems' rehabilitation purposes. However, these introduced species have negative impacts on novel ecosystems, such as disrupting ecosystems' functioning by altering water and soil cycles (Thompson *et al*., 2014; Liao *et al*., 2012), increasing fire hazard (Calviño-Cancela *et al*., 2018), reducing local biodiversity and modifying natural landscape (Vilà *et al*., 2011). In Portugal, the main exotic species are *Eucalyptus globulus* Labill. (Myrtaceae) and *Acacia longifolia* Andrews. (Leguminosae), two species native from Australia and introduced in the 19th century for different reasons (Alves *et al*., 2007; Peperkorn *et al.*, 2005). In the case of *E. globulus*, due to its fast growth, high productivity, and wood product quality (Turnbull, 1999), it was extensively planted for pulpwood production industries and occupies nowadays ca. one quarter of the forested area (ICNF, 2019). Most plantations have been planted intentionally and are managed with short rotation systems with 10-12 years tree cutting cycles and periodic clearing of the understory vegetation (Soares et al., 2007). Nonetheless, isolated *E. globulus* trees are often left uncut, hereafter referred as seed-trees, and many plantations are poorly managed, resulting in the presence of older trees with great reproductive capacity, potentially increasing the risk of

dispersal. However, *E. globulus* potential invasive capacity is a controversial topic, since qualitative studies classified it as invader in some parts of the world (Sanz-Elorza *et al*., 2001; Rejmánek and Richardson, 2013; Marchante *et al*., 2014), while other authors classified this species with a moderate risk of invasion, including in well managed plantations, which reduces its expansion beyond plantation edges (Larcombe *et al*., 2013; Fernandes *et al*., 2016; Ziller *et al*., 2018).

Another important exotic species is *A. longifolia*, considered nowadays as one of the most aggressive invaders, accounting with 18 % of the Portuguese mainland area occupied by alien species (Morais *et al*., 2017). This species was introduced for dune stabilization and recently, it has been described as an "ecosystem-engineer" (Stock *et al.*, 1995; Marchante *et al*., 2004; Yelenik *et al*., 2006) mostly determined by its inherent ability to fix atmospheric nitrogen through Legume–Rhizobia symbioses. Biological nitrogen fixation occurs inside root nodules, which includes a complex and reciprocal signalization process between the host plant and compatible bacteria (Andrews and Andrews, 2017). *Acacia* spp. do not have a specific bacterial partner, being a promiscuous woody species, that possibly exploits soil bacterial diversity to find partners for symbiotic success, particularly relevant in the context of invasion (Rodríguez-Echeverría *et al*., 2007; 2011). The identification of who is taking part in nodule's bacteriome remains a major challenge. Until now, several studies showed *Bradyrhizobium* as the most common partner in native and introduced environments, followed by *Rhizobium* (Rodríguez-Echeverría *et al*., 2010), while *Mesorhizobium* and *Sinorhizobium* appear mostly in the native range (Lafay *et al*., 2001; Marsudi *et al*., 1999; Nick *et al.*, 1999a, b). In fact, nitrogen-fixers are among the functional and taxonomically diverse rhizosphere communities (Kamutando *et al*., 2018).

Once *E. globulus* and *A. longifolia* are native from Australia, they are highly adapted to post-fire regeneration, both by bud resprouting and massive seed germination (Silva and Marchante, 2012; Águas *et al*., 2014, Calviño-Cancela *et al.*, 2018; Carvalho *et al*., 2010). In fact, fires are common perturbations in regions with Mediterranean type-climates (such as Portugal and Australia), characterized by long dry summers (Salis *et al.*, 2014). Under the current climate change scenario, it is known that the Mediterranean region will be undoubtably challenged, since it is expected an all year round warming more determinant in summer, and a widespread dryness ascribed to modifications in precipitation patterns (IPCC, 2021), resulting in a shift in fire regime extending the normal summer fire season (from July to September) with increasing off-season fires (Turco *et al*., 2019). For example, in Portugal, 2017 was a particularly dry and warm year, which resulted in several large wildfire events from June (early in the season) to mid-October (late in the season). As a consequence of the June fires ca. 52.000 hectares (ha) burned, while the October fires devastated an even larger area (ca. 190.000 ha) (ICNF, 2017). Fire events are a critical factor in these species' behavior, on one hand, regarding *E. globulus* dispersal dynamics that under off-season fires is still unknown and on the other hand, what happens on *A. longifolia* nodulation and bacterial diversity inside root nodules.

In this study, we aim to assess (1) the effects of off-season fires and pre-fire management alongside with the presence of seed-trees in *E. globulus* sapling dispersal and (2) if fire alters bacterial community inside *A. longifolia* root nodules.

2. Material and Methods

Eucalyptus globulus managed and unmanaged plantations and seed-trees surrounding areas were selected on areas affected by the off-season fires that occurred in June (early in the season) and in October (late in the season) of 2017 and in unburnt areas nearby; plots were sampled through distance transects composed by 3x3 m plots where sapling cover was assessed. Regarding *A. longifolia*, 5x5 m plots were selected in unburnt and burnt areas affected by October fire, where root nodules were collected by digging up saplings. Nodules were disinfected and bacterial diversity was isolated in YMA plates to identify symbiotic partners, through fingerprinting with M13 and rRNA 16S amplification.

Data analysis

Generalized Linear Mixed Model (GLMM) was performed in order to assess the factors that influenced *E. globulus* natural regeneration using Fire occurrence (No fire, June or October fire event), Management (managed and unmanaged) and Type (plantation or isolated seed-trees). To compare *A. longifolia* diversity between unburnt and burnt zones, Shannon-Wiener diversity index and Pielou evenness index were used.

3. Results and Discussion

3.1. *Eucalyptus globulus* behavior after off-season fire

Firstly, GLMM showed that Fire occurrence and pre-fire Management were the main factors influencing *E. globulus* saplings cover ($p < 0.001$). This species natural regeneration is very limited in absence of fire, since vegetation presence will compete with seedlings (Garau *et al.*, 2009) and litter accumulation constrain seedling emergence (Águas *et al*., 2017) (tab.1). After fire, seeds will find favorable conditions to germinate, however it is dependent on post-fire climatic conditions. In fact, after the June fire followed by summer months, regeneration was lower comparing with October fire followed by rainy season, given that seeds require wet and bare soil to germinate (Rejmánek and Richardson, 2011). However, pre-fire management highly restrain this species dispersal, since seed accumulation in the canopies is limited by frequent tree cutting cycles, preventing trees from reaching their full potential of seed production that occurs from 7 years old (Kirkpatrick, 1975). Furthermore, unmanaged conditions showed higher sapling cover especially after an October fire, representing the worst-case scenario, since trees are older leading to a greater accumulation of capsules up in the canopy. Additionally, seed-trees are an important propagules' source due to their age and seed production potential, being less sensitive to post-fire conditions and pre-fire management actions, influencing this species dispersal dynamics.

Table 1 – Eucalyptus globulus sapling cover (mean ± SE, %) for managed and unmanaged plantations and managed and unmanaged surrounding areas of seed-trees in absence of fire (no fire) and after June and October 2017 fires. Different letters indicate significant differences between no fire and the two fire dates (post hoc pairwise Tukey tests).

	Plantation		**Seed-tree**	
	Managed	**Unmanaged**	**Managed**	**Unmanaged**
No fire	0.58 ± 0.13^{a}	0.02 ± 0.02^{a}	0.07 ± 0.03^{a}	0.07 ± 0.04^{a}
June fire	0.10 ± 0.10^{ab}	1.38 ± 0.82^{ab}	2.56 ± 0.74^{ab}	9.35 ± 2.45^{cd}
October fire	1.70 ± 0.53^{a}	19.70 ± 4.35^{d}	6.72 ± 1.84^{bc}	14.00 ± 2.78^{e}

3.2. *Acacia longifolia* behavior after off-season fire

Considering *A. longifolia* nodulation, it seems that this process is potentiated after fire with a higher number of nodules present in young acacia saplings in post-fire environment (mean value of 14.0 comparing to 10.1 in unburnt zones), despite no statistically significant differences. However, there were differences in diversity and composition of bacteriome inside root nodules, with higher diversity present in unburnt zone (H' = 1.0) comparing to burnt zone (H' = 0.74) (tab. 2), underlining its promiscuity (Thrall *et al*., 2005). This higher diversity was expected once, under unburnt conditions, soils are inhabited by a greater abundance and diversity of bacteria in rhizospheric environment (Kamutando *et al*., 2018). After fire, symbiosis seems to be more specialized towards nitrogen-fixing bacteria, considering the disruption of plant-soil-biota feedbacks (Kulmatiski and Kardol, 2008) and a higher dominance of nitrogen-fixing bacteria observed. This more specialized bacteriome could be determinant for *A. longifolia* post-fire regeneration, increasing fitness, along with the absence of interspecific competition.

In this study, cultivable bacteria belonged to 5 different classes, including Alphaproteobacteria with *Bradyrhizobium* sp. as the most represented genera in both zones, Betaproteobacteria with *Paraburkholderia* sp. as the second most represented genera, and Gammaproteobacteria, mostly represented by *Pseudomonas* sp., from phylum proteobacteria; Actinobacteria from phylum actinobacteria and Bacilli from phylum firmicutes. Furthermore, there was also present an intraspecific diversity with *Bradyrhizobium cytisi* as the most abundant species in both zones.

Pielou evenness index showed a dominance of a genera in both unburnt and burnt zones (J' = 0.75 and J' = 0.67, respectively), which corresponds to the presence of *Bradyrhizobium* genus; in fact, this genus is the most common partner included among nitrogen-fixers and rhizobia group (Madigan and Martinko, 2006). Indeed, this genus has been already described as an important partner in native and introduced environments (Rodríguez-Echeverría *et al*., 2010), and its presence in both studied conditions reveals a close relationship with *A. longifolia* that may have a facilitating role. Furthermore, Paraburkholderia spp. and Pseudomonas spp. were also highly represented among isolates and are already included in Plant Growth Promoting Bacteria (PGPB), that could perform different functions apart from possible nitrogen fixation, once *Paraburkholderia* was already described

as nitrogen-fixing inducer and *Pseudomonas* was identified as non-rhizobial nodule inducing bacterial endophytes (NRE) (Martínez-Hidalgo and Hirsch, 2017). This apparently multifunctional bacteriome could be the reason why *A. longifolia* is such an effective invader.

Table 2 – Diversity of cultivated bacteria (%) isolated from A. longifolia root nodules from young saplings sampled in unburnt and burnt zones.

	Genera	Unburnt zone	Burnt zone
Alphaproteobacteria	*Althererythrobacter* sp.	1.0	0
	Bradyrhizobium sp.	36.2	45.8
	Paracoccus sp.	1.0	0
	Rhizobium sp.	1.0	0
Betaproteobacteria	*Caballeronia* sp.	2.0	0
	Duganella sp.	9.0	0
	Paraburkholderia sp.	16.0	13.6
Gammaproteobacteria	*Moraxella* sp.	2.0	0
	Pseudomonas sp.	13.8	10.2
Actinobacteria	*Micrococcus* sp.	2.0	6.8
	Nocardioides sp.	1.0	1.6
Bacilli	*Paenibacillus* sp.	2.0	0
-	Not identified	13.0	22.0

4. Conclusions

Fire seems to have a determinant role in these exotic species behavior in studied areas, influencing dispersal dynamics of *E. globulus* and altering *A. longifolia* bacteriome inside nodules. *Eucalyptus globulus* establishment is highly dependent on fire occurrence and also on post-fire climatic conditions, but also the management practices implemented prior to fire. It is important to highlight the potentiated dispersal after October fire, as well as, the presence of seed-trees as a key propagule source. Furthermore, *A. longifolia* symbiosis seems to be influenced by fire, with a more specialized interaction with nitrogen-fixing bacteria that can be referred as the "first settlers" within symbiosis reestablishment after fire. However, unburnt conditions highlighted for the fact that this invasive species is a generalist mutualist, capable of establishing symbiosis with a greater diversity of rhizospheric bacteria.

Abstract

To enhance the economic viability and address the labour shortage in the forestry industry, alternative solutions using robotization and automation are emerging. However, due to technological barriers and lack of solid business models, successful commercialization in the forestry sector is yet to be challenging. As an initial market analysis for developing a business model for new forestry machineries, this study was conducted to reveal clusters of EU countries to seek the potential market opportunities outside of Portugal. To identify similar market conditions and restrictions, EU countries were clustered using Minimum Spanning Tree (MST) based clustering analysis clustering algorithm and selection of variables while considering the geographic, economic, and social conditions of each country.

1. Introduction

Robotization and automation of forestry machinery are emerging as an alternative to address significant challenges in the forestry industry in terms of economic viability, safety, labour shortages, and environmental performance (Lideskog, Karlberg, and Bergsten 2015; Couceiro et al. 2019)). However, such a technological shift has not yet had significant commercialization in the forestry sector except for logging due to technological challenges and a lack of solid business models (Teece 2010; Lideskog, Karlberg, and Bergsten 2015). A well-developed business model is essential for increasing the value of technology and opportunities into economic outputs through customers and markets leading to the success of a business (Chesbrough 2002; 2010). Thoroughly analyzing the main components of a business model is an essential process to create a solid framework for developing the business model (Couceiro et al. 2019). Especially, determining the value proposition and market segments are crucial in measuring and predicting the potential of new products and services.

In most developed countries, the forestry sector is highly internationalized, concerned with its sustainability, diversity and increasing complexity, responding to the growing competition (Melo, Cunha, and Ferreira 2017). Although the forestry industry in Portugal is rich in opportunities, mainly due to the abandonment of rural and deprived areas and the lack of investment in maintenance and conservation, the potential has not yet been fully exploited (Melo, Cunha, and Ferreira 2017). Different countries around the world have distinct levels of economic, social, and environmental issues in forestry due to several factors that each country faces, e.g. geographic characteristics, economic capabilities. The possibility of such issues which may directly lead to potential risks is influenced by the situations that a given country has. For example, damages from natural disasters may vary depending on a country's risk management capabilities. According to literature (Toya and Skidmore 2007), countries with higher income and educational attainment, greater openness, more complete financial systems, and smaller government are more likely to experience fewer losses. Thus, there is a need to investigate the geographic, economic, and social features to draw implications in a variety of scenarios, including potential market opportunities. In this sense, the use of different indicators can be a solution for analyzing the current situation of the forest sector at a national level.

As an initial phase for building a business model for new forestry machines, this study was conducted to reveal clusters of EU countries to seek the potential market opportunities outside of Portugal. To identify similar market conditions and opportunities, EU countries were clustered using a hierarchical clustering algorithm, an unsupervised learning branch from the Artificial Intelligence.

2. Methodology

2.1. Data collection

The main statistical data source used for the analysis was from major international organizations such as the Food and Agricultural Organization of the United Nations (FAO). The FAO statistical databases (FAOSTAT) platform is freely accessible and contains the largest statistical database on agriculture, fishery, and forestry in the world, with approximately 20,000 indicators covering 245 countries and territories, with around 2,000,000 users each year (FAOSTAT, 2022). The FAOSTAT database is used widely in peer-reviewed literature, serving as the basis for many Agriculture, Forestry, and Other Land Use (AFOLU)-related analyses (Tubiello et al. 2013). FAOSTAT is useful to make the cross-country comparisons because it has the user-friendly interface and the possibility to track the different items that we need in one place. To reflect the economic, social, and environmental issues in the forestry sector, twenty-seven indicators for 2015 (year) were selected related to forest production, land use, and social capital in FAOSTAT. The selected indicators had to respect the following criteria: (i) be fact based; (ii) be based on available data for twenty-seven EU countries; (iii) be easily interpreted. In creating the final list of indicators, new ad hoc indicators were created. One of the ad hoc indicators was, for example, "The production quantity of Pulpwood (m^3) per Forest Land (1000 ha)"

2.2. Data pre-processing

As the variables were reported in different units, to determine distances between the EU countries, it was necessary to standardize them and eliminate dependence. According to (Arabie et al. 1996), when the number of variables is large, there is a possibility that variables that do not contribute to cluster classification exist, and these variables may interfere with finding a cluster structure. Finding structure in a high-dimensional variable space with a small dataset is a general problem in both classification and cluster analysis. This may be due to the presence of several "noisy" noninformative variables and/or redundant features from strongly correlated or more generally strongly dependent variables that may produce, for instance, multicollinearity (Fraiman, Justel, and Svarc 2008). The basic methodology for the detection of redundant variables is correlation analysis under unsupervised dataset that there are no output variables to predict. The most used measures are Pearson correlation coefficient for a linear correlation, and Spearman and Kendall correlation coefficient for a nonlinear correlation (Marshall 1996; Chok 2010). According to previous research, the use of Pearson correlation coefficient is not robust in forms of associations other than linear or normal associations (Kowalski 1972; Speed 2011).

2.3. Clustering analysis based on Minimum Spanning Tree (MST)

Hierarchical cluster analysis as a multivariate statistical tool has also been widely used to group the data by simultaneously clustering objects and variables (Newman 2004). Hierarchical clustering has the advantage that it does not require a knowledge on the number or size of groups to look for beforehand. However, it does not tell us how many groups should be used to get the best division (Jain, Murty, and Flynn 1999; Xu and II 2005; Fortunato 2010). Another problem is the lack of the ability to detect clusters which are not defined by regular geometric curves (Grygorash, Zhou, and Jorgensen 2006; Zhong, Miao, and Fränti 2011; Wu et al. 2013; Tewarie et al. 2015) Detecting clusters with irregular boundaries has become a research interest in recent years. In particular, the clustering algorithm using the Minimum Spanning Tree (MST) has recently attracted a lot of attention (Gower and Ross 1969). MST is a tree that minimizes the total weight or lengths of the edges of the tree under a weighted, undirected graph.

3. Results and Discussion

As a result of the Shapiro-Wilk test for normality, twenty-nine indicators in 2010 and twenty-six indicators in 2015 did not follow a normal distribution. With large enough sample sizes (> 30 or 40), the violation of the

normality assumption should not cause major problems (Ghasemi and Zahediasl 2012). However, the dataset which this research dealt with is small sample size and its normality is violated. Thus, for variable reduction, the Kendall correlation measure was employed. It is known to be more robust and slightly more efficient than the Spearman correlation coefficient (Croux and Dehon 2010).

Following the above-mentioned methodology, the first step was the elimination of some higher correlated dependent and statistically significant variables (significance level = 5%) for the selection of appropriate features. The three indicators, such as "Share of Net value added of forestry in total net value added", "Proportion of naturally regenerating forest in forest area", "Proportion of land under meadows and pastures in agricultural area", consequently had been eliminated by correlation analysis. Finally, the analysis enabled the grouping of twenty-seven EU countries into clusters using thirty-seven different variables. When analyzing the similarity without SDG indicators between EU countries, twenty-nine indicators were used except eight SDG indicators.

Before correlation analysis, normalization (Min-Max scaling) was used to make variables comparable to each other on equal grounds. The variables were shift and rescaled so that they end up ranging between 0 and 1. The method did not change the shape of the distribution of data while adjusting the values. If the shape of the distribution is changed, it introduces bias into analysis because the distribution of a lot of collected data is not Gaussian. Applying Prim's algorithm for shaping a complete graph based on Manhattan distance among monitored features into MST. Finally, a network community detection technique was applied to identify the clusters of EU countries.

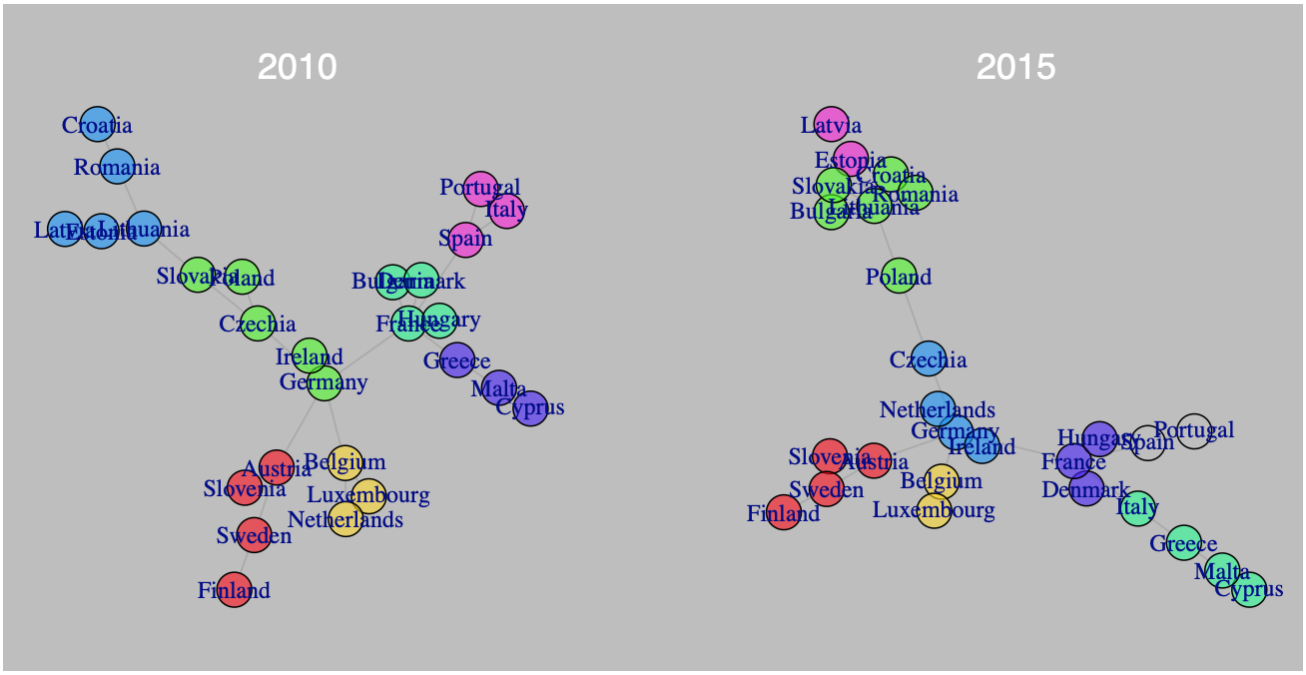

Figure 1- ***Network communities of EU countries with MST based on the Manhattan distance, and each cluster is identified by a special color***

Our analysis of the different indicators related to forestry through clustering analysis based on MST was performed on the EU27 countries for two time periods 2010 and 2015. Fig. 1 shows that there is a difference in the network community composition depending on different periods. There were six clusters created, representing the seven groups of EU-27 countries in 2010, while eight clusters were created in 2015.

Table1. Sorting countries into clusters using dataset 2010

1	2	3	4	5	6	7
Austria	Belgium	Czechia	Bulgaria	Croatia	Cyprus	Italy
Finland	Luxembourg	Germany	Denmark	Estonia	Greece	Portugal
Slovenia	Netherlands	Ireland	France	Latvia	Malta	Spain
Sweden		Poland	Hungary	Lithuania		
		Slovakia		Romania		

The results of year 2010 are presented by two clusters of five members, two of four members and three of three members (Table 2). On the other hand, the results of year 2015 are presented by one cluster of three members, one of five members, two of three members and three of three members (Table 2). The group consisting of Austria, Finland, Slovenia, and Sweden did not change during the two periods in 2010 and 2015, and Portugal and Spain, which were in the same group in 2010, were analyzed as belonging to the same group in 2015 as well. On the other hand, in Italy and Luxembourg, the group to which they belonged also changed over time.

Table 2. Sorting countries into clusters using dataset 2015

1	2	3	4	5	6	7	8
Austria	Belgium	Bulgaria	Cyprus	Czechia	Denmark	Latvia	Portugal
Finland	Luxembourg	Croatia	Greece	Germany	France	Estonia	Spain
Slovenia		Lithuania	Malta	Ireland	Hungary		
Sweden		Poland	Italy	Netherlands			
		Romania					
		Slovakia

Abstract

Recent wildfires in Arctic regions have burned unprecedented swaths of land, demonstrating a detrimental change in the arctic fire regime and release large amounts of ancient carbon that have been stored for millennia in the organic soils into the atmosphere. These events highlight the vulnerability of these biomes to climate change and the importance of protecting them. Arctic fires are poorly understood and difficult to be detected due to their remote location. Here, we present a novel rig capable of studying smouldering arctic fires at the lab scale by reducing environmental and soil temperatures. The rig consists of a chamber with low air temperatures, a reactor with a temperature-controlled base to imitate the influence of permafrost, and the fuel sample of organic soil with preconditioned temperatures. The smouldering of organic soil was investigated across a range of realistic temperatures in the Arctic: -7 °C, 2 °C, and 21 °C. The experimental results show that smouldering can be sustained in soil temperatures below the freezing point of water. While insignificantly affect spread rate, the range of temperature in this study was found to have profound effect on the depth of burn, increasing by up to 66% as base temperature decreased from 21 to -7 °C. The critical moisture content above which smouldering is not self-sustain was found to be between 110% and 120% which is lower than the value in the literature because the lower temperature of the reactor base in this study resulted in higher heat losses than the reactor in the literature. As the average soil temperature increases with climate change, the critical moisture content will increase and may lead to more frequent fires in the Arctic. This study is the first experimental work on smouldering Arctic wildfires with findings that can improve our understanding on the effect of cold temperatures, and presents a novel methodology to investigate Arctic fires at laboratory scale.

1. Introduction

In pristine condition, the organic soil in peatland is protected from fire, due to the cold and high moisture conditions (Turetsky *et al*. 2015). With global warming and land-use changes, the condition of peatland is disturbed and can lead to the drying of the organic soil. Once dry, the soil can be ignited and burn for weeks to months (Page *et al*. 2002) because the fire of the organic soil is governed by smouldering combustion, which is the slow, low temperature, flameless burning of charring porous fuel, and the most persistent type of combustion phenomena (Rein 2016). The difficulty in peat fire mitigation has been reported to requires abundant resources of million to billion L of waters that was often difficult to fulfil, leading to the persistent emission of carbon (Ramadhan *et al*. 2017).

In the Arctic, there are reports of fires that were ignited during the summer, survived the winter season by burning underground, and returned to the surface once the snow has melted (Rein and Huang 2021). Such fires that resurface after winter season have been referred to as overwintering fires. In the summer, both flaming and smouldering are part of the wildfire. The flames of the wildfires will be extinguished by rainfall, cold weather or firefighting. However, smouldering hotspots can survive below ground and not be quenched by water or winter because of the insulation effect of the topsoil and snow cover. In the Spring, the overwintering fires grow helped by the dry conditions and warmer temperatures (Scholten *et al*. 2021).

Smouldering dynamics have, primarily, been studied to understand wildfires in tropical and temperate peatlands. Lin *et al*. (2021) investigated the critical MC to ignition in regard to temperatures in the Arctic. However, no laboratory experiments have explored the dynamics of smouldering wildfires in the Arctic, such as spread rate and burning depth. Here we introduce a novel experimental set-up to address this gap by conducting experiments varying both temperature and MC to understand their effects on the dynamics of smouldering wildfires in the Arctic.

2. Method

The effect of temperature on smouldering dynamics was explored by using a novel rig developed by Christensen (2020). The rig was designed to control three parameters: the ambient air (or chamber) temperature (T_c), the soil temperature (T_0), and the temperature of the bottom boundary of the reactor (T_b) in which the peat was burned. To control the air temperature, a large chamber with an internal dimension of 120 × 80 × 80 cm was constructed using vermiculite and lined with a fibreboard insulating material (Figure 1). A 40 × 40 cm extraction hood was mounted through the top of the chamber with a variable speed mechanical fan installed to control the extraction rate of the smoke from the smouldering samples. A fine metal mesh (0.5 mm) skirt extends down from the hood, as illustrated in Figure 1, to reduce any significant air currents from developing which would affect the smouldering dynamics. The experiments were conducted inside the mesh skirt. A compressed airline was passed through a vortex tube which directed cold air with adjustable temperature (T_i) through an inlet at the bottom of the chamber. A thermocouple was placed within the mesh cage at the same height as the top edge of the reactor to measure T_c. T_c was varied from ~20°C down to ~10°C by adjusting T_i down -7 ± 2°C.

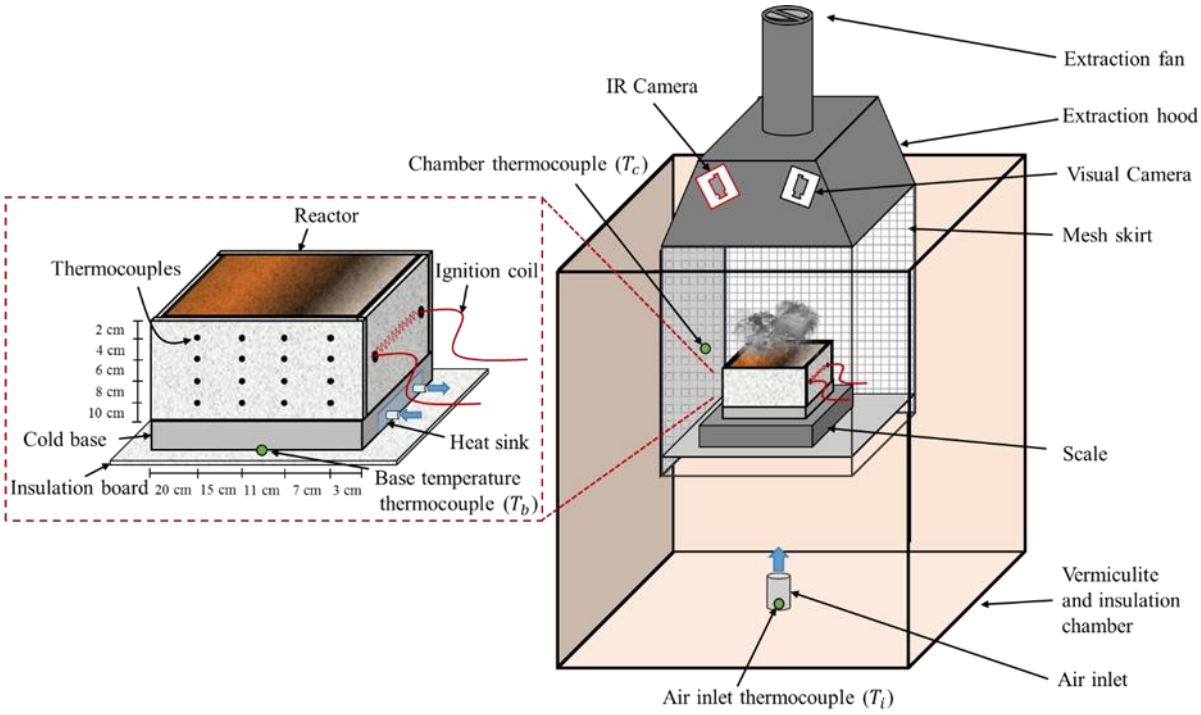

Figure 1- Illustration of the Experimental Low-temperature Smouldering Apparatus (ELSA). Left figure shows key features of the reactor which is filled peat soil. The internal dimension of the reactor measures 20 × 20 × 10 cm. On the right, key features of the rig are highlighted. The dimensions of the chamber are 120 × 80 × 80 cm.

The reactor has internal dimensions of 20 × 20 × 10 cm (Figure 1). The walls were constructed from an insulating fibreboard (k= 0.7 W·m^{-1}·K^{-1}, ρ= 310 kg·m^{-3}, c_p= 1090 J·kg^{-1}·K^{-1}). The bottom of the reactor was a thin aluminium plate so to allow for the effective conduction of heat. To control the temperature of the bottom boundary of the reactor, an aluminium base (22 × 22 × 2.5 cm) was placed. The base was designed with an inset heat sink through which a temperature-controlled water – glycol mixture was pumped. The temperature of the mixture was varied by a benchtop recirculating chiller (Polyscience LS-series compact chiller). A thermocouple was mounted to the base to measure the temperature at the interface between the base and the aluminium plate (T_b) as indicated in Figure 1.

A commercial peat (Shamrock Irish Moss Peat, Bord na Móna Horticulture) was used due to its accessibility, material consistency and frequent use in literature (Huang *et al*. 2016), allowing for improved isolation of peat soil variability and comparison to literature results. This soil has a C/H/N/S proportion of 54.1/5.1/1.3/0.5% by mass respectively, and an inherent inorganic content of 2.5 ± 0.6% (Hu *et al*. 2019). Sample preparation was conducted according to Christensen *et al*. (2019). The peat was dried at 80 °C until no mass loss was observed in measurements of 6 h apart. Water was added to the dried peat to achieve a desired MC, and the peat was put in a sealed container to homogenise for 24 h. MC is considered as the mass of the water divided by the mass of

the dry matter. The MC was verified by taking a 100 g subsample of the peat and drying it in an oven at 90°C for 6 hours (this was found to sufficiently dry sub samples of any moisture content). Where the initial temperature of sample (T_0) was required to be altered, the reactor and sample was placed in a fridge or freezer for at least 12 hours before starting the experiment.

The samples were ignited using an 18 cm, helically wound nichrome coil, 1 cm in diameter through which 100 W of power is supplied, which has been shown to be a strong ignition source (Huang *et al*. 2016). A scale is used to measure the mass of the sample every minute. 16 thermocouples were inserted along the centreline of the reactor at 3, 7, 11 and 15 cm from the ignition side and at 2, 4, 6 and 8 cm depths, as illustrated in Figure 1. This is a similar thermocouple array to that used in (Huang *et al*. 2016). Both infrared (FLIR Duo R) and visual cameras (GoPro) were mounted above the reactor to capture the behaviour and spread of the smouldering.

To explore the effect of soil temperature on smouldering dynamics, three temperature conditions were targeted: below zero, near zero, and room temperature. This covered a range of temperatures from frozen conditions to summer conditions in Arctic regions, where the active layer is warm. Temperature condition (T_{cond}) was defined as a set of three temperatures set up: base temperature (T_b), chamber temperature (T_c), peat soil initial temperature (T_0). Table 1 shows T_{cond} setup in this work. Experiments with MC of 50% and 100% were conducted at all three condition temperatures, with one to three experiments conducted per soil condition.

Table 1- Summary of average temperatures for the three temperature conditions (T_{cond}) in this study: below freezing point (-7°C), at freezing point (2°C), and at room temperature (21°C). The uncertainties reported here are the standard deviation of measured temperature across all experiments at the given condition temperature.

Condition temperature (T_{cond})	Below freezing point -7°C	Freezing point 2°C	Room temperature 21°C
Base temperature (T_b)	-6.8 ± 0.6°C	2.1 ± 1.3°C	20.7 ± 0.3°C
Chamber temperature (T_c)	10.1 ± 1.4°C	9.5 ± 2.2°C	21.8 ± 1.5°C
Initial soil temperature (T_0)	-11.3 ± 1.5°C	3.8 ± 0.4°C	18.0 ± 0.1 °C

3. Results

Figure 2a presents the spread rates measured using the IR images and shows a slightly decreasing relationship with decreasing condition temperature. This is likely due to the increased sensible energy required to heat the fuel at low temperatures and to melt the frozen MC. Figure 2b shows that MC has a more substantial effect on spread rate than condition temperature, with horizontal spread rates decrease with MC. For samples with 50% MC, the spread rate decreased 14% between 21°C and -7°C conditions. This difference increased to 18% in samples of 100% MC. As such, condition temperature was found to have a minor but insignificant influence on horizontal spread rates as confirmed by a nonsignificant linear regression ($p>0.05$), but was significantly influenced by MC as confirmed by a significant 2-sample t-test ($p<0.05$).

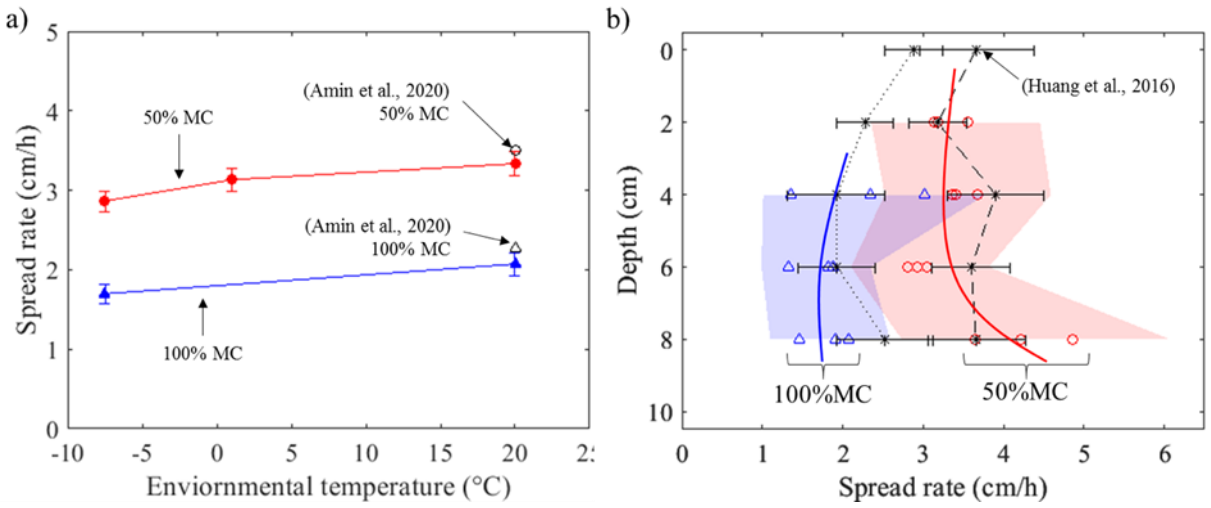

Figure 2- a) illustrating the effect of condition temperature on spread rate, measured using infrared (IR) imaging, in sample of 50% and 100% moisture content (MC). Results are also compared against IR spread measurements of a

similar reactor with an insulated base at room temperature presented by Amin et al. (2020). IR data was not available for samples with 100% moisture at 2°C. b) showing the effect of depth on spread rate on both samples with 50% and 100% MC at various temperature conditions and compared to spread rates presented by Huang et al. (2016). Error bars are based on uncertainties in measurement. Triangle and circle symbols represent spread rate from samples of 100% MC and 50% MC. Blue and red lines are approximate trends of horizontal spread rate with depth from samples of 100% MC and 50% MC. Temperature at 2 cm depth in samples of 100% moisture never exceeded 100°C and so could not be measured. Data from Huang et al. (2016) are represented by black lines: dotted line for sample of 100% MC and dashed line for sample of 50% MC.

The depth of burn is found by linearly interpolating between the peak temperatures of adjacent thermocouples and finding the location of the 200°C threshold. The burning depths in this study are presented in Table 2 along with the burning depth found in (Huang *et al*. 2016). Two effects are noticeable in the depth of burning in regard to both condition temperature and MC. Firstly, decreasing condition temperatures increases the burning depth, with a linear model confirming the significance of this trend ($p<0.05$). At 50% MC the burning depth increased by 66% between 21°C and -7°C, while in samples of 100% MC the increase was 13%. This change in depth of burning is likely due to the additional energy required to melt and heat the soil causing the optimal balance between oxygen supply and heat losses to exist deeper within the soil. Secondly, comparing the depth of burning estimated here to that presented by Huang *et al*. (2016) who conducted experiments at room temperature, using the same source of peat and a similar reactor but with an insulated bottom face, it is evident that the effect of the energy loss through the base results in shallower burning depths. This difference is enhanced with MC.

Table 2- Estimated burning depth by using 200°C as an indicator of char formation and linearly interpolating between peak temperatures measured by thermocouples. Depth of burning measured by Huang et al. (2016), is also presented for comparison.

	Depth of burning (cm)			
	-7 °C	2°C	21°C	Huang *et al*. (2016)
50% MC	2.5 ± 0.2	1.8 ± 0.3	1.5 ± 0.3	3 ± 1
100% MC	5.4 ± 0.6	4.6 ± 0.2	4.8 ± 0.5	9 ± 1

Additional experiments were performed to explore how the condition temperature influenced the critical MC of ignition in this work. It was found that smouldering could be successfully sustained in MC of 110% however would fail at 120%. This was true across all condition temperatures, and is lower than the value of 160% MC found by Hu *et al*. (2019) who used the horizontal reactor with an insulated base.

4. Conclusions

In this work, we have studied the smouldering dynamics of peat fire in the Arctic using a novel experimental rig able to separately control the temperature of the ambient air (10 to 21°C) and bottom boundary of the smouldering sample (-7 to 21°C). The initial temperature of the peat sample was varied from -11 to 18°C. We found that the range of ambient air, bottom boundary, and initial soil temperatures in this study have insignificant effect on spread but reduce burning depth up to 66% as the bottom boundary temperature decreased from 21 to -7°C. The critical moisture content to ignition in this study was found to be between 110 and 120% which is lower than the value in the literature (160%). This study is the first experimental work on smouldering Arctic wildfires with findings that can improve our understanding on the effect of cold temperatures on the smouldering dynamics of peat fires, and presents a novel methodology to investigate Arctic fires at laboratory scale.

Abstract

The 2017 wildfires marked a dramatic milestone in Portuguese society, which corresponded to extreme intensity and the inherent loss of life, property, and thousands of burned forest hectares. This high impact led to a paradigm shift regarding prevention and firefighting, highlighting the need for an integrated fire management approach and assuming as imperative the integration of wildfire risk reduction on spatial planning at the municipal level. This turning point was expressed in the prolific legislative production, namely in the guidelines for preventing and fighting wildfires, given by the Resolution of the Council of Ministers (RCM) n.º 157-A/2017; on the principles set out in the Directive for Preventing and Fighting Wildfires, defined by the RCM n.º 20/2018; in the approval of the National Plan for the Integrated Management of Wildfires (PNGIFR), emanated from the RCM n.º 45-A/2020, which established the need to implement an Integrated Management System for Wildfires (SGIFR), whose vision and objectives were defined in the RCM n.º 12/2019, and its operating rules were enacted in the Decree-Law n.º 82/2021.

As such, the SGIFR establishes, at a national level, strategic guidelines with a view to risk reduction, changing the behaviour of owners, users, and other beneficiaries of the rural territory. In addition, SGIFR proposes integrating wildfire risk reduction in spatial planning through the insertion of a fire hazard map, namely in the master plan's constraints map (i.e., the map where are identified the administrative easements and public utility restrictions that may constitute limitations or impediments to any specific form of land use). The constraint map is one of the documents of the Municipal Master Plan, i.e., the fundamental legal instrument in the management of the municipal territory that defines the strategic framework for territorial development and the spatial organization model of the municipal territory.

This paper identifies the weaknesses of the approach proposed by the SGIFR to promote wildfire risk reduction through spatial planning. Firstly, we used an online questionnaire answered by 175 municipalities of Portugal, in order to examine the local technicians' experience in applying the legislation of spatial planning and wildfire management policies. In a second step, we collected data from a Delphi survey with 27 experts and from a focus group with 9 experts with the aim to confirm or disconfirm the importance of each need for integration between land use planning and rural fire management, indicated by the questionnaire of 175 municipalities. One of the main weaknesses is related with the integration of the fire hazard map in the constraints map of the Municipal Master Plan, considering the high inter-annual variability of fire hazard and the long-term definition of the municipal development model. This procedure will create building permit constraints which can limit the development and continue to favour the depopulation of the rural areas.

This paper contributes to bridging a critical gap in knowledge on the role of spatial planning in the reduction of wildfire hazard and exposure, given that the characteristics of fire hazard are distinctive from other natural hazards (e.g., floods, costal erosion, earthquakes).

1. Introduction

Wildfire losses are increasing in many parts of the world related with the expansion of wildland urban interfaces and the occurrence of extreme wildfires, whose intensity and frequency are expected to increase due to climate

change (Keeley & Syphard, 2016). As these events overwhelm the control capacity (Tedim et al, 2018; Tedim et al., 2020), a stronger focus on prevention and mitigation, within a adaptative planning framework, is required. Spatial planning and development regulations are recognized as an instrument for reducing wildfire hazard and exposure across wildland-urban-interface (Mowery et al., 2019, Mockrin et al., 2020; Gatti & McGee,2021; Gonzalez-Mathiesen et al., 2021). While among other natural hazards (e.g., floods, coastal erosion, earthquakes) there is a long experience using spatial planning to reduce risk, in wildfire domain remain some critical gaps in knowledge and operationalization strategies (Mockrin et al., 2020), as wildfires are complex socio-ecological processes that mostly has anthropic origin.

In Portugal, the National Plan for the Integrated Management of Wildfires (PNGIFR), emanated from the Resolution of the Council of Ministers (RCM) n.º 45-A/2020, which established the need to implement an Integrated Management System for Wildfires (SGIFR), and its operating rules enacted in the Decree-Law n.º 82/2021, intent to integrate wildfire management into spatial planning instruments. The main instrument for this integration is the hazard map that is going to be one more layer of the Constraints Map of the Municipal Master Plans. The national hazard map was published in March of 2022 by the Portuguese Institute for the Conservation of Nature and Forests and was produced using a methodology that considers deterministic factors (Verde & Zêzere, 2010; Oliveira, Gonçalves, & Zêzere, 2021). The Municipal Master Plans (PDM's) inform spatial planning development and the buildings permits. The Master Plans regulate, at spatial level, the land use in order to promote the sustainable development in a given municipal territory, while its Constraints Map express restrictive areas that limit the desirable development at a site, safeguarding the biophysical and cultural character of the territory, as well as avoiding the occupation of areas with the highest hazard index. In this context, SGIFR determines that the interdiction of building permits in high and very high wildfire hazard areas (APPS) and major restrictions in very low, low and medium hazard areas, which have, by a SGIFR legal obligation, to be integrated in the Constraints Map of Master Plans.

This paper contributes to research on the difficulties, needs, and impact of the integration of wildfire hazard map into spatial planning namely into the Municipal Master Plans, first stablished by the Forest Fire Defence System (SDFCI - Decree-Law n.º 124/2006, of 28 June) and now determined by the Integrated Management System for Wildfires in the Continental Territory (SGIFR - Decree-Law n.º 82/2021. First, it identifies the difficulties that local governments face in the implementation of the new legislation, namely in the integration of wildfire hazard map into spatial planning. Second, it measures the consensus among experts. Third, pertinent recommendations are presented.

The overall research question is: What are the benefits and disadvantages of the hazard map integration in the Constraints Map of the Master Plans? The paper is organized as follows: Section 2 summarizes the mixed – methods used to collect and analyse data; Section 3 is dedicated to the analysis of legal environment of spatial planning and wildfire management integration; Section 4 presents the results about the identification of major difficulties and suggestions of local technicians, collected by an online survey and a Delphi survey, concerning the risk reduction in spatial planning at municipal level; Section 5 formulates the discussion about the challenges and opportunities regarding the integration of fire hazard map in the constraints map of the municipal Master Plans; and Conclusions are stated in Section 6.

2. Data and methods

2.1. Review of government documents

To prepare the two steps method used in this research, we started by reviewing government documents.

2.2. Data collection

As a first step, an online survey was sent between April and June of 2022, to 275 municipalities (the municipalities of Lisbon, Porto and São João da Madeira, were excluded because are urban areas). The questionnaire was formed by two questions: i) "*What are the main difficulties you face with the implementation of the SGIFR (DL n.º 822021, of October 13, in its latest version)?"*; ii) "*Do you agree with the decision to integrate the wildfire hazard map in the Constraint Map of the spatial plans? Please justify your reply.*". The response rate was 64%. It exceeds the necessary minimum sample size (161 replies for a confidence level of 95% and a margin of error of 5%), using Kish (1995) and Laureano (2013) equation**,** for extrapolating conclusions from the results.

The 175 municipality responses were organized by five territorial regions within the SGIFR governance structure: North (with 53 replies; 62% of the region's municipalities), Centre (with 50 replies; 73% of the region's municipalities), Lisbon and Tejo River Valley (with 24 replies; 44% of the region's municipalities), Alentejo (with 25 replies: 53% of the region's municipalities) and Algarve (with 10 replies; 63% of region's municipalities) (Figure 1). Thirteen (13) municipalities chose to remain anonymous.

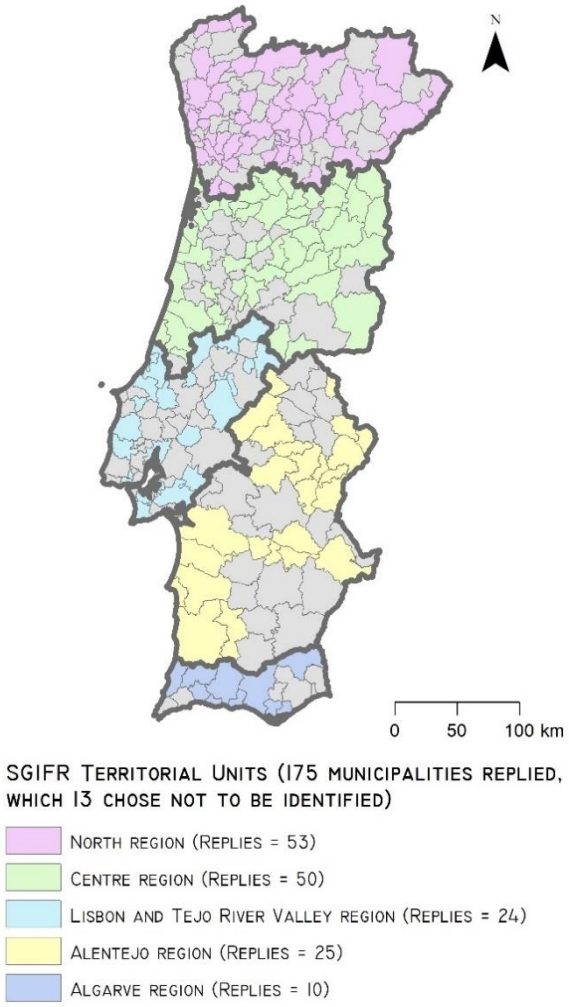

Figure 1 – Municipalities that responded the online survey per region.

The data collected was analysed in NVivo software, version 1.6.1 (1137). Coding in NVivo enabled to categorization of the survey open responses and consequently made it possible to count the frequency of each response.

In a second step, a workshop was held at Guarda Municipal Council on June 3, 2022, where a Delphi questionnaire was operated with 27 experts in spatial planning and wildfire management in order to differentiate the importance of the main categories emanated from the previous step. Thus, an one round real-time Delphi survey was supported by a 5-point *Likert* scale (*1 - Completely disagree; 2 - Disagree; 3 - Fairly agree; 4 - Agree; 5 - Completely agree*).

Procedures for measuring consensus vary widely, so there are several methods available to determine the convergence of opinion among Delphi participants (Rayens & Hahn, 2000; Gracht, 2012; Beiderbeck et al., 2021). These authors support the use of the interquartile range (IQR), where the low values are an indicator of consensus *([0 - 1] Most agreement]1 - 2[Average agreement [2 - 3] Low agreement*) (Gracht, 2012). According to Rayens & Hahn, (2000), a null interquartile range indicates complete consensus. Despite this, it was still decided to use the arithmetic mean (Mean). In this sense, an arithmetic mean value above 3.5 (integrating the answers *4 - Agree*; *5 - Completely agree*) expresses a tendency of concordant answer, while an average value lower than 2.5 (*1 - Completely disagree*; *2 - Disagree*) reflects a discordant trend. On the other hand, another indicator was used, namely the percentage of concordant answers (*Level of Agreement Responses*), which helps

the analysis of the response trend. The IQR of Delphi responses was calculated in Statistical Package for the Social Sciences 26 (IBM, 2022).

Finally, a focus group, in the workshop held in Guarda municipality with nine experts in spatial planning and wildfire management, was conducted to elicit, spontaneously, knowledge that had not been collected by the online questionnaire and the Delphi survey due to its more formatted nature.

3. Spatial planning and wildfire management integration: legal environment

The National Program for Spatial Planning Policy (PNPOT), the main Portuguese instrument for spatial planning on a national scale, in its revised version of 2019, approved by the Law n.º 99/2019, of September 5, stated that the "*articulation of the master plans with the instruments of forest management, forest defence and wildfire fighting, is paramount in order to build a more integrated planning approach that better responds to the challenges of the territories and to safeguard people and goods*".

RCM n.º 12/2019, of January 21, approved the mission of the Integrated Management System for Wildfires (SGIFR), namely the protection of people and property from wildfires, based on the clear definition of responsibilities concerning the management of the rural territory and the protection of people and buildings against wildfires, integrating all actors in a joint action within prevention and suppression processes. The same initiative enshrined the urgent establishment of the National Plan for the Integrated Management of Wildfires (PNGIFR) as a replacement for the previous National Plan for the Defence of Forests against Wildfires (PNDFCI), which saw its goals exceeded as a result of the accumulation of fuel and systemic frailties aggravated by heat waves or extreme weather events with increasing personal and property damage.

This context of vegetation accumulation and of perception bias of risk by populations that did not change risk behaviours required to the adoption of multiple and integrative solutions. Thus, the RCM n.º 45-A/2020, June 16th, gave the motto for the PNGIFR: guiding the integrated management of wildfires in a territory that seeks to be lived by a population with context-sensitive behaviours under efficient risk management options. The PNGIFR introduced an innovative risk governance model, identified strategic objectives and measures to be implemented, clarifying the roles and responsibilities of the various entities that cooperate to achieve the defined goals.

Subsequently, the Integrated Management System for Wildfires in the Continental Territory (SGIFR) promulgated by Decree-Law (DL) n.º 82/2021, defined the norms and institutional articulation processes in the integrated management of wildfires with two axes of intervention: protection against wildfires, oriented towards the safeguarding of people and buildings, and rural fire management, oriented towards the defence and valorisation of rural territories, considering its protection role by reducing conditions for the occurrence and progression of wildfires.

The SGIFR revoked the previous Forest Fire Defence System (SDFCI). which had been instituted by Decree-Law n.º 124/2006, of 28th June. As such, the previous requirement to draw up Municipal Plans for the Defence of Forests against Wildfires (PMDFCI) of the SDFCI was replaced by the requirement of Municipal Programs for the Execution of Integrated Management of Wildfires of the SGIFR.

Unlike the Master Plans (PDM's), the PMDFCI's and its hazard maps, as they were not, legally, spatial plans, were not directly binding on individuals as they did not meet the requirements of public advertising and public discussion, essential for the production of effects by any normative act, as enshrined in the respective paragraph 2 of article 119 and paragraph 5 of article 64 of the Portuguese Republic Constitution (Oliveira, 2018), situation only solved by the Law n.º 76/2017, 17th August.

In light of this goal of spatial planning and wildfire risk reduction alignment, the SGIFR, as the previous SDFCI, stipulates the integration of fire hazard index classes (very low, low, medium, high, very high) in the constraints map of the PDM's, and defines constraints on building permits within and outside the areas of high and very high fire hazard index classes, which are designated Priority Areas for Prevention and Safety (APPS).

4. Results

4.1. Main difficulties faced by the municipalities with the implementation of the SGIFR

4.1.1. The results from the online survey

The forestry technicians that responded to the online survey identified several difficulties regarding the integration of hazard map into the constraint map of Master Plans (table 1).

The main difficulties (table 1) are:

i) "new hazard map does not correspond to the existing reality in the territory" due to the spatial resolution; the fact that is not based on the Master Plan's urban spaces; the redundancy of the previous hazard maps, among others aspects. The greatest worries regions are from Centre region (22% of replies) and from North region (19% of replies) (supplementary table S1) that have around 50% of their territory in high and very high hazard index (table S2), but also from Alentejo (16% replies), where 56% of the surface presents low or no wildfire risk

ii) "land use map (COS) 2018 does not reflect the existing reality at the local level", which is a main worry from Algarve region (10% of replies);

iii) "obstacles to cultural and sporting activities)" as the articles 67 and 68 of SGIFR establish the prohibition of many activities in high and very high hazard areas and in days with high weather risk. This is a worry of the Centre region (4% of replies) (1% of national replies);

iv) "difficulties in surveying and mapping burned areas", being a worry of Alentejo municipalities ($% of replies) (1% of national replies);

v) "confusion between the concept of Hazard (structural) and Fire weather index (daily)", stated by 4% of Centre region replies (1% of national replies);

vi) "difficulty in understanding the criteria for defining hazardous areas", evidenced by 2% of Centre replies (1% of national replies);

vii) "the execution of the fuel management strips has contributed to colossal forest destruction", conduced by North region (2% of replies) (1% of national replies);

viii) "the current dimensions of the fuel management strips [around the houses] are not justified, as there is no gain in defence beyond 30 meters in size", concluded by North region (2% of North replies) (1% of national replies).

Table 1 – Main difficulties faced by the municipalities with the implementation of the SGIFR: responses to online survey (N=175).

	Responses (N=175)	**%**
RISK MANAGEMENT TOOLS		
New hazard map does not correspond to the existing reality in the territory (spatial resolution; not based on the Master Plan's urban spaces; redundancy of the previous hazard maps, among others)	30	17 %
Land use and land cover map (COS 2018) does not reflect the existing reality at the local level	2	1%
Obstacles to cultural and sporting activities (articles 67 and 68 of the SGIFR)	2	1%
There are difficulties in surveying and mapping burned areas	2	1%
Confusion between the concept of Hazard (structural) and Fire Weather Index (daily)	1	1%
Difficulty in understanding the criteria for defining hazardous areas	1	1%
The execution of the fuel management strips has contributed to colossal forest destruction	1	1%
The current dimensions of the fuel management strips are not justified, as there is no gain in defence beyond 30 meters in size	1	1%

4.1.2. Consensus of the Delphi panel

Subsequently, the robustness of the consensus in the Delphi survey responses (N = 27 experts) regarding the difficulties and needs regarding the integration of the hazard map in the constraint map of Master Plans was analysed. Those who generate a strong consensus were "hazard map does not correspond to the existing reality in the territory (spatial resolution; not based on the Master Plan's urban spaces; redundancy of the previous hazard maps, among others)" (mean=4.41; IQR=1; level of agreement responses=85%), "Land use map (COS) 2018 does not reflect the existing reality at the local level" (mean=4.11; IQR=1; level of agreement responses=85%); "confusion between the concept of Hazard (structural) and Fire Weather Risk (daily)" (mean=3.93; IQR=1; level of agreement responses=78%); and "difficulty in understanding the criteria for defining hazardous areas" (mean=4.37; IQR=1; level of agreement responses=89%) (table 2).

Table 2 – Main difficulties faced by the municipalities with the implementation of the SGIFR: consensus analysis of Delphi panel responses (N=27).

	Mean of Delphi Group (N = 27)	**Interquartile Range (IQR) [0 - 1] Most agreement]1 - 2[Average agreement [2 - 3] Low agreement**	**Level of Agreement Responses = Agreements / S opinions expressed**
RISK MANAGEMENT TOOLS			
Hazard map does not correspond to the existing reality in the territory (spatial resolution; not based on the Master Plan's urban spaces; redundancy of the previous hazard maps, among others)	4.40	1	85%
Land use map (COS) 2018 does not reflect the existing reality at the local level	4.11	1	85%
Confusion between the concept of Hazard (structural) and Fire Risk (daily)	3.92	1	78%
Difficulty in understanding the criteria for defining hazardous areas	3.85	1	70%
Obstacles to cultural and sporting activities (articles 67 and 68 of the SGIFR)	3.75	2	54%
The execution of the fuel management strips has contributed to colossal forest destruction	3.41	3	48%
The current dimensions of the fuel management strips are not justified, as there is no gain in defence beyond 30 meters in size	3.41	2	48%
There are difficulties in surveying and mapping burned areas	3,00	2	33%

4.2. Agreement with the decision to integrate the wildfire hazard map in the Constraints Map of the Master Plans

4.2.1. Results from the online survey

Regarding the integration of the wildfire hazard in the constraints map of Master Plans, most municipalities agree with their integration (74%) (table 3). Within the regions, the results are:

i) Lisbon and Tejo River Valley respondent municipalities agree with the integration (96% of replies, where high and very high hazard represent 24% of the territory);
ii) Alentejo respondent municipalities agree with the integration (92% of replies, where high and very high hazard represent 5% of the territory);
iii) North region respondent municipalities agree with the integration (79% of replies, where high and very high hazard represent 49% of the territory);
iv) Centre region respondent municipalities agree with the integration (74% of replies, where high and very high hazard represent 51% of the territory);

v) Algarve region respondent municipalities agree with the integration (60% of replies, where high and very high hazard represent 34% of the territory).

Table 3 - Agreement with the decision to integrate the wildfire hazard map in the Constraints Map of Master Plans: responses to online survey (N=175).

	Responses (N=175)	**%**
YES	130	74%
DECISION MARKING		
The integration of the hazard map facilitates decision making regarding the licensing of construction and expansion of buildings in rural areas depending on the hazard	37	21%
The integration of the hazard map in Constraint Map of Master Plan is necessary in order to bind individuals	5	3%
The hazard map must be integrated into the Master Plan constraint map only if it is prepared by the municipality	1	1%
HAZARD MAP METHODOLOGY		
The methodology of the hazard map standardizes the criteria, at a national level, for the elaboration of this cartography, leaving no room for discrepancies	5	3%
The methodology for executing the hazard map should be reviewed and should be dynamic	4	2%
The artificialized territories in the Land Use Map (COS 2018) do not correspond to the urban spaces of the Master Plan, which makes procedural analysis difficult in the context of the constraints to the construction of the SGIFR	2	1%
EXPECTED IMPACTS		
But the structural hazard map leads to major restrictions	3	2%
The hazard map must not lead to the prohibition of occupation of rural areas, increasing their vulnerability, abandonment, and inherent increase in hazardousness	1	1%
Hazard index encourages the management of rural areas insofar as the less dangerous nature of the plots will increase their financial value	1	1%
NO	45	26%
EXPECTED IMPACTS		
The structural hazard map leads to major restrictions	9	5%
MISMATCHES IN THE PLANNING FRAMEWORK		
Hazard index, due to its dynamic nature, becomes impracticable to be transposed to Master Plan's Constraints Map	5	3%
There is an incompatibility between the rigidity of the Spatial Plans and the dynamics of transformation of the Territory	1	1%
The hazard map must maintain its independent character from the Spatial Plans, supporting forestry planning and rural fire management	1	1%
LEGAL ENVIRONMENT		
The hazard map binds individuals without having been published for public consultation	3	2%
HAZARD MAP METHODOLOGY		
The hazard map should be carried out by the municipalities	1	1%
The hazard map was created by identifying spaces with high fire recurrence and from a standpoint of definition of defence areas, so it cannot be used as a building constraint	1	1%

However, both those who agree and those who disagree present suggestions for improvement in this subject.

The concordant responses were categorized in Decision Making, Hazard Map Methodology, and Expected Impacts.

Regarding decision making, the concordant respondents stated that "the integration of the hazard map facilitates decision making regarding the licensing of construction and expansion of buildings in rural areas depending on the hazard" (21% of national replies; 33% of Lisbon and Tejo River Valley; 24% of Alentejo region replies; 21% of North region replies; 20% of Algarve region replies; 14% of Centre region replies)

In addition, "the integration of the hazard map in Constraints Map of Master Plans is necessary in order to bind individuals" (3% of national replies; 4% of North region replies; 4% of Centre region replies; 4% of Alentejo region replies).

However, there are municipalities that consider that "hazard map must be integrated into the Master Plan constraint map only if it is prepared by the municipality" (1% of national replies; 2% of North region replies) explaining.

Concerning hazard map methodology one of the positive aspects is that "the methodology of the hazard map standardizes the criteria, at a national level, for the elaboration of this cartography, leaving no room for discrepancies" (3% of national replies; 8% of Lisbon and Tejo River Valley replies; 2% of North region replies).

Nevertheless, the are municipalities that establish some conditions like "the methodology for executing the hazard map should be reviewed and should be dynamic" (2% of national replies; 6% of North region replies), and that "the artificialized territories in the Land Use Map (COS 2018) do not correspond to the urban spaces of the Master Plan, which makes procedural analysis difficult in the context of the constraints to the construction of the SGIFR" (1% of national replies; 10% of Algarve region replies; 2% of Centre region replies).

About the expected impacts, the concordant respondents acknowledge that "the structural hazard map leads to major restrictions" (2% of national replies; 4% of Centre region replies), "the hazard map must not lead to the prohibition of occupation of rural areas, increasing their vulnerability, abandonment, and inherent increase in hazardousness" (1% of national replies; 10% of Algarve region replies), and "hazard index encourages the management of rural areas insofar as the less dangerous nature of the plots will increase their financial value" (1% of national replies; 4% of Lisbon and Tejo River Valley replies).

Discordant respondents, on the other hand, presented answers that were grouped into four themes: Expected Impacts, Mismatches in the Planning Framework, Legal Framework and Hazard Map Methodology.

For these respondents, the main expected impacts are related to major restrictions determined through the hazard map (5% of national replies; 10% of Algarve region replies; 6% of North region replies; 6% of Centre region replies).

Within mismatches in the planning framework, they say that "hazard index, due to its dynamic nature, becomes impracticable to be transposed to Master Plan's Constraint Map" (3% of national replies), "there is an incompatibility between the rigidity of the Spatial Plans and the dynamics of transformation of the Territory" (1% of national replies; 2% of Centre region replies) and that "the hazard map must maintain its independent character from the Spatial Plans, supporting forestry planning and rural fire management" (1% of national replies; 10% of Algarve region replies).

Among legal environment, they state that the hazard map binds individuals without having been published for public consultation" (2% of national replies; 10% of Algarve region replies; 4% of Centre region replies).

In regard to hazard map methodology, "the hazard map should be carried out by the municipalities" (1% of national replies; 2% of North region replies) and "the hazard map was created by identifying spaces with high fire recurrence and from a standpoint of definition of defence areas, so it cannot be used as a building constraint" (1% of national replies; 2% of North region replies).

4.2.2. Consensus of the Delphi panel

Regarding the justification of the concordant and discordant answers, and the suggestions for improvement, there is a consensus in: "the methodology for executing the hazard map should be reviewed and should be dynamic" (mean=3.56; IQR=1; level of agreement responses=89%); "the artificialized territories in the Land Use Map (COS 2018) do not correspond to the urban spaces of the Master Plan, which makes procedural analysis difficult in the context of the constraints to the construction of the SGIFR" (mean=3.56; IQR=1; level of agreement responses=63%); "the methodology of the hazard map standardizes the criteria, at a national level, for the elaboration of this cartography, leaving no room for discrepancies" (mean=3.15; IQR=1; level of agreement responses=37%); "the structural hazard map leads to major restrictions" (mean=3.96; IQR=0; level of agreement responses=81%); "the hazard map binds individuals without having been published for public consultation" (mean=4.15; IQR=1; level of agreement responses=77%); and "hazard index, due to its dynamic nature, becomes impracticable to be transposed to Master Plan's Constraint Map" (mean=3,52; IQR=1; level of agreement responses=52%).

Table 4 – Agreement with the decision to integrate the wildfire hazard map in the Constraints Map of Master Plans: responses to online survey (N=175): consensus analysis of Delphi survey responses (N=27).

	Mean of Delphi Group (N = 27)	**Interquartile Range (IQR) [0 - 1] Most agreement]1 - 2[Average agreement [2 - 3] Low agreement**	**Level of Agreement Responses = Agreements / S opinions expressed**
YES			
HAZARD MAP METHODOLOGY			
The methodology for executing the hazard map should be reviewed and should be dynamic	4.37	1	89%
The artificialized territories in the Land Use Map (COS 2018) do not correspond to the urban spaces of the Master Plan, which makes procedural analysis difficult in the context of the constraints to the construction of the SGIFR	3.56	1	63%
The methodology of the hazard map standardizes the criteria, at a national level, for the elaboration of this cartography, leaving no room for discrepancies	3.15	1	37%
EXPECTED IMPACTS			
But the structural hazard map leads to major restrictions	3.96	0	81%
The hazard map must not lead to the prohibition of occupation of rural areas, increasing their vulnerability, abandonment and inherent increase in hazardousness	3.85	2	63%
Hazard index encourages the management of rural areas insofar as the less dangerous nature of the plots will increase their financial value	3.15	2	44%
DECISION MARKING			
The integration of the hazard map in Constraint Map of Master Plan is necessary in order to bind individuals	3.89	2	63%
The hazard map must be integrated into the Master Plan constraint map only if it is prepared by the municipality	3.7	2	1%
The integration of the hazard map facilitates decision making regarding the licensing of construction and expansion of buildings in rural areas depending on the hazard	3.59	2	63%
NO			
LEGAL ENVIRONMENT			
The hazard map binds individuals without having been published for public consultation	4.15	1	77%
MISMATCHES IN THE PLANNING FRAMEWORK			
There is an incompatibility between the rigidity of the Spatial Plans and the dynamics of transformation of the Territory	3.81	2	62%
Hazard index, due to its dynamic nature, becomes impracticable to be transposed to Master Plan's Constraint Map	3.52	1	52%
The hazard map must maintain its independent character from the Spatial Plans, supporting forestry planning and rural fire management	3.15	2	42%
EXPECTED IMPACTS			
The structural hazard map leads to major restrictions	3.96	0	81%
HAZARD MAP METHODOLOGY			
The hazard map should be carried out by the municipalities	4,00	2	69%
The hazard map was created by identifying spaces with high fire recurrence and from a standpoint of definition of defense areas, so it cannot be used as a building constraint	3.69	2	54%

It is not surprising that the highest participation rate and greatest concern with hazard related restrictions was from municipalities in the North region and the Center region, as these are the regions that have around of 50% of their territory in high and very high hazard index (table S2).

As discussed in the focus group, the constraints on building in areas with high and very high hazards are stranglers for the territorial development and could increase the depopulation of the interior, which will generate even less human capacity for fuel management and, thus, could increase the hazard. As for the integration of the hazard map in the Master Plan constraint map, it was discussed that the hazard map is a cartography that can undergo annual changes and it makes no sense to integrate it into a constraint map of the Master Plan that is only reviewed every 10 years.

5. The integration of the fire hazard map in the constraints map of the municipal master plan: challenges and opportunities

The Portuguese authorities estimate fire hazard, based on a deterministic approach (Verde & Zêzere, 2010; Oliveira, S., Gonçalves, A., & Zêzere, J. L., 2021). This approach uses fire probability, slope and land cover factors, aggregating it in quintiles, which correspond to five hazard classes, in order to create the fire hazard map as specified by SDFCI (Decree-Law n.º 124/2006). Therefore, the fire hazard map has usually been the product of multiplying probability and susceptibility to wildfires, while potential damage has been the product of multiplying the economic value and vulnerability (AFN, 2012). As such, the fire risk assessment is based on multiplying the Fire Hazard with the Potential Damage. In the case of the Fire Hazard inputs, it should be noted that the probability results from dividing the number of recorded wildfire occurrences and the number of years in its series, expressed as a percentage. As such, the time series of wildfire occurrences must be as long as possible (Parente et al., 2016).

Using the number of occurrences as a methodological input for the hazard map calculation works for the majority of fires and it is a prolific exercise, but do not apply to extreme fires conditions (Tedim et al., 2020), whose intensity and recurrence are expected to increase with a changing climate (Keeley & Syphard, 2016).

Susceptibility, on the other hand, derives from the multiplication of susceptibility classes depending on two factors, namely slope and land use/cover. In this context, the susceptibility is increasing as the slope increases. Regarding land use, forest land use classes are associated with greater susceptibility, while agricultural classes have a low to medium susceptibility. At this point, several methodological challenges arise. Regarding the slope calculation, it is imperative to use a Digital Terrain Model with the maximum possible spatial resolution, so that the areas with the greatest susceptibility are identified with high accuracy.

The accuracy between reality and what is mapped is also a challenge in terms of land use mapping. In this subject, the Corine Land Cover (CLC) cartography with a minimum mappable unit of 25 hectares (ha) and a time series with five reference years (1990, 2000, 2006, 2012 and 2018), or the Land Use and Occupation Map (COS) with a minimum mappable size of 1 ha and time series with five reference years (1995, 2007, 2010, 2015 and 2018), are commonly used. Even concerning cartography with a smaller and, therefore, more exact mappable size unit, it is important to consider the disadvantages of the COS use at local scale, depending on its level of accuracy and generalization rules adopted at the time of its preparation.

The COS vectorial map derives from the orthophotomaps interpretation, related to the previous years (up to 2 years before), with a spatial resolution of 20 linear meters and the mentioned 1 ha in terms of minimum mappable area. By this combination of factors, the COS map, when used, is already out of date. Another issue is that its spatial resolution is not compatible with the identification of isolated housing, scattered housing, or road network. In the case of the master plans, the maps should be done at a scale of at least 1/1000, so that human infrastructures are effectively represented (buildings and local road network). In this context, an opportunity in the calculation of the fire hazard is the use of land use maps with higher resolution and smaller mappable units that allow greater accuracy to the real land use, carried out with a constant periodicity that allows the expression of the dynamic influence of land use and land cover changes on fire hazard index of a given territory.

However, the integration of the fire hazard map in the constraint map of the master plans can be an opportunity or a threat, depending on the spatial resolution and degree of generalization of the COS that serves as an input of fire hazard index.

This integration can, therefore, generate a spatialization of the areas with the greatest fire hazard that is crystallized in the municipal master plans, thus, failing to assume the impact on the hazard index reduction of the fuel management initiatives and the dynamics of land use and land cover change. Another threat can arise from the trend that master plans are only revised in 10, 20 or more years.

In this way, it emerges the challenge to improve the calculation of fire hazard due to the constant search for inputs permanently updated and with greater accuracy, considering that integrating fire hazard into the constraint map of the municipal master plans could fail the risk reduction strategy due to the lack of recognition of its dynamic character.

Regarding the factors currently considered for the calculation of the hazard index, it is important to mention that extreme wildfires do not comply with them, given their intensity and degree of uncertainty (Tedim et al. 2018; 2020). As such, integrating risk reduction in spatial planning is paramount, but the strategy to be carried out must be dynamic and adaptive, without falling into the temptation of completely eliminating uncertainty and risk, which is impossible.

6. Conclusions

The integration of the fire hazard map in the constraints map of the Municipal Master Plans, proposed by the SGIFR, represents a challenge, considering the high inter-annual variability of fire hazard, the long-term definition of the municipal development model and the methodology (including the data accuracy) used to assess hazard. The procedure imposed by the current wildfire policy will create building permit constraints that can limit the development of rural areas and the growth of rural agglomeration. These restrictions could continue to favour the depopulation of the rural areas and the creation of more hazardous landscapes by abandonment.

The current existing static regulation system poses growing mismatches, economic, environmental, and social losses. The integration of spatial planning and wildfire risk reduction policies should more comprehensive. Multisector approaches able to mobilize synergies in an adaptive regulation system are paramount and, in this sense, the present paper identified the most pressing opportunities to improve the hazard map and spatial plans alignment.

Numerical simulation, fireman thermal response, energy balance integral equations, mass balance integral equation

Abstract

This work presents the design and radiative heat transfer in a fireman in wildfire environment. The fireman body model, used in this work, is divided into 35 elements. Each element is subdivided into several layers, constituted by fat, muscle, core and skin, and can be protected from the outside environment by several clothing layers. The geometry of the fireman and the fire front are developed using numerical models. Fireman thermal systems consider energy and mass balance integral equations. The energy balance integral equations consider the conduction, convection, evaporation and radiation, amount other phenomena, while the mass balance integral equations consider the convection and diffusion, amount other phenomena. The fireman has subjected two vertical fire fronts. The fireman and the fire front geometry was developed and are used to evaluate the view factors that each fireman section is subjected. The view factors are used to evaluate separately the influence of the two fire front and the Mean Radiant Temperature are used to evaluate integrated the influence of both fire front.

1. Introduction

In this study the influence of two fire fronts in the fireman are analysed. The view factors are used to evaluate separately the influence of each one in the fireman, while the Mean Radiant Temperature (see (ISO, 2005), (Fanger, 1970), (ASHRAE, 2017)) is used to evaluate integratelly the influence of the two fire front in the fireman. However, in order to evaluate the view factors and the Mean Radiant Temperature the fireman and fire front geometry are important to generate in detail.

The numerical model used in this study considers the fireman geometry and the fireman thermal response. In the fireman thermal response special attention is made in the radiative phenomenon.

The human body geometry considers 34 cylindrical elements and 1 sphere element (see (Conceição and Lúcio, 2001), (Conceição et al., 2018) and (Conceição and Awbi, 2021)). In the cylindrical elements are considered the neck, chest, upper abdomen, lower abdomen, right upper shoulder, right lower shoulder, right upper arm, right lower arm, right hand, left upper shoulder, left lower shoulder, left upper arm, left lower arm, left hand, right upper thigh, right lower thigh, right upper leg, right lower leg, right foot, left upper thigh, left lower thigh, left upper leg, left lower leg, left foot and 10 fingers. In the sphere element the head is considered.

In the fireman thermal response, it is important to consider the radiative heat exchanges to evaluate the thermal interaction between the surrounding surfaces and the fireman body surfaces. In this study the shading devices is also considered. See this methodology applied in plan surfaces in (Conceição et al., 2010), (Conceição, Gomes and Awbi, 2019) and (Conceição and Lúcio, 2010). The numerical model considers also the convective heat exchanges between the body surface and the surrounding airflow, the heat conduction through the bodies' tissues, water heat loss by evaporation from the skin surface and clothing of the fireman. In the numerical model the energy and mass balance integral equations is used.

In the radiative heat exchange the view factors between the fire front and the fireman should be evaluated. The view factors, among others works, can be analysed in (Jiang et al., 2017), (Vorre, Jensen and Le Dréau, 2015) and (Lai, Maing and Ng, 2017).

2. Numerical model

The fireman thermal response is based on the energy balance integral equations for the body tissues and clothing and the mass balance integral equation for the water in the body tissues and clothing.

The energy balance integral equations consider the following phenomena:

- The conduction phenomenon appears between the various layers of each body element and between the various layers of clothing.
- The convection phenomenon appear between the bodies external surface (skin and clothing) and the surrounding air environment.
- The evaporation phenomena appear between the bodies external surface (skin and clothing), subjected to water vapour, and the surrounding air environment.
- The radiation phenomenon appears between the bodies external surface and the fire front, whose modelling uses the Mean Radiant Temperature values. Between the clothing levels and between the skin and the clothing the radiation phenomenon are also verified.

The mass balance integral equations consider the following phenomena:

- The water vapour convection appear between the bodies external surface (skin and clothing) and the surrounding air environment.
- The diffusion phenomenon appears between the clothing bodies and between the skin and the clothing surfaces.

The systems of equations defined above are solved by the Runge-Kutta-Fehlberg algorithm with error control.

3. Numerical methodology

The fireman model has a height of 1.8 m and consists of 35 elements. It is equipped with three layers of clothing, the outer layer corresponding to the typical equipment (including the helmet) of a fireman fighting a forest fire.

In this study two fire front, being static in the numerical simulation, are considered:

- The fire front number 1 has 10 m wide and 1 m high and is located in front to the fireman;
- The fire front number 2 has 8 m wide and 1 m high and is located in the side to the fireman.

The fireman distance between each fire front is:

- 5 m from the fireman to the fire front number 1;
- 6.5 m from the fireman to the fire front number 2.

The fireman is placed at a distance of 5 m perpendicular to the central zone of the fire front, as shown, respectively, in Figure 1 and Figure 2.

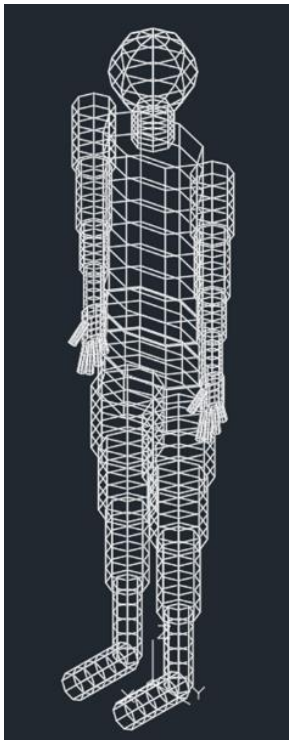

Figure 1- Fireman three-dimensional model

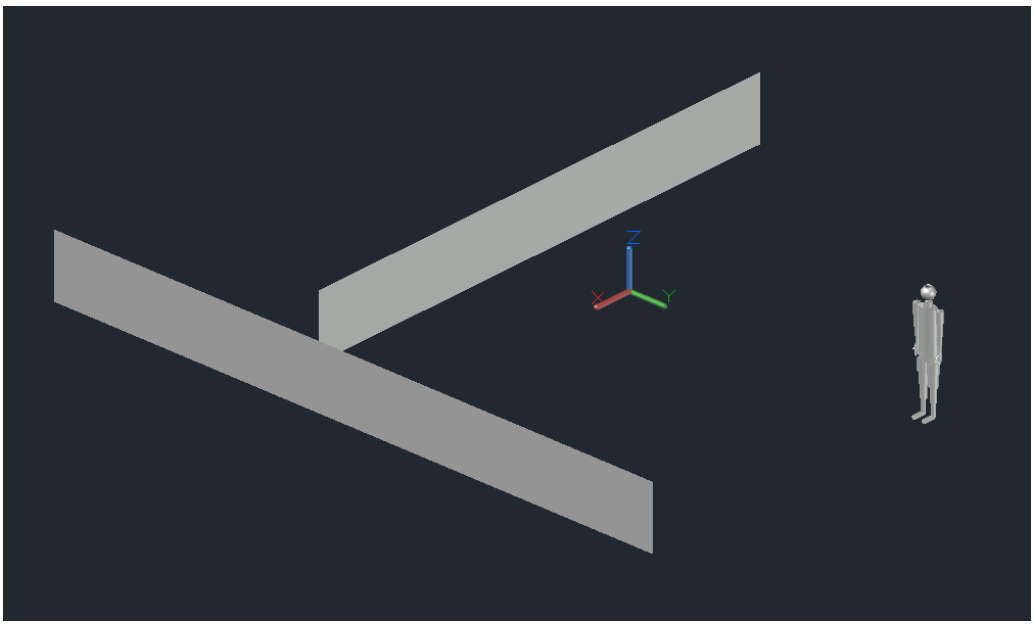

Figure 2- Location of the fireman in relation to the fire front number 1 and number 2

4. Results

This section presents the results obtained in the view factors for the fire front number 1 (see figure 3) and the view factors for the fire front number 2 (see figure 4). The Mean Radiant Temperature distribution, that is influence of the two fire front is presented in Figure 5.

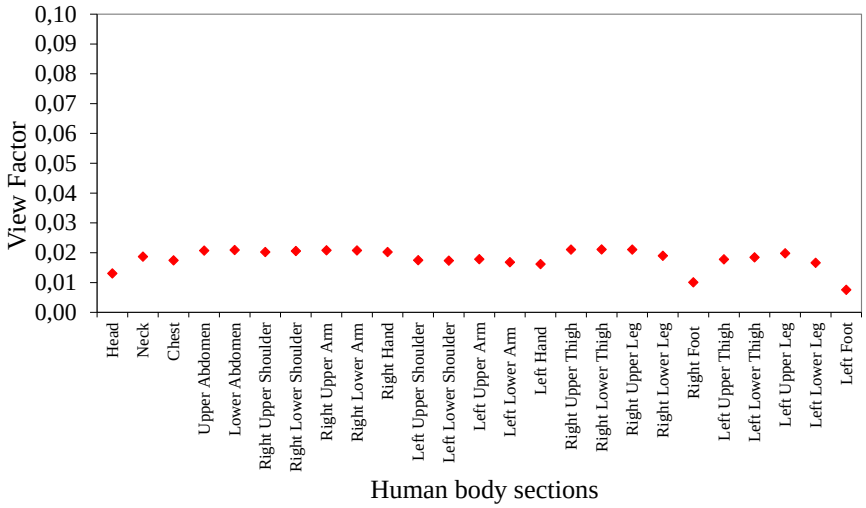

Figure 3. View factor that the fireman are subjected in the fire front number 1.

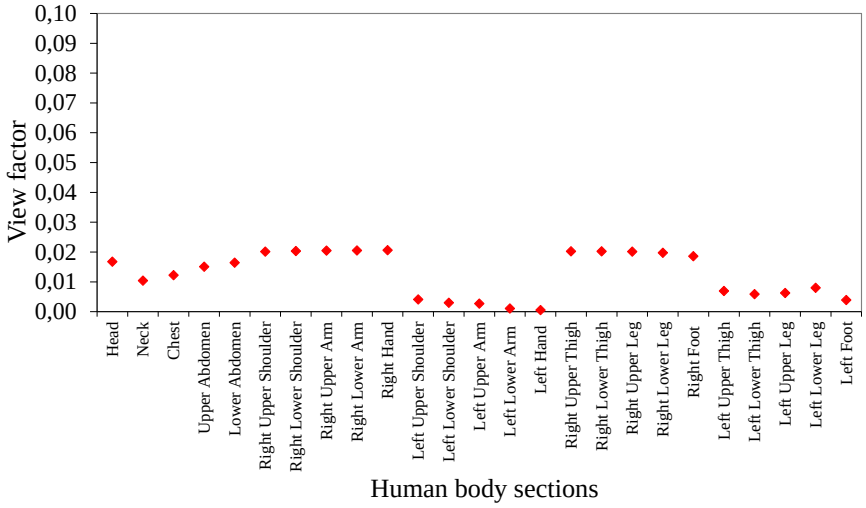

Figure 4. View factor that the fireman are subjected in the fire front number 2.

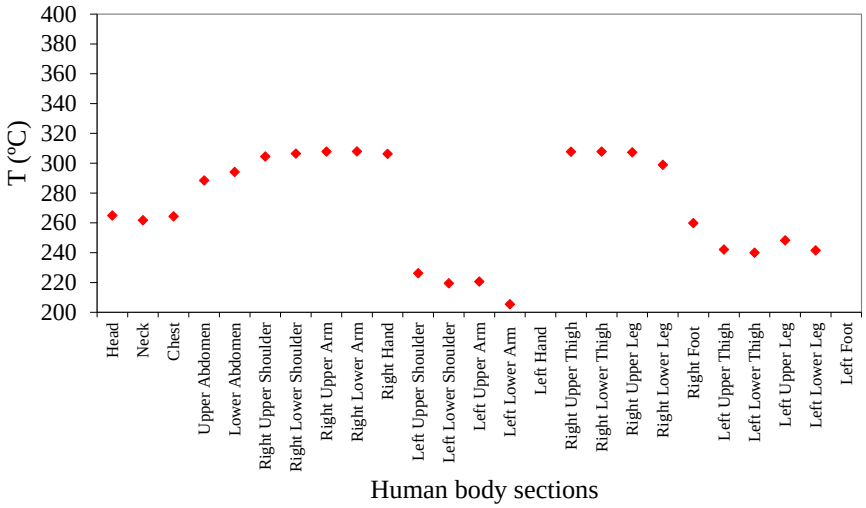

Figure 5. Mean Radiant Temperature distribution in the fireman.

In accordance with the obtained results the fire front located in front to the fireman present similar distribution of the view factor in the human body. In general, the view factor value is similar, however the head and the feet's presents slight low values.

When the fire front is localized in the lateral area to the fireman, the left upper and the left lower member, mainly the upper arm, present lower view factor values. Thus, these human body sections are protected from the radiation flux of the fire front number 2.

Finally, the Mean Radiant Temperature present the contribution of the radiant heat flux come from the two fire fronts, calculated trough the view factors. In the present study, namely in the fire front number 2, the protection promoted by the trunk is verified in the left arm. The low view facts verified also in the foot and hear are also verified in the Mean Radiant Temperature.

Thus, this kind of situation, namely when the occupant are subjected simultaneous to several fire front, this methodology consider simultaneously the real radiative effect that the fireman are subjected.

5. Conclusions

In this paper a design and radiative heat transfer in a fireman in wildfire environment is evaluated. In accordance with the obtained results, the fireman and the fire front geometry is very important in the calculation of the view factors and the Mean Radiant Temperature used to evaluate the heat exchanges that the fireman is subjected.

The human body geometry considers 35 human body elements. The grid generation refinement considered in cylinders and sphere is important in the view factors calculus. In the fire front geometry, considered as a plan vertical surface, the grid generation refinement is also an important factor in the view factors calculus.

The Mean Radiant Temperature is calculated based in the view factors obtained individually in each fire front.

This methodology is important to evaluate individual the effect that each fire front promoted in the fireman, using the view factor concept, and is important to evaluate simultaneously the integral effect that all fire front promoted in the fireman, using the Mean Radiant Temperature.

Tourism demand, wildfires, spatial econometrics, climate change

Abstract

Fire intensity and size incite visitation decrease and recreational losses, relevant tourism variables for European economies. As a result of climate change, the wildfires recurrence is becoming more evident. Due to significant gaps in analyzing the relationship between wildfires and tourism demand, this paper aims to explain how tourism demand reacts to wildfires in Portugal. We use a spatial econometric model to analyze the relationship between total burned areas and overnight stays in a touristic establishment in a given municipality and its neighboring municipalities. Our results show that wildfires negatively affect the overnight stays in the same location but also cause spillover effects in neighboring municipalities. Also, the wildfire occurrences are positively related to the number of overnight stays after three months, suggesting a delay in tourism activities.

1. Introduction

Climate change relates to shifts in the mean climate and variations in the frequency and intensity of extreme weather events. The increased frequency and intensity of extreme precipitation, droughts, tropical cyclones, and compound extremes, including fire weather, are evident, as shown in the IPCC 6th Assessment Report (IPCC 2021). In particular, the recurrence and duration of wildfires, as a result of climate change, has increased in many countries all over the world, including Greece, Spain, and Portugal (Giannakopoulos, Kostopoulou et al. 2011, Hall, Scott et al. 2011, Marques, Borges et al. 2011, Doerr and Santín 2016). Consequently, economic activities, specialization, and other economic geography variables are also predicted to shift in the coming years (Yohe and Schlesinger 2002, Conte, Desmet et al. 2021). A region that is expected to be severely affected by climate change and fires is the Mediterranean.

In the Mediterranean, tourism constitutes a significant economic activity, totalizing 217 billion euros in international tourism receipts, 23% of the world total, in 2014. The Mediterranean climate is the principal element tourists consider regarding travel planning, especially relevant for summer tourism (Giannakopoulos, Kostopoulou et al. 2011, Roson and Sartori 2014). Hence, the dependence of tourism activities on climate resources makes the industry one of the most vulnerable to climate change (Dogru, Bulut et al. 2016, Dogru, Marchio et al. 2019).

Portugal, as a Mediterranean country, has historical wildfires. Natural ignitions in the European Mediterranean basin, such as lightning, are standard where the atmospheric conditions feature low humidity and little or no precipitation. However, the modified socio-economic, environment and land patterns, in Portugal, as well as in other European Mediterranean countries, led to changes in the traditional causes of fire ignition in recent decades, whose origins have predominantly become anthropogenic instead of natural (Pereira, Trigo et al. 2005, de Zea Bermudez, Mendes et al. 2009). Currently, Portugal has the highest incidence of wildfire events in the Mediterranean basin and the whole of Europe, which have also become larger and more intense (Meira Castro, Nunes et al. 2020).

As in other similar regions, wildfires in Portugal are more prone to occur in the summer, when high temperatures and relative air humidity are low. In the same period, tourism activities are at their highest, and studies already

look to patterns of seasonality and global warming implications in summer tourism (Vergori 2017, Koutroulis, Grillakis et al. 2018). The tourist accommodation sector registered 2.5 million guests and 7.5 million overnight stays in August 2021 in Portugal, versus 1.5 million guests and 3.6 million overnight stays in November 2021. This summer tourism peak is responsible for a seasonal increase in the income of associated economic sectors, such as food and hospitality. The average daily rate (ADR) amounted to EUR 115.8 in August, and EUR 98.7 in July, versus EUR 47.1 in February (INE 2021).

Although the broad impacts of climate change in tourism have been analyzed (Scott, Gössling et al. 2012, Kaján and Saarinen 2013, Dogru, Marchio et al. 2019, Scott, Hall et al. 2019), more specific studies only focus on tourism activities that will suffer most immediately from climate change, expectedly, the decrease in snow and skiing activities (Dawson and Scott 2013, Gilaberte-Búrdalo, López-Martín et al. 2014, Steiger, Scott et al. 2019). Some of these studies use simplified regression models to evaluate the effect on ski tourism variables resulting from increased temperatures (Demiroglu, Kučerová et al. 2015, Damm, Greuell et al. 2017).

Studies on wildfire impacts in tourism are even in more remarkable absence, as noted by Arabadzhyan, Figini et al. (2021) in a review on coastal tourism. Such may be explained both by the difficulty in collecting and treating data and coordinating analysis between two vastly different scientific areas and by the fact that the tourism boom is still very recent in some wildfire-prone regions, such as Portugal. Additionally, the years of the pandemic and substantial restrictions on travel further hinder the collection of information, although new analyses are emerging (Marques, Guedes et al. 2021). Existing analyses include Sánchez, Baerenklau et al. (2016) that develop a Kuhn–Tucker model of recreation demand, with survey data, to look to relationships between wildfires and wilderness access, looking to the effects on visits, showing significant potential welfare loss. In Portugal, Otrachshenko and Nunes (2022) use yearly data in a two-level analysis in a panel regression model with fixed effects to reveal that burned areas negatively impact the number of tourist arrivals.

As evidenced, the literature presents significant gaps in analyzing the relationship between wildfires and tourism demand. In the context of climate change, with perspectives of future worsening of extreme events in the Mediterranean region, and with the growing importance of the tourism sector for regional socio-economic development, it becomes critical to understand how tourists change their journeys in the evidence of those events.

This paper aims to understand how tourism demand reacts to wildfires and how tourists adjust their destination / monthly travel intentions within monthly time lags. Do tourists postpone their trips for a few months when faced with the evidence of the fires? Will they change their intentions to visit at similar times in the following years? This study builds on previous analysis and develops a model to address these questions. Looking at all mentioned works, we conclude that regression analyses, adequately tuned to the variables in question, can produce valuable results. We apply spatial econometric techniques not yet used in this field to develop a novel spatial regression model that considers the possibility of spillovers in time and space, contributing to the economic geography literature on climate change impacts. The model analyses wildfires over monthly time units and municipalities, capturing their effects on the variation in the distribution of tourism along with the municipalities mentioned above.

2. Data and Methodology

2.1. Data

This study uses wildfires data provided by the Portuguese Institute for Conservation of Nature and Forests (ICNF) (ICNF 2021). The database includes monthly distributed data on the burned area in hectares by municipalities from 2017 to 2020. The total burned area includes forests and shrubs lands and rural areas. The percentage of wildfires events during summers increased severely from 49% to 70% from 2019 to 2020.

As a proxy for tourism demand, the municipality's number of tourist guests and monthly overnight stays were obtained from the Statistics Portugal website (INE) from 2020 to August 2021 (INE 2021b, INE 2021c).Figure 1 and 2 shows the occurrence of wildfires of more than 1000ha in continental Portugal during summers 2019 and 2020, respectively. Comparing figure 2 with tourism demand, in 2020 and 2021 summers (Figure 3), it is possible to see the lowest tourism records in the same municipalities with the most significant fires. In Proença-a-Nova (Pr-a-Nova in Figure 2), for example, had the most significant wildfire in 2020 summer (Figure 2), and

this municipality registered the lowest tourism demand rate in 2020 and 2021 (Figure 3). This data shows possible wildfires interfering in summer tourism demand in the same year and one year later after the wildfire event.

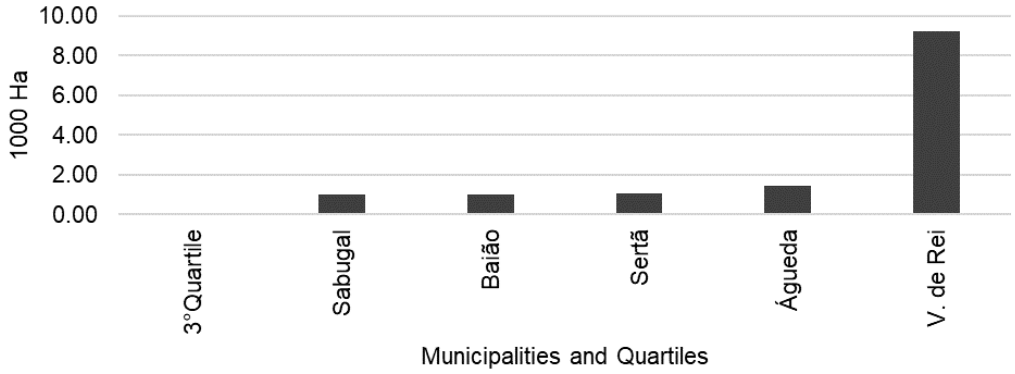

Figure 1- Burned areas per Municipalities of the 4th Quartile, summer 2019. Source: (ICNF 2021).

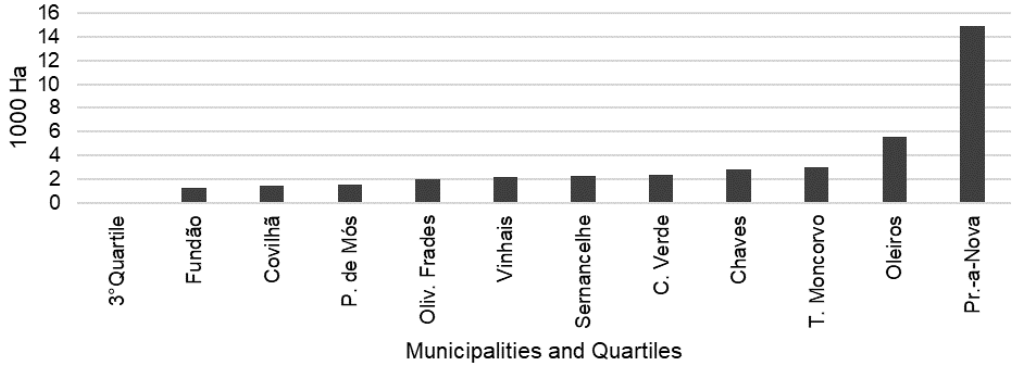

Figure 2- Burned areas per Municipalities of the 4th Quartile, summer 2020. Source: (ICNF 2021).

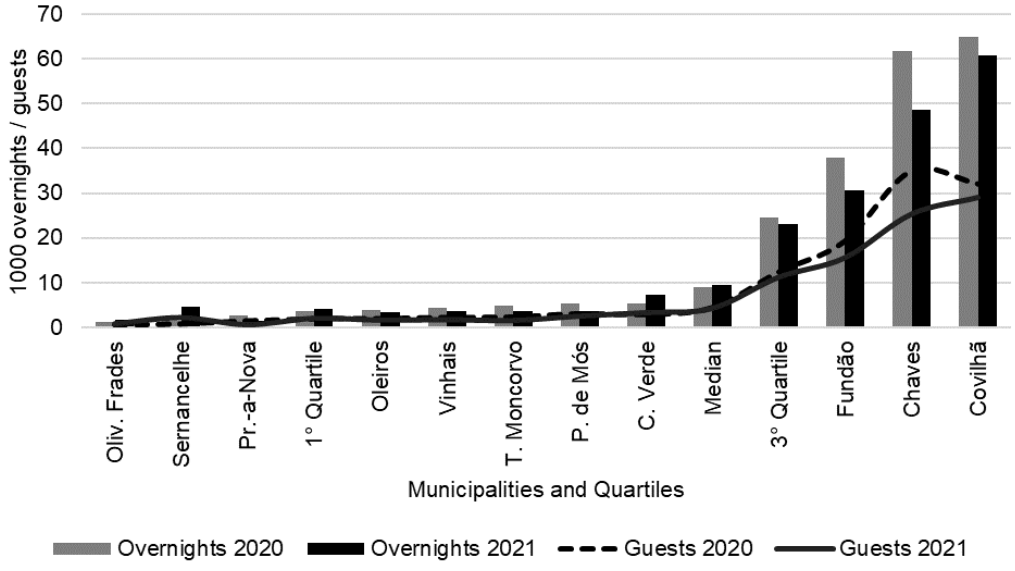

Figure 3- Tourism demand, per representative Municipalities with wildfires in 2020 - summers 2020 and 2021. Source: INE (2021b); INE (2021c).

In the same way, a similar effect appeared when comparing figure 4 with the tourism demand in 2020 summer for the same municipalities illustrated in figure 1. For example, Vila de Rei municipality, wherein 2019 had the

most significant wildfire registered during summer (Figure 1), and in the next year (2020) had the lowest summer tourism demand recorded (Figure 4), showing a one-year later effect.

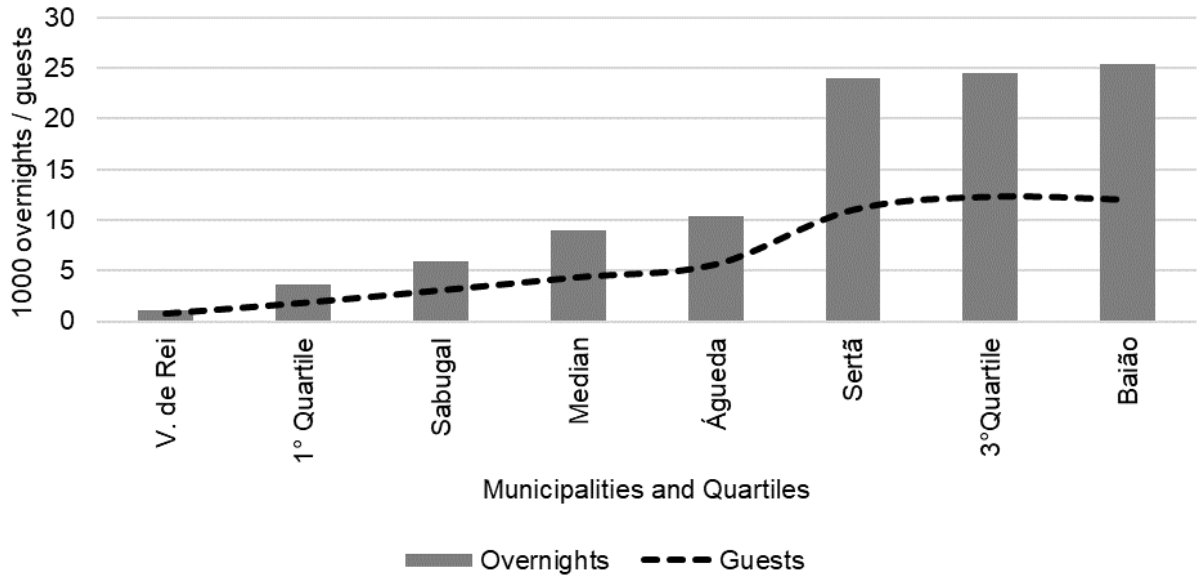

Figure 4- Tourism demand, summer 2020, per Municipalities with wildfires in 2019. Sourc e: INE (2021b); INE (2021c).

2.2. Methodology

In this paper, we use a spatial econometric regression to look at the effects on neighbor regions. We estimate the relationship between total burned areas and overnight stays in a touristic establishment in a given municipality by month. The main equation has the following specification:

$$Stays_{i,m,y} = \beta_0 + \beta_1 Burned_{Area\,i,m,y} + \theta_i + month_m + year_y + \varepsilon_{ii,y}$$

where $Staysi,m,y$ is the number of overnight stays, considered in relation to each person, by municipality, $Burnedi,m,y$ stands for the total area of burned forest, agriculture land, and shrub. The terms θi, $monthm$, and $yeary$, are the municipality, month and year fixed effects, respectively.

The municipality fixed effects control for time-invariant unobserved local characteristics that may affect the number of overnight stays, such as the area of the municipality, the landscape, the location or the supply of cultural and environmental amenities that do not vary in 2020 and 2021. Monthly and yearly fixed effects control for any common changes across municipalities and for the seasonal nature of the touristic demand as well as COVID19 restrictions implemented nationally wide.

The coefficient of interest is $\beta 1$ which measures the change in the number of overnight stays due to an increase in one hectare in burned area.

The model is estimated with contemporaneous information for overnight stays and burned area, but the $\beta 1$ estimator potentially suffers from omitted variable bias, if there are other factors that affect tourist demand and the burned area simultaneously.

Wildfires in one given municipality can also affect tourism demand in neighboring municipalities. In order to control for that, we estimate a set of models including a spatial lag of the burned area in other municipalities, weighted by a spatial weight matrix. This matrix is row-standardized and is based on the power functional form as follows:

$$w_{ij} \begin{cases} \dfrac{d_{ij}^{-2}}{\sum_{j=1}^{n} d_{ij}^{-2}}, i \neq j \\ 0, \end{cases}$$

The model with spatially lagged burned area has the following specification:

$$Stays_{i,m,y} = \beta_0 + \beta_1 Burned\_Area_{i,m,y} + \beta_2 WBurned\_Area_{i,m,y} + \theta_i + month_m + year_y + \varepsilon_{ii,y}$$

where $WBurnedi,m,y$ denotes the spatial lag of $Burnedi,m,y$.

3. Results

The analysis of effects on the number of overnights spent by tourists resulting from wildfires is presented below in Table 1. The model comprises 1, 3, 6, 9 and 12 monthly temporal lags, identified with *"L#"*, to capture the changes in intentions. For each temporal lag, a spatial lag, noted with *"W"*, is also considered, showing the effects of wildfires on neighboring municipalities in local tourism demandable. These results are presented in Table 2.

According to Table 1, burned area is positively related to the number of overnight stays after three months. This can be the result of postponed reservations or the decrease in prices that might occur if wildfires reduce the attractiveness of the municipality in the following days. The negative effect appears to be statistically significant after twelve months of the wildfires. On average, one hectare of burning area reduces overnight stays in almost 3 units.

Table 1 - Results of the spatial regression model with time lags.

Table 2 presents the results of the model with the temporal and spatially lags of the burned area. The negative effects of the burned area on overnight stays are now statistically significant on the contemporaneous month of the wildfire, as well as on the twelve months lag. A novel result is the impact of wildfires in neighboring municipalities. The magnitudes are much higher than the magnitude of the coefficient for the same location. The positive effect after three months is also significant, as in Table 3, as well as the effect of the neighboring wildfires.

We construct the model considering fixed effects from external variables, such as climate temperature and the occurrence of COVID 19. However, a further analysis that may be carried out is to consider the effect of COVID 19 on the tourism demand in Portugal. In addition, we hope to analyze further the effects of wildfires on tourism revenues and their impact on regional and national GDP.

Abstract

The firefighters' lifestyle has important consequences in their well-being. A sample of 861 Portuguese firefighters answer an adapted version of the FANTISTIC checklist that included questions related to family and friends' relationships, physical activity, nutrition, sleep and stress, alcohol and tobacco consumption's, and heath behaviors. We observed that the majority did not have physical activity in the professional context, only sometimes had a healthy nutrition, was overweight, had a tobacco consumption higher than that observed in the Portuguese population and a consumption of alcohol identical to that observed in Portuguese population, about 10% never sleep well and about 50% sometimes sleep well, about 40% only sometimes had capacity to manage stress and about 49% only sometimes relax in free time. Furthermore, we observed that the firefighter's lifestyle was an important predictor of his(er) general well-being, namely his(er) flourishing (e.g., meaning and purpose in life, positive relationships, self-esteem, feelings of competence, optimism, and involvement in daily activities), after control the gender, age, marital status, tenure as firefighter, and hours of work per week. We concluded that is important to develop an intervention to promote the lifestyle of Portuguese firefighters: encouraging the practice of physical exercise, healthy eating, non-consumption of tobacco or dangerous consumption of alcohol and promoting of a healthy sleep and management of stress. These programs must adjust to the idiosyncrasies of corporations and transform those same idiosyncrasies in valid and essential resources. In fact, some of the cultural or operational characteristics (e.g, combination of professionals and volunteers) must be considered so that these programs can be successfully implemented.

1. Lifestyle and Well-being on Firefighters

Previous research has supported the influence that lifestyle factors and behaviors, namely food, sleep, physical activity, body mass index, social, alcohol consumption and tobacco consumption, have on well-being. (e.g. Dale, Brassington & King, 2014; Kilani et al., 2020; Prendergast, Schofield & Mackay, 2016), particularly in firefighters in the UK (Siddall et al., 2014) and Finland (Airila, 2015).

2. FANTASTIC as a valid measure to evaluate lifestyle

The FANTASTIC Lifestyle Assessment Inventory is a lifestyle assessment tool that incorporates physical, emotional, and social factors. There are several advantages of this tool: having only one page, it can be completed quickly; components are easily remembered; it is holistic; can be used for self-assessment; scores are benchmarks for ongoing assessments; results are available immediately; can be immediately combined with a personalized prescription and follow-up plan; saves time by incorporating lifestyle data into a single fill; issues are relevant and based on daily life; it includes only behaviors that can be controlled, minimizing "victim blaming".

Several studies have been using the FANTASTIC Inventory to study lifestyle of the general population (Ramírez-Vélez & Agredo, 2012; Ramírez-Vélez et al., 2015; Rodriguez-Añez, Reis & Petroski, 2008), healthy

individuals (Kim, Kim, & Kim, 2007) and different population groups (e.g., paramedics and Armed Forces (Wilhelm et al., 2016), students (Decina, Mcgregor & Hagino, 1990; Kamien & Power, 1996; Kim, Park, Joe & Cho, 2006; Lo, Francis-Cracknell, & Hassed, 2017), individuals with suicidal behaviors (Wilhelm et al., 2016), deliberate self-harm (Wilhelm et al., 2007), hypertension (López-Carmona et al., 2000), diabetes (Rodríguez Moctezuma et al., 2003), metabolic syndrome (Triviño et al., 2009), cancer (Dennis, Waring, Payeur, Cosby & Daudt, 2013), elderly (Deluga et al., 2018), and patients from family practice (Kason & Ylanko, 1984)).

In this study was used an adaptation of the FANTASTIC Lifestyle Assessment Inventory to the Portuguese firefighter population. The first aim was to know the lifestyle of the Portuguese firefighters, namely related to physical activity, nutrition habits, alcohol and tobacco consumption's, sleep quality and management of stress. The second aim was relating the lifestyle with the firefighters' well-being, namely their flourishing, which refers to the existence of meaning and purpose in life, positive relationships, self-esteem, feelings of competence, optimism, and involvement in daily activities Diener et al., 2010).

3. Hypothesis

In order to test whether there is an influence of lifestyle on the well-being of Portuguese firefighters, the following hypothesis was put forward:

Hypothesis: Firefighters with a better lifestyle have better well-being (i.e. flourishing).

4. Procedure and Sample

The National School of Firefighters sent an email to all the commanders of the different corporations in the Portuguese mainland, asking that it be disseminated by its operational staff. This email had a link to access the questionnaire placed on the Qualtrics platform for two weeks. The anonymity of the participants was ensured.

The sample consisted of 861 firefighters: 578 (67%) men and 283 (33%) women; 540 (62.7%) aged up to 40 years and 321 (37.3%) over 40 years old; 53,4% was married, 45,8% was single and 0,3% was Widower; 472 (54.8%) firefighters for more than 10 years; 492 (57.1%) working less than 40 hours a week as a firefighter and 369 (42.9%) working more than 40 hours a week as a firefighter, with a mean of 34.72 hours (SD = 22.92).

Flourishing was measured through 8 items (Silva e Caetano, 2012) (e.g. I lead a purposeful and meaningful life), answered on a 7-point scale, 1 (strongly disagree) to 7 (strongly agree), where a higher score is indicative of better well-being (Cronbach's alpha = 0.83).

5. Results and conclusions

5.1. Firefighters' Lifestyle

Table 1. Synthesis of FANTISTIC results

Physical Activity	**Individual**	**Collective in professional Context**
Never	18%	58,4%
1 time a week	44,8%	28,8%
3 or more time a week	36,7%	12,8%
Nutrition	**Healthy eating**	**Consumption of high-calorie foods**
Never/almost never	14,3%	12%
Sometimes	59%	81,2%
Always/almost always	26,7%	6,9%
Tobacco consumption	**Yes**	**No**
	36,2%	63,88%

5.2. Firefighters' lifestyle and flourishing

After controlling for the effect of demographics (gender, age, marital status, time as a firefighter, working hours per week), lifestyle is a significantly predictor of flourishing (cf. Table 2). Thus, the Hypothesis that firefighters with a better lifestyle have better well-being (i.e. flourishing) was supported.

Table 2. Hierarchical Regression of Firefighters' Lifestyle in Flourishing

	Flourishing	
Step 1	*Beta*	*Beta*
Gender	.24	.20
Age	.04	.05
Marital status	.05	.03

Step 2		
Lifestyle		.35**
F	1.20	19.67**
Adj. R-Sq.	0	.12
R-Sq. Change	.01	.12**

** $p < .01$

This study found that the lifestyle habits of Portuguese firefighters are mainly very good and excellent, which is in line with the studies by Deluga et al. (2018) (with seniors), Triviño et al. (2009) (with middle-aged adults), Ramírez-Vélez e Agredo (2012) (with colombian adults) and Ramírez-Vélez et al. (2015) (with colombian university students). We can observe critical factors regarding each one of the considered categories.

Although the FANTASTIC Lifestyle Assessment Inventory is a measure from 1984, it has had a lot of use in recent years. Its small size and ease of response proved to be especially suited for firefighters.

We can conclude that to improve the firefighters' well-being we must increase their lifestyle, namely the practice of healthy habits related to physical activity, nutrition, alcohol and tobacco consumption, sleep, and stress management.

Abstract

Peatland wildfires present challenge to the mitigation of climate change due to the large amount of ancient carbon emission. Once ignited, the organic soils in peatland can burn for a long periods (weeks to months) and are difficult to extinguish. Peat fire is governed by smouldering combustion which is the slow, low temperature, flameless burning of charring porous fuel, and the most persistent type of combustion phenomena. The detection and monitoring of peatland wildfires are often conducted by remote sensing like satellite. However, there is currently a missing gap between spread of peat fires in the small laboratory scale and the large field scale. This work covers this gap by conducting field-scale controlled experiment of peatland wildfires. The experimental campaign, GAMBUT, was conducted in the peatland of Sumatra, Indonesia, covering an area of 408 m2. Smouldering spread rate was measured by infrared cameras and subsurface thermocouples. The smouldering sustained up to 10 days and nights, and survived against three rainfalls. Observation from infrared images show that horizontal smouldering spread rate fluctuates during propagation. However, no significant difference was found between average horizontal spread rates from the measurements of infrared camera and thermocouples, i.e. 0.3±0.13 cm/h to 0.8±0.2 cm/h. The spread rates here agree with the trend in the literature of laboratory experiments, fit within in the ranges of high moisture (MC) and inorganic (IC) contents of the soil (MC between 23 to 141% and IC between 49 to 72%). Even though slower, the fires thrived up to 10 days and against three rainfalls, demonstrating the persistency of smouldering peat fires and calling for a consideration of degraded peatland with high inorganic content to be consistently included in the mapping and monitoring of peatland area. GAMBUT presents a unique understanding of peatland wildfires at field conditions and aims to contribute to the better monitoring and mitigation acts.

1. Introduction

Peatlands contribute to the massive amount of carbon storage in the world, estimated to be up to 700 Gt (Yu 2012). In pristine conditions, the organic soil in peatland is protected from fires either due to the high moisture content, and the cold condition such as the case of permafrost in the Arctic region. However, recent increase of frequency of severe wildfires around the world, especially those of peatlands in the Arctic region, identifies that the ancient carbon that has been stored in peatlands for millennia is under threat to be released to the atmosphere

(Young *et al.* 2016). Once ignited, the organic soil (peat) can burn for weeks to months and difficult to be extinguished, surviving against rainfalls and firefighting responses (Rein 2016).

Peat fire is dominantly governed by smouldering combustion, which is the slow, low temperature, flameless burning of charring porous fuel, and the most persistent type of combustion phenomena. Smouldering peat fire spreads in both horizontal and vertical direction (in-depth into the subsurface layer). Recent laboratory studies have been conducted to understand both directions of smouldering spreads (Huang *et al.* 2016; Huang and Rein 2017; Christensen *et al.* 2020), and reveal the heat transfer effect on the faster spread in the subsurface layer than the surface layer. This phenomena can cause an overhang formation in which the surface layer stays unburned while the subsurface continues to propagate (Huang *et al.* 2016).

Currently, there is limited controlled experiment in the field to explain the different smouldering behaviour between surface and subsurface layers to improve the monitoring and mitigation of peatland wildfires in the field scale. Most studies in the field were conducted forensically such as the measurements were conducted on actual peatland wildfires with minimum control on the ignition methods, measurements location, and fire spread area (Page *et al.* 2002; Usup *et al.* 2004; See *et al.* 2007; Simpson *et al.* 2016; Smith *et al.* 2018). Pastor et al. (Pastor *et al.* 2017) conducted systematic peat fire experiment in the peatland of Peruvian Andes with each experimental area of 50×50 cm, and 1 out of 18 tests show temperatures up to 400°C and 3 show temperature above 100°C. This work aims to add to the previous field studies, contribute to the systematic methodology of peatland wildfires experiment in the field, and better understanding of surface peat fires spread in the field scale.

2. Methodology

The experimental campaign, GAMBUT, was conducted in Rokan Hilir regency, Sumatra, Indonesia, from 19 to 29 August 2019 (Santoso 2021). More detailed discussion of the study area can be found in Santoso (2021). The site in this study is in a tropical wet climate with a mean annual rainfall of 2,080 mm (Badan Pusat Statistik Kabupaten Rokan Hilir 2015); mostly covered by palm trees, ferns, and sedges; and closely located with an artificial reservoir (water pond) (Figure 1). The experiments were conducted in 12 days across changing precipitations. Three rainfall events equated to 4.8 mm of water column height occurred in the afternoon of day 6, 1.4 mm in the night of day 6, and 2.5 mm in the night of day 9 (Santoso 2021).

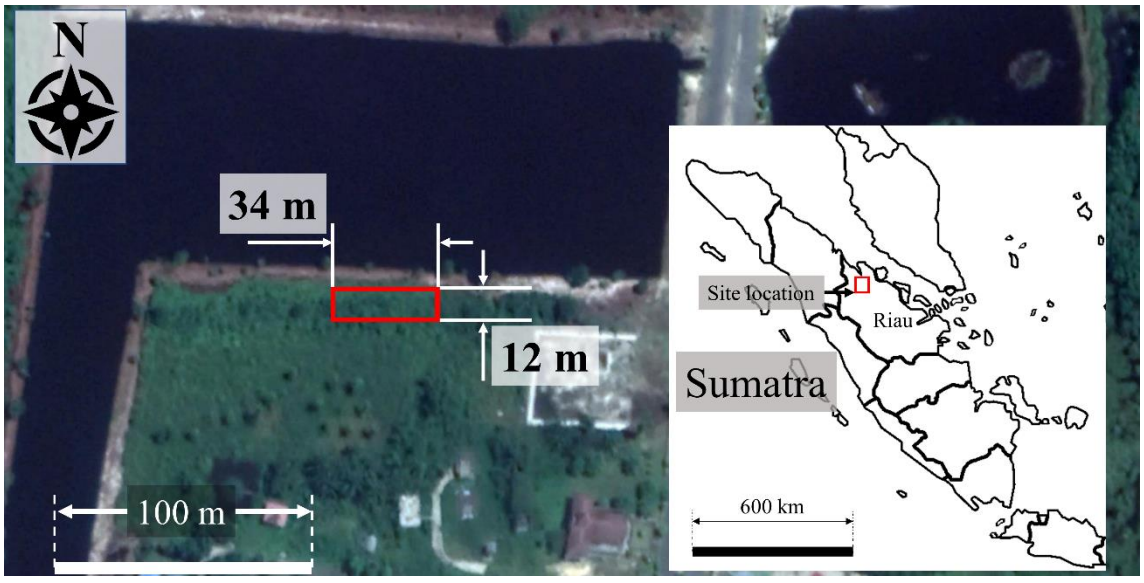

Figure 1- Top view of the site for GAMBUT experiment near a reservoir (Google Earth, 2021). The experiment area is indicated by the red rectangle. The site is a secondary peat swamp forest in Rokan Hilir, Sumatra, Indonesia (1°36'17.1"N 100°58'30.5"E). Inset picture shows Sumatra Island in which the site is indicated by a red rectangle (Golbez, 2021, CC BY) (Santoso 2021).

The experiments in this study were conducted in three plots of land, each with dimensions of 10 by 10 m (Figure 2a). Firebreaks were made around the perimeter of each plot by digging trenches of 50 cm wide and 50 cm deep which were filled with sand to prevent fires from spreading beyond these plots. From the left to right of Figure

2, the plots are indicated as Plot 1, Plot 2, and Plot 3. In each plot, two peat fire experiments were conducted (Figure 2b). In Plot 1, these two peat fire experiments are indicated as fire area of Plot 1 North (P1N) and Plot 1 South (P1S). In Plot 2, the fire area are Plot 2 North (P2N) and Plot 2 South (P2S), while the fire area in Plot 3 are Plot 3 North (P3N) and Plot 3 South (P3S). In total, six peat fire experiments were conducted during this field experiment campaign. In this study, fires in the north and south sides of the plots were well separated and did not spread into each other. Ignition was conducted by slash-and-burn and ember ignition. Slash-burn ignition was conducted by burning piles of dried surface vegetation of a dimension of 8 m length, 1 m wide, and 50 cm high, while ember ignition was conducted by filling an ignition pit shown in Figure 2b with smouldering charcoals. Details of ignition methods can be seen in (Santoso 2021).

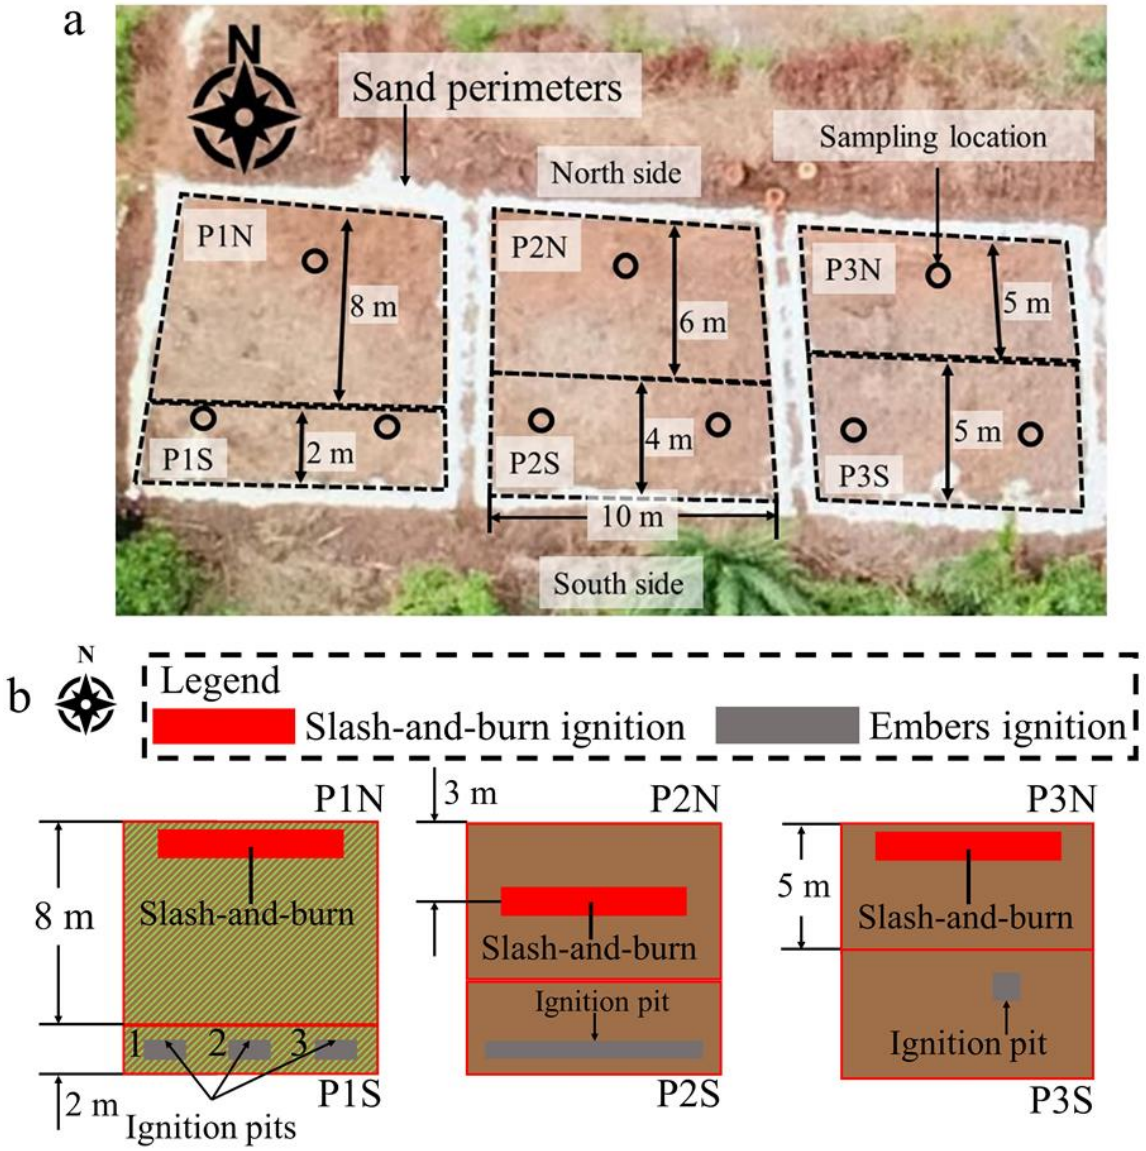

Figure 2- a) Top view of the 12 × 39 m of experimental area after surface vegetation treatment (Nugroho, 2018, CC BY). Black circles represent peat sampling locations for measurements of bulk density, moisture content (MC), inorganic content (IC), and elemental content. b) Schematic of the fire areas and different ignition methods. Red and grey rectangles refer to slash-and-burn and ember ignitions, respectively. Green diagonal lines refer to the surface litter that is kept intact on plot 1. Fire areas indicated by P1N, P2N, P3N, P1S, P2S, and P3S are Plot 1 North, Plot 2 North, Plot 3 North, Plot 1 South, Plot 2 South, and Plot 3 South, respectively (Santoso 2021).

Plot surfaces were cleaned from palm trees, ferns, sedges, and surface litter vegetation, except plot 1 where surface litter vegetation was kept intact (Figure 2b) to obverse its effect on the effectiveness of slash-and-burn ignition. The visual difference from above as shown by Figure 2a is not obvious since the litter vegetation left on Plot 1 have been significantly dried naturally, thus the colour of the vegetation have turned brownish, similar to the surface of dried peat in Plot 2 and Plot 3.

Infrared (IR) images were recorded using a FLIR Duo-R camera, mounted on a crane with an angle-adjustable hand to adjust the field of view of the camera. This crane was mounted on a rail to allow convenient IR image measurement along the plots, on both the north and south sides (Figure 3). Active fire area on the surface was obtained by analysing the acquired IR images. For the analysis of IR images, a similar approach used in (Amin *et al.* 2020) was adopted and a threshold value of camera intensity well above the surrounding area (0.1) was chosen. The images were converted to greyscale and the pixels where the normalized intensity increases above the intensity threshold were marked (subset in Figure 3). The area inside the marked perimeter line was then calculated to be the active fire area. The scaling from pixel dimension to physical length was possible by using a geo-reference plate with a dimension of 0.17 × 0.14 m, also shown in the subset of Figure 3.

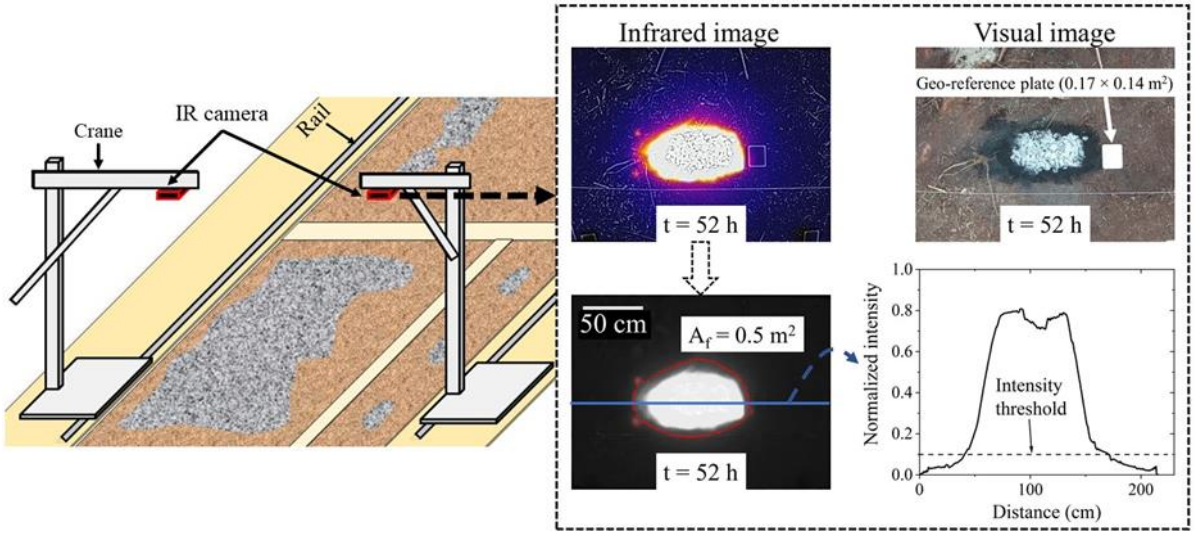

Figure 3. Infrared imaging setup and analysis to measure smouldering spread and area. The normalized pixel intensity threshold is chosen to be 0.1 to represent the point at which the intensity started to steeply increase, indicating the outer perimeter of the peat fire area. A_f and t are the active fire area and time since ignition, respectively (Santoso 2021).

Thermocouples were used to smouldering spread rate at the subsurface level. Due to the uncertain peat fire propagation direction, thermocouples were placed at certain points based on the visual observation and the likelihood of propagation direction. To obtain spread rate data, two thermocouple points were located at a known distance, 15 cm. The spread rate is then calculated from the known distance (15 cm) and the time-lapse of the two consecutive thermocouples reached maximum temperature or 300°C which is above peat char oxidation temperature (230°C). Each thermocouple point contains two K-type thermocouples at 10 cm (shallow layer) with probe diameter of 1.5 mm, and at 30 cm depth (deep layer) with probe diameter of 3 mm. Details of thermocouple placement can be seen in (Santoso 2021). As peat fires progressed and passed a thermocouple point, the thermocouples were then moved to a new location, if the thermocouples were not burnt. Continuous MC measurements were also conducted in P2N fire area by placing module soil moisture sensors at 4 different depths (10, 20, 30, and 40 cm) below the slash-and-burn location (Figure 2b). This live measurement of MC adding to the spread rate measurements by the thermocouples.

3. Results

Figure 4 shows horizontal spread rates analysed from series of infrared images on fires in P1S and P3S. Smouldering spread rate on the surface can be seen to fluctuating during propagation. Rainfalls can also be seen to have minimum impact on both the fluctuations and the average spread rate. In this work, horizontal spread rate measured from infrared images is ranged from 0.1 to 0.5 cm/h. The spread rate in this work is smaller than the values in the literatures (Prat-Guitart *et al.* 2016; Huang *et al.* 2016; Hu *et al.* 2019; Amin *et al.* 2020; Christensen *et al.* 2020), mainly because both the MC and IC in the field here is higher than the soil conditions in the literatures. Figure 5 shows that the spread rate in this work agree with the trend in the literatures, fit within the ranges of high MC and IC soil conditions. No significant difference between horizontal spread rate measured by IR camera (0.3±0.1 cm/h) and subsurface thermocouples (0.8±0.2 cm/h).

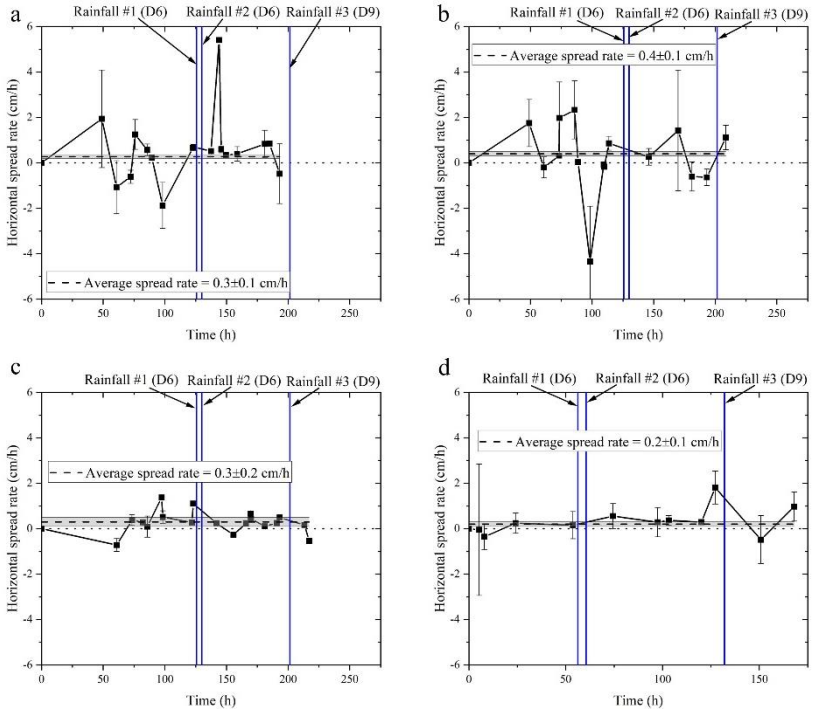

Figure 4- Horizontal spread rate from infrared camera images for a) pit 1 of P1S, b) pit 2 of P1S, c) pit 3 of P1S, d) P3S. The precipitation of the three rainfalls are 4.8 mm in the afternoon of day 6, 1.4 mm in the night of day 6, and 2.5 mm in the night of day 9. Details of weather conditions during GAMBUT can be seen in (Santoso 2021).

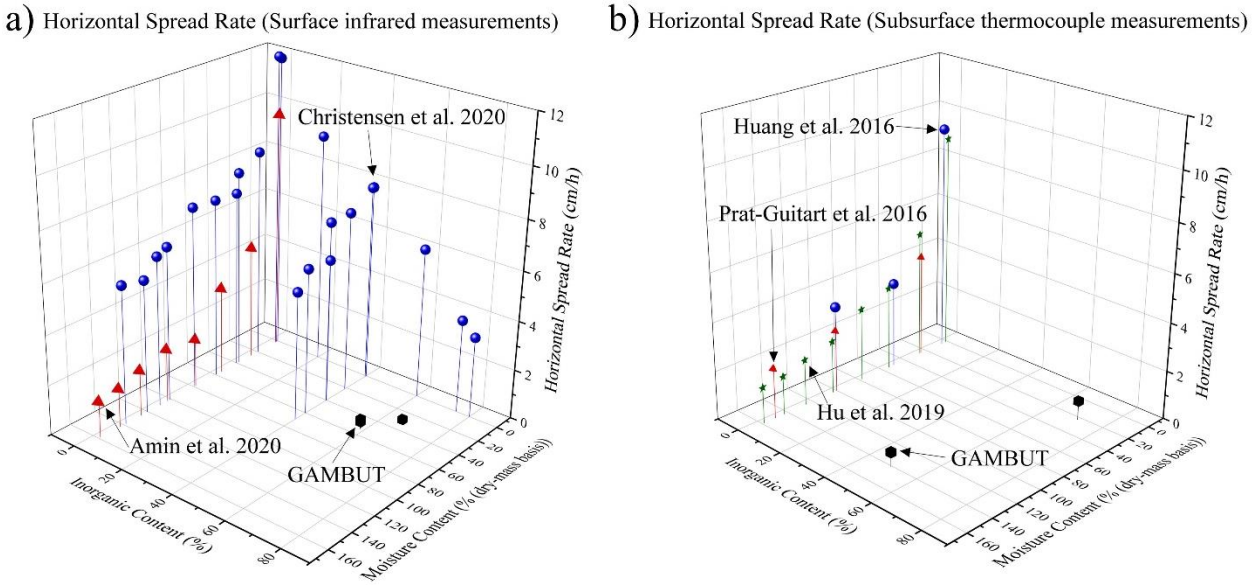

Figure 5- Horizontal spread rates from GAMBUT and literatures (Prat-Guitart et al. 2016; Huang et al. 2016; Hu et al. 2019; Amin et al. 2020; Christensen et al. 2020). a) Horizontal spread rate based on infrared images and b) based on subsurface thermocouple measurement at level more than 2 cm below surface up to 20 cm deep.

4. Conclusions

Here, we report horizontal spread rate measurements from GAMBUT field experiment of peatland wildfires in Sumatra, Indonesia. The smouldering peat fires during this experiment survived up to 10 days against three rainfalls. Horizontal spread rate was measured by using infrared camera and subsurface thermocouple. There is no significant difference between horizontal spread rate observed on the surface by infrared and measured at the subsurface by thermocouples. The spread rate reported here is 0.3±0.1 to 0.8±0.2 cm/h and agree with the laboratory results in the literature, fit within soil conditions with high moisture (MC) and inorganic (IC)

contents, i.e. MC between 23 to 141% and IC between 49 to 72%. The persistent nature of the smouldering observed here also proves that degraded peatlands with high inorganic content are still required to be consistently monitored and mapped for prevention and conservation measures. GAMBUT presents a unique understanding of peatland wildfires at field conditions and aims to contribute to the better monitoring and mitigation acts.

Abstract

One of the environmental factors affecting the forest ecosystem is fire. Local volunteer firefighters are often those who first respond to forest fires. This study was conducted aimed to determine the factors affecting their willingness to participate in firefighting in the northern Zagros forests of Iran (Sardasht County). For this purpose, after extracting Sardasht fire statistics during a 14-year period (2006-2019), the villages with the highest frequency of fires in the above period were selected. Organizing, facilities and equipment, indigenous knowledge and education for firefighting were selected as factors affecting the willingness to participate in firefighting. The research tools were a questionnaire and face-to-face interview. The statistical population included 649 households. According to Morgan's Table, the number of samples required for the distribution of questionnaires was n=242. The questionnaire questions were designed openly and closed with scores based on the Likert scale and the factors affecting villagers' willingness to participate in firefighting were investigated by face-to-face interviews. The results of statistical analysis of data showed that organizing, knowledge and facilities had a significant effect on the participation of respondents. This study showed that for the villagers, organizing was the most effective factor and facilities was the last factor affecting their willingness to participate. Also, a positive and significant relationship was found between the participation and the level of education. Therefore, it is necessary for the promotion department of the Iran's Forests, Range and Watershed management Organization (FRWO), along with the protection unit of the organization, to provide special programs and policies for the organizing of the public, rural and volunteer firefighting forces before the fire spreads to control it in principle.

1. Introduction

According to the statistics published by the Iran's Forests, Rangelands and Watershed management Organization (FRWO), hundreds of fires occur annually in different parts of Iran, which ranks fourth among the countries of the Middle East and North Africa in terms of the amount of forest destruction due to fires (Beygi Heidarlou et al., 2014).

The participation of local people is one of the main factors of the final decision-making and acceptance of ecosystem management practices. Firefighters are the basis of any forest fire prevention and control system in which volunteer firefighters and members of non-governmental organizations play an important role. The success of fire fighting plans or mechanical stress reduction progrmmes may be influenced by how local societies think.

The Zagros forests with an area of about 4,749,000 hectares (Roozitalab et al., 2018) have a special place and importance among the vegetation areas of western Iran. Fires in Zagros are devastating, amounting to 6,500 hectares per year, which mostly are caused by human beings. In order to manage the fire crisis in this vegetation area, it is necessary to know the factors affecting the participation of people and local societies in the fight against fire and how they change in terms of time and place. Specifically in this study, we seek to answer the

following question:

- What are the most important factors affecting the willingness of local societies in Sardasht to participate in firefighting in the Zagros forests?

2. Methods & Materials

2.1. Study area

Sardasht with an area of 138,000 hectares in northwestern Iran has been selected as the study area in this study (Figure 1). According to the latest official statistics (2016), the population of Sardasht is 118,849 people. Sardasht is located between 45°13´48´´ to 45°42´00´´ E longitude and 35°37´36´´ to 36°28´12´´ N latitude. The average height above sea level is 1515 m (Beygi Heidarlou et al., 2020). This area is often covered with dense forests with trees such as Quercus infectoria Oliv, Q. libani, Q. brantii, Vitis vinifera L., Ficus carica and Pyrus glabra. Sardasht forests cover an area of 83,000 hectares (Beygi Heidarlou et al., 2019), Important causes of deforestation in recent decades include cutting down of trees for fuel, frequent fires, pruning to provide fodder, clear-cutting of forests and ploughing of forest soil to agricultural activities and vineyards and the constant presence of livestock, especially goats, in the forests.

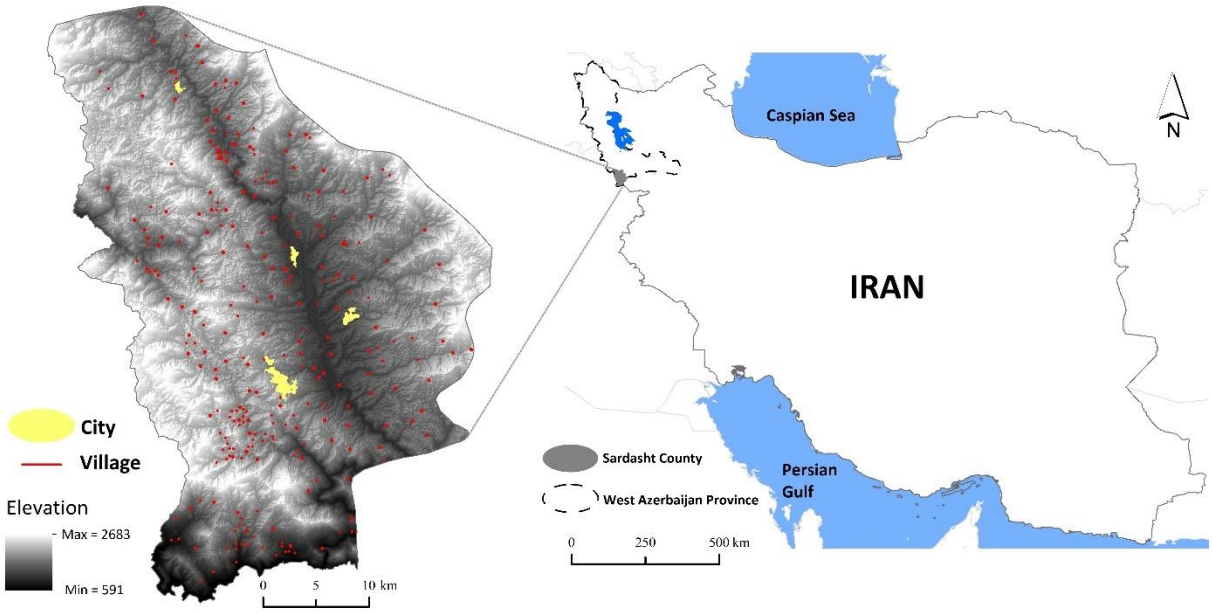

Figure 1. Geogrphical location of study area.

2.2. Research methodology

14 villages with the highest frequency of fires (2006-2019) in their customary system were selected. the present study was conducted by descriptive-survey research method. The study population included 242 residents of the villages who were selected using the Krejcie-Morgan sample size table in 2020 (Table 1).

Table 1. List of villages, number of households and number of measured samples in the study.

Row	Villages name	N of households	Population	N of samples households
1	Molasheikh	56	219	21
2	Gurangan	22	85	8
3	Baskedu	2	6	2
4	Banavile-Hajimine	16	64	6
5	Shalmash	57	201	21
6	Shivashan	9	25	3
7	Niskabad	16	68	6
8	Aghlan	80	307	30
9	Belav	12	61	4
10	Shendre	20	69	7
11	Bizile	39	137	15
12	Torshian	6	19	2
13	Cheku	107	400	40
14	Dolatu	207	834	77
Total	-	649	2505	242

Data were collected using a researcher-made questionnaire. In addition to individual, professional and sociological questions, this questionnaire contained 35 items representing willingness to participate, organizing, facilities and equipment, indigenous knowledge and firefighting training (education) factors provided by literature and Interviews with experts and specialists. The respondents were then asked to determine the effect of each of these factors on their willingness to participate in firefighting on a 5-point Likert scale. The validity of the questionnaire was confirmed using the knowledge of experts and university professors. Cronbach's alpha test was used to investigate the reliability with a coefficient of 0.899, which in social research indicates the appropriate reliability of the measurement tool.

2.3. Statistical analysis

The data obtained from the questionnaires were analyzed by SPSS Windows (version 25). Confirmatory factor analysis (CFA) was used to confirm the classification of factors affecting the willingness to participate in firefighting. The value of Kaiser-Mayer-Olkin (KMO) statistic was 0.867 and the value of Bartlett's Test of Sphericity was 1787.58 (at 0.0001 level), which indicate the appropriateness of the data for factor analysis. Also, in order to increase the interpretability of the items related to the attitude of the respondents, the Varimax method was used and a total of five factors (organizing, willingness to participate, education, indigenous knowledge, and facilities and equipment) were extracted based on eigenvalues and the previous factor criteria. At the next stage, stepwise regression was used to determine the factors affecting the willingness of villagers to participate in firefighting.

3. Results

3.1. Characteristics of the statistical population

The demographic information is presented in Table 2.

Table 2. Results of demographic characteristics of the studied community

Characteristic	Class	Frequency (%)	Characteristic	Class	Frequency (%)
Gender	Female	0.83	Education	Illiterate	18.75
	Male	99.17		High school diploma	47.08
Age (year)	15-20	3.31		Diploma	16.25
	21-30	35.12		Associate degree	3.33
	31-40	33.47		Bachelor’s degree and higher	14.58
	41-50	14.05	Number of livestock available (livestock)	< 25	39.39
	51-60	8.26		26-50	23.23
	61-71	5.79		51-100	17.17
Number of household members (persons)	1-2	8.3		101-150	12.12
	3-4	46.06		> 151	8.08
	5-6	34.44	Marital status	Single	24.79
	7-8	9.54		Married	75.21
	9-10	1.66	Job	Unemployed	4.13
Type of livestock	Goats and sheep	52		Employee	5.49
	Cow	47		Beekeeper, farmer and rancher	45.04
	Other	1		self-employment	45.04
Average monthly income ($)	< $ 55	27.59	Agricultural area (ha)	< 0.5	10.71
	$ 55-110	41.87		0.6-1	28.57
	$ 110-165	14.78		1.1-2	24.49
	> $ 165	15.76		2.1-5	28.57
Participate in training classes	Yes	7.44		> 5	7.65
	No	92.56			

3.2. Factor analysis results

The study result was a reduction in 22 indicators to five factors, which explained about 57% of the variance of participation and indicated the satisfactory factor analysis and indicators used to investigate the dimensions of willingness to participate in this study (Table 3).

Table 3. Variance and igenvalue of factors of people willingness of participation in firefighting programs.

Component	Eigenvalue	Extraction Sums of Squared Loadings			Rotation Sums of Squared Loadings		
		Eigenvalue	% of Variance	Cumulative %	Eigenvalue	% of Variance	Cumulative %
1	6.45	6.45	29.31	29.31	3.73	16.97	16.97
2	2.17	2.17	9.86	39.17	2.63	11.93	28.90
3	1.62	1.62	7.38	46.55	2.19	9.97	38.87
4	1.27	1.27	5.75	52.30	2.15	9.79	48.67
5	1.08	1.08	4.89	57.19	1.88	8.52	57.19

Extraction Method: Principal Component Analysis.

Finally, the last stage is to perform factor analysis, naming the factors that have already been named according to the nature and type of items and indicators of willingness to participate, and according to the expert point of view, the indicators have been named according to their nature. The first, second, third, fourth and fifth factors, which explained about 16.97, 11.93, 9.97, 9.79 and 8.52% of the variance related to factor analysis, respectively, according to the nature of the available variables were named as 1) organizing, 2) willingness to participate, 3) education, 4) indigenous knowledge and 5) facilities and equipment. Factors one to five consist of seven, four, three, four and three variables with the factor loads specified in Table 4, respectively. These variables play a greater role in the total variance of the variable. Also, during factor analysis, variables or questions that have less factor load or correlations i.e. their coefficient of determination (R^2) is less than 0.4, were not included in the analysis.

Table 4. Variables related to each factor and the amount of factor load obtained from the rotated matrix.

Factor	Measuring indices of participation	Factor Load
Organizing	Q6: I am ready to give the necessary training to the villagers in different seasons of the year to prevent fires.	0.572
	Q7: I am willing to participate in firefighting if I pass firefighting training courses and have the equipment.	0.6
	Q8: In the village, one or more responsible and knowledgeable people are needed for the volunteer forces to carry out the orders.	0.765
	Q9: As soon as a fire breaks out, I follow the instructions of the person in charge in the village.	0.75
	Q10: Provide the equipment needed to extinguish the fire before the fire occurs to the people or the village head.	0.566
	Q11: Organizing before putting out a fire will help succeed in putting out the fire.	0.689
	Q12: In organizing, a responsible person must be chosen.	0.56
	Q13: Each organization should be repeated manually in specific time periods.	0.572
Willingness to participate	Q1: I am willing to work with natural resources officers as a volunteer to fight fires.	0.775
	Q2: I am willing to accept responsibility for leading a public firefighting team.	0.542

	Q3: Until the firefighters arrive, we will put out the fire with the help of the villagers.	0.697
	Q5: In the event of a fire, I will try to put it out myself.	0.645
Education	Q29: Teaching how to use devices and equipment is effective in the success of firefighting.	0.72
	Q30: Teaching how to behave and move fire in pastures and forests has an important role in extinguishing fires.	0.822
	Q31: Training should be provided by natural resource experts.	0.597
Indigenous knowledge	Q20: To spread the fire to the top of the hill.	0.736
	Q21: In the event of a small fire, it must be attacked directly.	0.561
	Q23: The rate of fire spread in pastures is higher than in forests.	0.693
	Q24: Relative humidity has the highest correlation with the occurrence and extent of fire spread.	0.654
Facilities and equipment	Q15: Individual facilities and equipment play an important role in firefighting.	0.512
	Q16: Heavy facilities and equipment play an important role in fire fighting.	0.81
	Q17: Motor facilities and equipment play an important role in fire fighting.	0.755

3.3. Stepwise regression test results

The results of factor analysis using stepwise regression showed that organizing, knowledge and facilities factors had a significant effect on the willingness to participate in firefighting. According to the results, three of five predictors in the study were included in the model. The results of the stepwise regression model summary also showed that based on the value of the adjusted R-squared, the three selected predictors had the ability to explain about 45% of the scatter of the dependent variable (participation) (Table 5).

Table 5. Summary of stepwise regression model.

Model	R	R Square	Adjusted R Square	Std. Error of the Estimate
1	0.638[a]	0.407	0.405	2.51
2	0.666[b]	0.443	0.439	2.43
3	0.673[c]	0.453	0.446	2.42

a. Predictors: (Constant), Organizing
b. Predictors: (Constant), Organizing, Indigenous knowledge
c. Predictors: (Constant), Organizing, Indigenous knowledge, Facilities and equipment

Table 6 shows the coefficients of each factor. According to the study results, the factor of organizing with a coefficient of 0.549 played the most important role in participation, followed by knowledge (0.165) and facilities (0.11).

Table 6. Coefficients of stepwise regression model

Model		Unstandardized Coefficients		Standardized Coefficients	t	Sig.	Correlations			Collinearity Statistics	
		B	Std. Error	Beta			Zero-order	Partial	Part	Tolerance	VIF
1	(Constant)	8.889	1.322		6.726	.000					
	Organizing	0.789	0.061	0.638	12.837	.000	0.638	0.638	0.638	1.000	1.000
2	(Constant)	5.943	1.484		4.003	.000					
	Organizing	0.725	0.062	0.586	11.720	.000	0.638	0.604	0.566	0.931	1.074
	Indigenous knowledge	0.263	0.067	0.197	3.947	.000	0.351	0.247	0.190	0.931	1.074
3	(Constant)	4.199	1.715		2.448	.015					
	Organizing	0.679	0.066	0.549	10.336	.000	0.638	0.557	0.496	0.816	1.226
	Indigenous knowledge	0.220	0.069	0.165	3.164	.002	0.351	0.201	0.152	0.843	1.187
	Facilities and equipment	0.129	0.065	0.110	1.994	.047	0.400	0.128	0.096	0.750	1.333

Dependent Variable: participation

The model presented by this regression fit will be as follows:

Participation = 4.199 + 0.549 (Organizing) + 0.165 (Indigenous knowledge) + 0.110 (Facilities and equipment)

4. Discussion

The study results showed that the respondents in this study were willing to fight voluntarily with natural resources officers against fire. Voluntary activities are often carried out in the context of society, with different standards, norms, resources and institutions. By volunteering and willing to participate in solving problems in society, people respond to what they see as social problems in their society, and so social capital increases as encouraging civic and voluntary participation and social trust (creating communication and cooperation between members) (Putnam, 2020). The respondents were also satisfied with accepting responsibility for leading a firefighting team and willing to fight against the fire with the help of villagers until firefighters arrive. The willingness to fight against the fire voluntarily can be done individually or collectively. In collective voluntary activities, the head of groups inspire, and oversee the activities of others (Eckstein, 2001). In the last two decades, the willingness to participate in firefighting voluntarily has been investigated by several researchers (Perkins, 1989, 1990; Perkins and Metz, 1988). Thompson III and Bono (1993) found that the strongest motivation for volunteering as a firefighter was to help society, followed by the will to help contain the fire. Perkins and Metz (1988) argued that firefighting represented powerful sources of solidarity and identity of society.

The respondents believed that facilities and equipment for firefighting play an important role. In the face of forest fires, what is very important is the availability of firefighting equipment and infrastructure (Clément, 2001).

The study results in relation to the native knowledge of the respondents showed that they were relatively aware of the basic principles of firefighting. They believed that: direction of fire spread is to the top of the hill; in the occurrence of a small fire, must be directly attacked; the spread of fire in the rangelands is faster than forests; and Relative humidity has the highest correlation with the occurrence and extent of fire spread, which is

consistent with the results of the Forthofer (2007), Plucinski et al. (2017), Maffei and Menenti (2019) and Ertugrul et al. (2021) studies.

At the pre-fire stage, the human management and firefighting training courses are important for local and national forces (Karimi et al., 2014). The respondents in this study believed that firefighting training and how to use devices and equipment play an important role in firefighting and preventing its spread. Vadrevu et al. (2010) in their study in southern India showed that informing and training the public, publishing risk maps and regional recommendations to authorities have played an important role.

The results of factor analysis using stepwise regression showed that the factors of organizing, knowledge and facilities had a significant effect

($\alpha = 0.01$) on the participation of respondents (Table 6), indicating the importance of these factors. According to the study results, organizing factor had a greatest effect among the other two factors on the participation of respondents, which is contrary to the opinion of officials of the FRWO and Natural Resources Department, which is the main cause of failure due to the lack of facilities. This study showed that for the villagers, organizing was the most effective factor and facilities was the last effective factor on their willingness to participate.

5. Conclusion

The participation of local societies in recent decades as a rational and human necessity is the most important variable of development and protection. In general, in order to promote the willingness for participation of local societies and foresters, it is necessary to organize, train basic measures and use the indigenous knowledge of villagers for firefighting and increase firefighting facilities and equipment in forest areas and natural resources. This will not be possible without considering the various dimensions of the attitude and willingness of villagers and forest dwellers for firefighting and try to improve it. Therefore, the necessary measures to increase the willingness of villagers and foresters for firefighting should not be delayed under the pretext of limited resources to address other dimensions of forest management.

The study results introduced the factor of organizing and knowledge as the first and second factors in terms of importance and the factor of facilities as the third factor for explaining the variance of the willingness for firefighting. Given the current different and opposite attitude towards forest firefighting among most of the top managers in the country, according to the study results, their attitude can be improved.

High efficiency of firefighting, control in a short period of time, quick access to fire extinguishers, professional readiness of local societies to deal with fire, use of firefighting equipment, continuous training classes, constant presence of physical fire control and fighting forces on site and quick access to its location, familiarity with the fastest ways to access the site of the fire, quick and uninterrupted access to individual, collective and motor facilities and equipment, and the presence of one or more local officials to maintain order at times of crisis are very important using different methods of fire control. Therefore, the relevant organizations should organize and train the public forces so that they are ready for firefighting in the event of a fire.

Indirect effects of climate change on forest structure alters fuel availability in wet Eucalypt forests

Fuel moisture content, fire, forest structure, climate change

Abstract

The direct effects of climate change are increasing the frequency of high-intensity fire events in many ecosystems across the globe, including wet Eucalypt forests of south-eastern (SE) Australia. Recurrent high-intensity fire can alter vegetation structure and composition, and the resultant alternative vegetation states may be more likely (positive feedback) or less likely (negative feedback) to burn again compared to the vegetation community replaced. These indirect effects of climate change have been reported for a range of different ecosystems across the globe. However, a common limitation to many empirical studies is the narrow temporal range of observations, often limited to a single fire season. In turn, this limits our understanding of the potential for vegetation-mediated indirect effects of climate change to generate positive or negative fire feedbacks across the range of climate conditions common to the region.

In wet Eucalypt forests of SE Australia, dead fuel moisture content (FMC) is a key determinant of fire activity and is therefore a useful metric on which to quantify the potential for feedbacks across alternative forest states. To quantify potential for indirect effects of climate change to alter future fire activity, FMC was modelled in the open and at seven alternative forest states to wet Eucalypt forest using a process-based FMC model. The model was run using a long-term climate dataset (1973 – 2020), which were transferred from macro- to microclimate values using forest structural properties derived from lidar. Hourly FMC outputs were summarised to fuel availability (FMC < 16% for at least one hour each day) to understand the potential for positive, negative of no feedbacks on potential fire activity.

The results showed that mean annual FMC was significantly different between alternative forest states across each of the 48 years of climate data – which act as independent replicates for different climate conditions in our experimental design. By quantifying these differences using the metric of fuel availability, we have demonstrated that statistically significant differences in FMC translate into meaningful differences in the context of potential fire activity. Overall, the results show strong positive and negative feedbacks across the alternative forest states compared to the mature wet Eucalypt forest that they replaced, which were greater than age-related differences within the wet Eucalypt forest sites. Overall, our results support the hypothesis that indirect effects of climate change, acting through vegetation conversion to alternative forest states, have a substantial impact on the potential for future fire activity, with important implications for land and fire managers in this region.

1. Introduction

Fire is a critical process in many ecosystems globally that influences the distribution, composition, and successional stage of vegetation communities (Pausas et al., 2017). While fire is important for the maintenance of many ecosystems, altered fire regimes can have negative impacts (Enright et al., 2015). Climate warming is elevating fire danger in many locations across the globe (Abatzoglou et al., 2019; Flannigan et al., 2000; Jolly et al., 2015) and increasing temperatures coinciding with more variable rainfall are expected to increase fire frequency in south-eastern (SE) Australia (Harris and Lucas, 2019). Repeated high-intensity fires can alter the

successional pathways of forest communities by overwhelming the utility of fire adaptive traits (Fairman et al., 2019), which can lead to abrupt shifts in ecosystem composition and forest structural properties (Bowman et al., 2014), in conjunction with an overall shift to forests of a lower age class. This may indirectly affect future fire activity if younger, or alternative forest states create microclimate conditions conducive to increased fire activity (Enright et al., 2015). This phenomenon is commonly referred to as fire-vegetation feedbacks, which can be positive or negative. Positive feedbacks relate to vegetation conditions likely to increase fire activity, while negative feedbacks include vegetation states likely to reduce potential fire activity (Tepley et al., 2018). Positive and negative fire-vegetation feedbacks have been reported across a range of different ecosystems, including in wet Eucalypt forests of SE Australia (Burton et al. 2019). However, a key limitation of these studies is the relatively narrow temporal range of observations – typically one or two seasons, which in turn limits our understanding of the potential for alternative forest states to generate positive or negative feedbacks across the range of climate conditions that are characteristic to the region.

Forests in productive regions can support high biomass loads that reaccumulate quickly after disturbance, so they almost always have enough fuel to sustain large fires (Cawson et al., 2018). Consequently, in these forests it is primarily the fuel moisture content (FMC) that limits fire activity, which is therefore a useful metric for understanding the potential for positive or negative feedbacks. Recurrent high-intensity fires in the dominant mature *Eucalyptus regnans* forests in this region have caused some areas to shift to alternative forest types, that are potentially more adapted to the novel short-interval fire regime (Fairman et al., 2016).

Field studies across a range of alternative forest states and age classes to mature wet Eucalypt forests (Brown et al., 2021; Burton et al., 2019) report both positive and negative feedbacks. However, a key limitation to these studies is that they have a limited timeframe of observation. Consequently, it is difficult to determine whether the feedbacks reported are due to the indirect effects of climate change on vegetation structure and composition, or more strongly related to the specific climate conditions throughout the period of observation. Given these limitations, and the variability in weather and climate conditions in SE Australia (Harris et al., 2019), modelling the potential for fire vegetation feedbacks across alternative forest states across the full range of climate conditions characteristic to the region would enhance our understanding of the potential for indirect effects of climate change to influence future fire activity.

Therefore, the aim of this study is to explore whether observed differences in dead FMC resulting from vegetation-mediated effects of climate change are replicated across the range of climate conditions experienced in the region, and, to evaluate the impact of this on potential fire activity.

2. Methods

To understand the potential for indirect effects of climate change (through changes to forest structure and composition) to influence future fire activity, dead FMC was modelled across seven alternative forest state field sites, and one above canopy open weather station (Figure 1). Dead FMC (represented by automated fuel moisture sticks) was modelled for 48 years using a calibrated process-based model (van der Kamp et al., 2017) that was driven by reconstructed climate data transferred to microclimate values (Brown et al., 2016; Jeffrey et al., 2001). The seven sites cover a range of alternative forest state sites to mature *Eucalyptus regnans* forests in SE Australia (which is assumed to be analogous to 80-year-old *E. regnans* in this study).

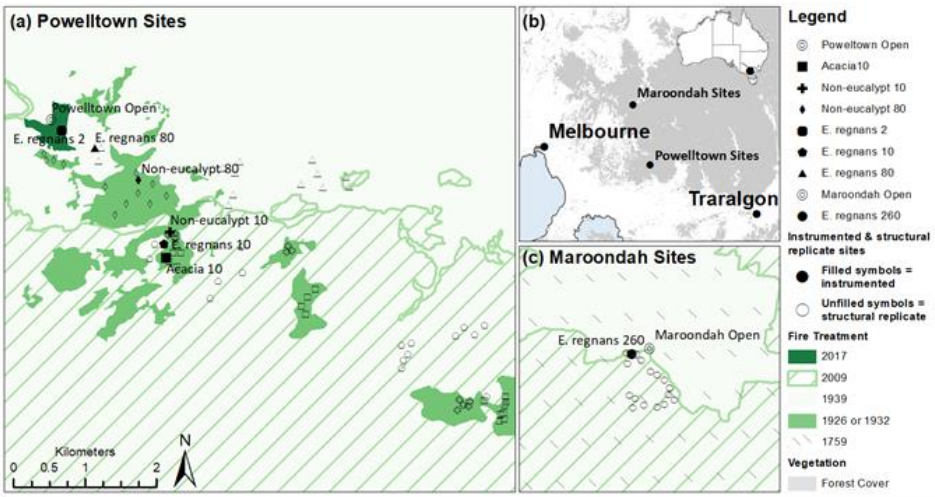

Figure 1. Location of the study areas, including seven instrumented field sites and two open (control) weather stations within the Central Highlands, Victoria, in SE Australia (b). Coloured and dashed areas indicate the fire disturbance conditions, denoting the most recent fires affecting forest structure at the alternative state forest sites. The 1939 fire (light green) affected the entire Powelltown (a) and Maroondah (c) regions.

Table 1. Site information for the open station and seven alternative forest states to wet Eucalypt forest used in this study; including four Eucalypt-dominated sites, one Acacia dealbata site, and two sites dominated by (typically) understorey species (Non-eucalypt).

Site name	Age	Rainfall (mm y^{-1})	Aspect (°)	Elevation (m)
Powelltown Open	-	1495	267	740
$Acacia_{10}$	10	1322	134	558
$Non\text{-}eucalypt_{10}$	10	1344	128	606
$Non\text{-}eucalypt_{80}$	80	1402	166	635
E. regnans$_2$	2	1481	153	735
E. regnans$_{10}$	10	1337	142	588
E. regnans$_{80}$	80	1448	204	672
E. regnans$_{260}$	260	1297	156	727

Hourly FMC data were summarised to mean annual FMC and a simple one-way analysis of variance (ANOVA) and Tukey's Honest Significant Difference (HSD) post-hoc test were conducted to detect statistically significant differences. To understand the importance of differences in FMC in the context of potential fire activity, fuel availability (FA) was assessed following Cawson et al. (2017), where fuels were considered available to burn on a given day if the site minimum modelled FMC is below 16% for at least one hour of that day.

3. Results

FMC modelled at the hourly scale (n=420 767) were summarised at a high level to mean annual FMC (n=48) for each alternative forest state. At this scale, there were significant differences in mean annual FMC ($F_{7,326}$ = 1307.2, $p < 0.001$), with a subsequent post-hoc test between group (alternative forest state) means finding significant differences across all groups at the $p < 0.05$ level. Substantial differences in FA were modelled across the alternative forest states compared to the mature wet Eucalypt forest they replaced. Mean annual days of fuel availability at *E. regnans*$_{80}$ ranged from 0 (1992, 1996, 2011) to 24 days (1976), with 19 days of FA in 2009 – the year of the 'Black Saturday' fires in Victoria, Australia. FA was consistently higher (lower FMC) at $Acacia_{10}$ and $Non\text{-}eucalypt_{10}$ compared to *E. regnans*$_{80}$, peaking at 242 days (1974) at $Non\text{-}eucalypt_{10}$ (Figure 2). In contrast, between 1973 and 2020, FMC did not fall below 16% at the $Non\text{-}eucalypt_{80}$ site, while FA of only 2 days was modelled at the *E. regnans*$_2$ site (1974 and 2009). Modelled FA at the regenerating (*E. regnans*$_{10}$) and multi-cohort (*E. regnans*$_{260}$) were similar to *E. regnans*$_{80}$, with both sites recording years with zero days of fuel availability, and peak years of 16 and 32 days, respectively.

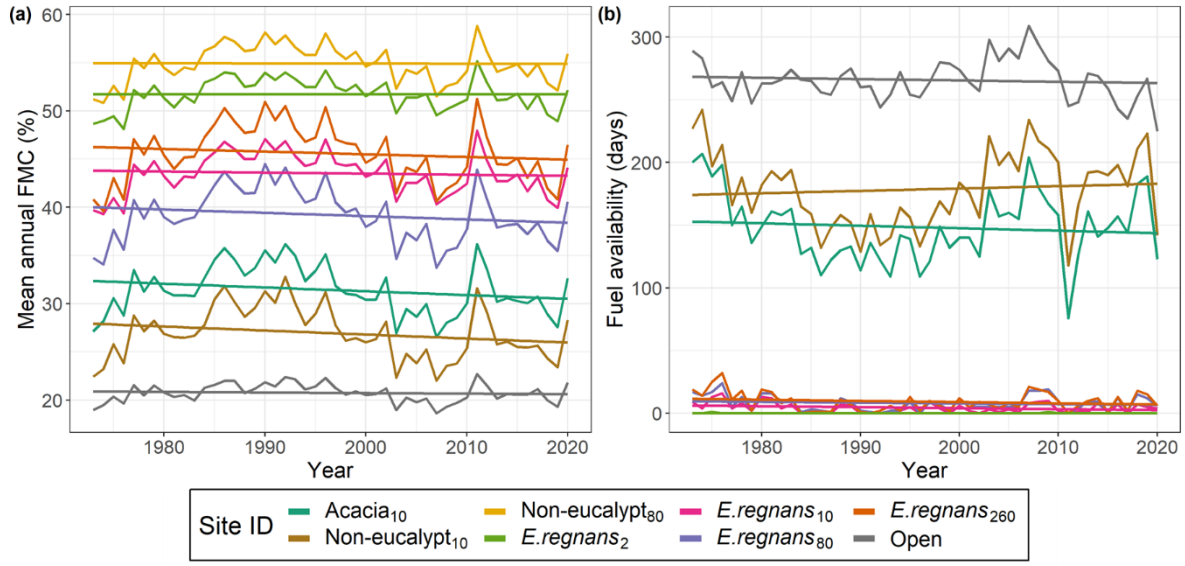

Figure 2. Modelled mean annual fuel moisture content (a) and fuel availability (b) for the alternative forest states between 1973 and 2020. The regression line indicates a simple linear model smoothed across each year of the 48-year climate dataset.

4. Discussion

Our research suggests that the impact of vegetation-mediated indirect effects of climate change on potential fire activity across seven alternative forest states is substantial. Across 48 years of modelled climate data, the results were broadly consistent with single-season observations reported by Burton et al. (2019) and Brown et al. (2021), suggesting that these comparatively shorter studies captured an appropriate range of climatic conditions. Across the 48-years of modelled data, FMC variability within and between the alternative forest states was greater than modelled FMC variability at the open site, suggesting that the indirect effects of climate change (that have altered forest structure and composition) may be more important than the direct effects on FMC in this ecosystem.

Overall, age related differences in dead FMC within E. regnans states were weaker than differences across different alternative forest state vegetation associations, with important implications for land management. We found short-term, positive fire feedbacks related to FMC for non-eucalypt forests in this region, which, as the forest ages, become negative feedbacks. In contrast, our results did not support the existence of positive fire feedbacks related to FMC across different ages of E. regnans forest. Consequently, our findings suggests that the maintenance of a Eucalypt-dominated canopy layer, potentially with patches of older non-eucalypt type forests will provide the most robust vegetation-state related buffer to future fire activity in the Central Highlands regions of SE Australia. Wet Eucalypt forests in SE Australia are a highly valued and contested forest system, and our findings enhance our understanding of ways in which these systems may be vulnerable, or resilient, to future climate change.

5. Conclusion

The indirect effects of climate change, acting through changes to vegetation structure and function, have a significant impact on fuel availability across wet Eucalypt forests in SE Australia. Indirect climate change effects resulted in both positive and negative feedbacks for potential fire activity compared to mature wet Eucalypt forest. Regenerating alternative forest states exhibited strong positive feedbacks, that were consistent across modelled data and observations in the literature. In contrast, feedbacks at *E. regnans* forests between 10-260 years were limited, while juvenile (2-year-old) *E. regnans* forests, and older (80-year-old) alternative state forests exhibited negative vegetation fire feedbacks.

Keywords

Wildfires, climate, drought, high mountains, vulnerable forests

Abstract

As Lebanon has experienced an increasing number of fires, this work aimed at assessing the potential impact of climatic conditions on fire occurrence in the country. The results showed an increasing trend of fire events especially in high altitudinal ranges of vegetation levels. Simultaneously, increasing drought conditions were observed in high mountain lands. The results of this study strongly supported a link between changing climatic conditions and fire occurrence in Lebanon. This has resulted in clear impact on vulnerable forest ecosystems, however, a more detailed analysis about the consequences of frequent and intense fires on both vulnerable community livelihood and the natural environment is yet to be assessed.

1. Introduction

Wildfire intensity, extent and frequency are increasing in the Mediterranean ecosystems, causing major impacts on the ecological, economic, social and health systems (Mitri et al., 2016). Like other Mediterranean countries, Lebanon has increasingly suffered from devastating wildfires across the country during the past two decades. The total burnt area reached 21,674 ha and the minimum total number of fires amounted to 2,249 fires for the period extending from 2008 to 2021 (MOE/UOB, 2021). The average annual burnt area increased to 1,449 ha after it was around 1,000 ha per year before the year 2019.

Intense and large-scale wildfires were major causes of Lebanon's forest severe degradation (El Halabi et al., 2014). Tree growth and survival, yield and quality of wood/non-wood forest products, wildlife habitat, recreational, environmental and cultural value of forests were all affected by wildfires. Additionally, wildfires were linked to human injuries/death and loss of properties (MOE/UOB, 2021). In principle, the main direct causes of fires in Lebanon included cleaning lands using fire, burning waste/agricultural residues, camp fires, fireworks and arson, among others (Mitri et al., 2016). Other indirect causes comprised socio-economic changes, increase in the extent of Wildland Urban Interface (WUI) and land cover/land use changes, among others (Mitri et al., 2016; MOE/UOB, 2021). Climate extremes represented a major wildfire driver. In reference to IPCC (2021) heat wave increase, temperature increase, precipitation decrease (i.e., drought period increase), severe wind storms and heavy rainfall are expected to occur in the Mediterranean region (i.e., including Lebanon), therefore exacerbating the wildfire situation. As Lebanon has observed an increasing number of fire events and unprecedented annual extent of burnt areas, this work aimed at assessing the potential impact of climatic conditions on fire occurrence in the country. The specific objectives were to 1) evaluate trends in fire occurrence over the period 2001 to 2021, 2) assess the relationship between climatic drought conditions and elevation and 3) assess the relationship between fire frequencies and elevation levels.

2. Study area and dataset description

2.1. Study area description

The study area covered the country of Lebanon located on the Eastern Mediterranean. In reference to MOE/UOB (2021), the average start date and end date of the fire season is April 19 and November 6, respectively. The average peak month in number of fire events is August while the average peak month in extent of burnt areas is

the month of September. Lebanon has a Mediterranean climate, with warm dry summers and cool wet winters. Most of the total annual precipitation (i.e., around 90%) occurs between November and March (Mitri et al., 2016; Mitri et al., 2015).

Lebanon is divided into four physiographic regions (i.e. coastal plain, Lebanon mountain range, Beqaa valley, and Anti-Lebanon Mountains). The Lebanon mountain range rises steeply from the coast to mountains reaching 3,088 meters above sea level (masl) and supports most of Lebanon's forests. The forest land and other wooded land in Lebanon cover around 13% and 11% of its territory, respectively (FAO, 2020). The major forest species are *Quercus calliprinos*, *Quercus infectoria*, *Quercus cerris var. pseudo cerris*, *Juniperus excelsa*, *Cedrus libani*, *Abies silicica*, *Pinus pinea*, *Pinus halepensis*, *Pinus brutia*, and *Cupressus sempervirens*. Around 33% of the national territory is classified as moderate to very high fire risk areas (Mitri et al., 2015). The sharp altitudinal gradients of temperature and precipitation lead to the appearance of different climatic zones running along mountain elevations. This explains the presence of five different vegetation levels (Abi-Saleh and Safi, 1998) as shown in **Figure 1**, namely the Thermomediterranean (0-500 m asl), Eumediterranean (500-1000 m asl), Supramediterranean (1000 -1500 m asl), Montanemediterranean (1500-2000 m asl) and Oromediterranean (>2000 m asl).

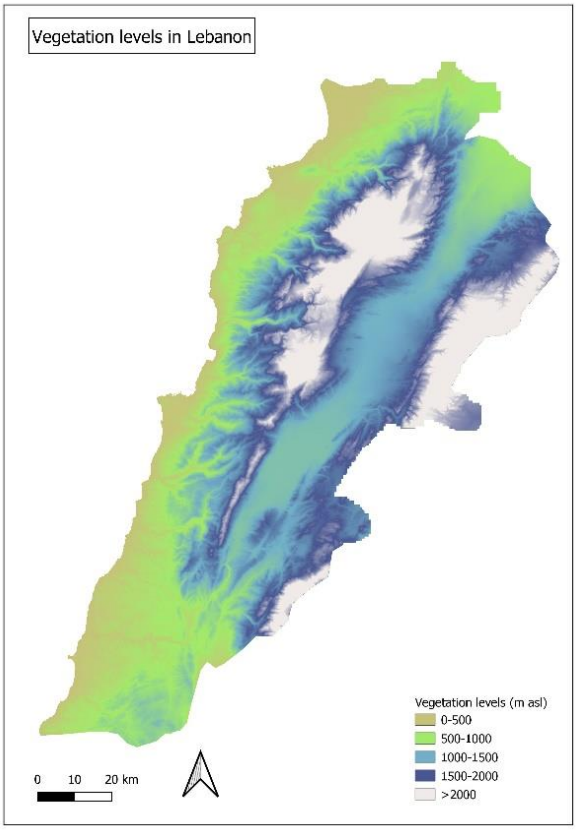

Figure 1. Altitudinal vegetation levels in Lebanon

2.2. Dataset description

Archived fire hotspots in Lebanon for the years 2001 throughout 2021 were collected in form of shapefile using the Fire Information for Resources Management System (FIRMS). Data courses included the J1 VIIRS C1, SUOMI VIIRS C2 and MODIS C6.1. The spatial climatic data needed to calculate the increase in the Keetch-Byram Drought Index (KBDI) between current averages and future averages were mostly obtained from simulated Global Climate Models (GCM). Datasets of historical averages (1950 to 2000) and future 30-year running averages (2010 to 2039) included: monthly maximum temperature, monthly precipitation and mean annual rainfall at 1x1 km of spatial resolution (Mitri et al. 2015). In addition, a Digital Elevation Model (DEM) of 25x25 m resolution and the 2017 land cover-land use map of Lebanon were employed.

3. Methodology

A total of 5095 fires were plotted against their years of occurrence between 2001 and 2021 to evaluate trends in fire events throughout the years. A Pearson correlation test (i.e., linear relationship between data) was performed to assess any significant increase in number of fires in most recent years.

Consequently, the relationship between climatic drought conditions and elevation above sea level was assessed. More specifically, the statistical relationship between increase in KBDI and high country lands was tested using Spearman correlation (i.e., non-linear relationship between data). This eventually helped in evaluating the increase of drought conditions in the range of high altitudinal vegetation levels and its possible relationship with fire occurrence in those areas. The ranges in elevation were chosen according to the categorization of Digital Elevation model (DEM) values into vegetation level zones (**Table 1**). A Pearson correlation test was performed in order to assess the link between fire frequencies and elevation levels. Furthermore, the fire occurrence in high mountain forest ecosystems (e.g., cedar, fir and juniper) was investigated.

Table 1-Vegetation levels (MOE/UNDP, 2011)

Vegetation level	Elevation (m)
Thermomediterranean	[0-500]
Eumediterranean	]500-1000m]
Supramediterranean	]1000-1500m]
Montanemediterranean	]1500-2000m]
Oromediterranean	>2000m

4. Results and discussion

4.1. Trends in fire occurrence (2001-2021)

The total number of fires per year was estimated from 2001 to 2021. **Figure 2** showed that the annual number of fires varied from 4 to 1077 fires, for the assessed period. The highest number of fires was in 2021 and the lowest one was in 2001. Moreover, the performed Pearson correlation test showed that the total number of fires increased significantly throughout years (p value = 0.000084, Pearson correlation coefficient = 0.752).

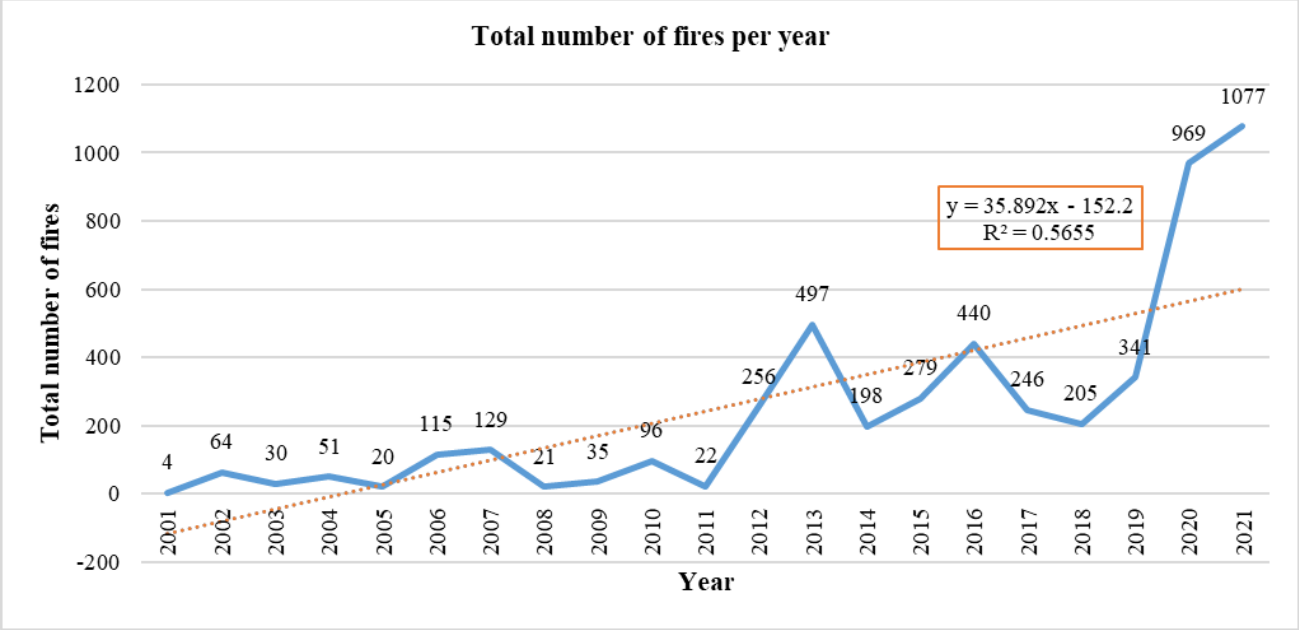

Figure 2-Total number of fires per year in Lebanon

4.2. Climatic drought conditions and elevation

The average KBDI increase varied between 9 (i.e., Supramediterranean level) and 27 (i.e., Oromediterranean level) (**Figure 3**). Moreover, a notable increase in KBDI was remarked in high altitudinal ranges of vegetation levels (i.e., above 1000 m). Accordingly, the relationship between KBDI increase and elevations was evaluated in ranges above 1000 m using the Spearman correlation test. The test showed a significant positive correlation between the 2 variables (p value = 9.182E-17, Spearman correlation coefficient = 0.308). Accordingly, it was assumed that any increase in fire occurrence within high altitudinal ranges of vegetation levels could be linked to increase of drought conditions in those areas.

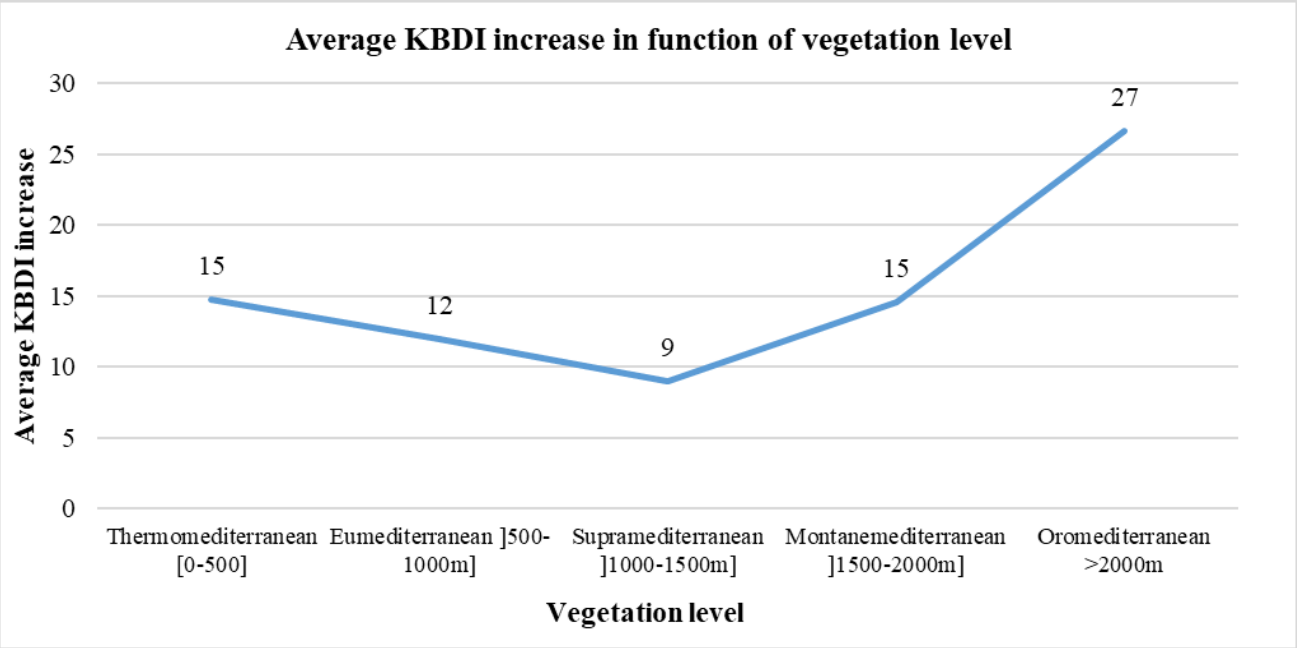

Figure 3-Average KBDI increase variation in function of vegetation levels

4.3. Fire frequencies and elevation levels

The variation in total number of fires in function of vegetation levels was also evaluated for the period extending between 2001 and 2021. **Figure 4** showed that the highest number of fire events occurred in Thermomediterranean level (i.e., 2644 fires) and the lowest number was in Oromediterranean level (i.e., 24 fires). In addition, the statistical analysis showed a negative significant correlation between the total number of fires and elevations (i.e., p value = 5.57 39E-109, Pearson correlation coefficient = - 0.537). These results were expected as high country lands encompass low density vegetation cover therefore lower fire hazard.

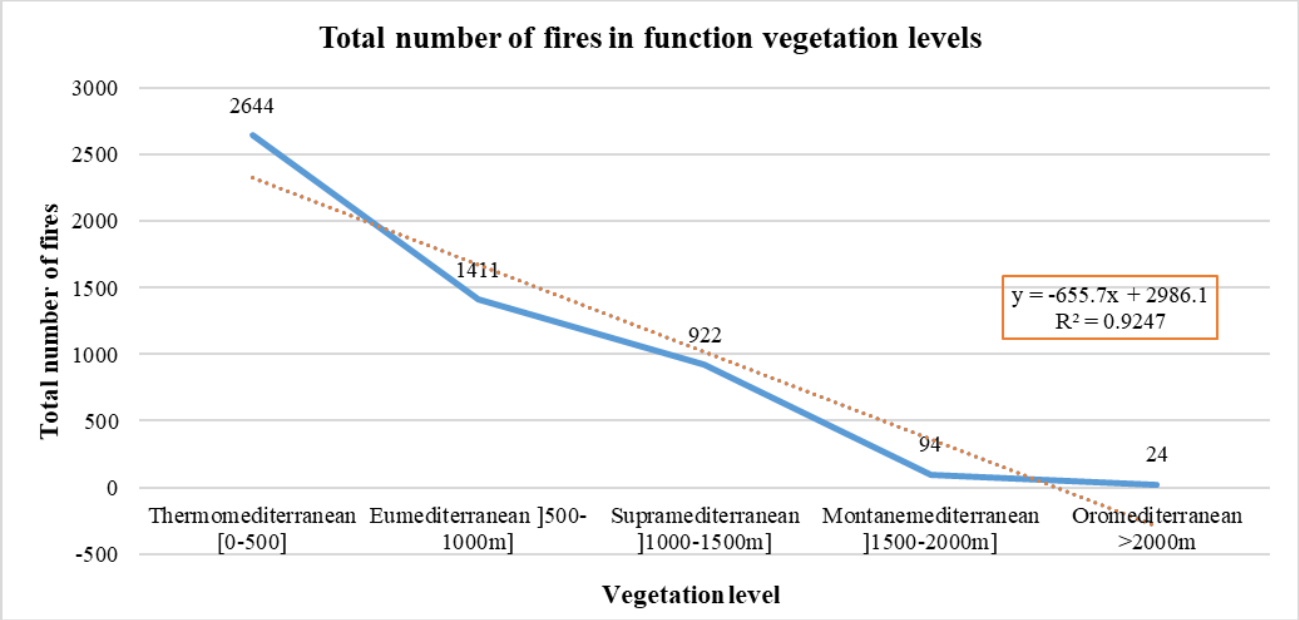

Figure 4-Total number of fires in function of vegetation levels

Yet, the multi-temporal variation in the total number of fires in each vegetation level was further assessed (**Figure 5** – **Figure 9**). The performed statistical analysis showed that the total number of fires increased significantly throughout years, in all vegetation levels. The results were summarized in **Table 2**.

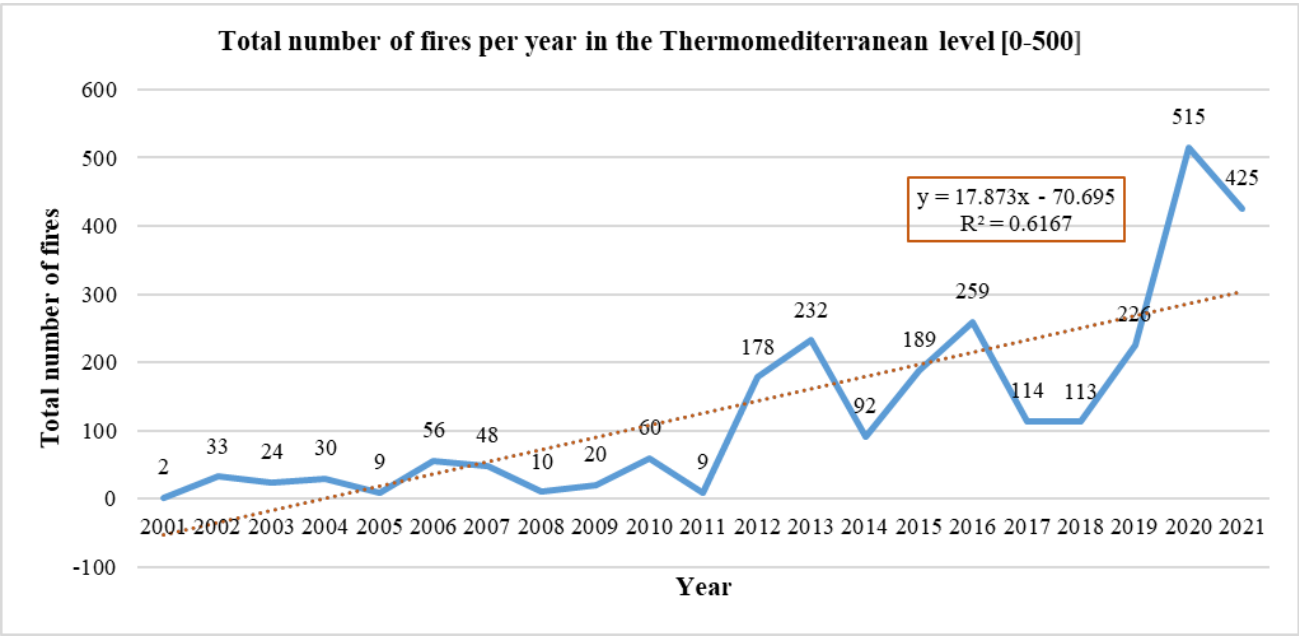

Figure 5-Total number of fires per year in the Thermomediterranean level

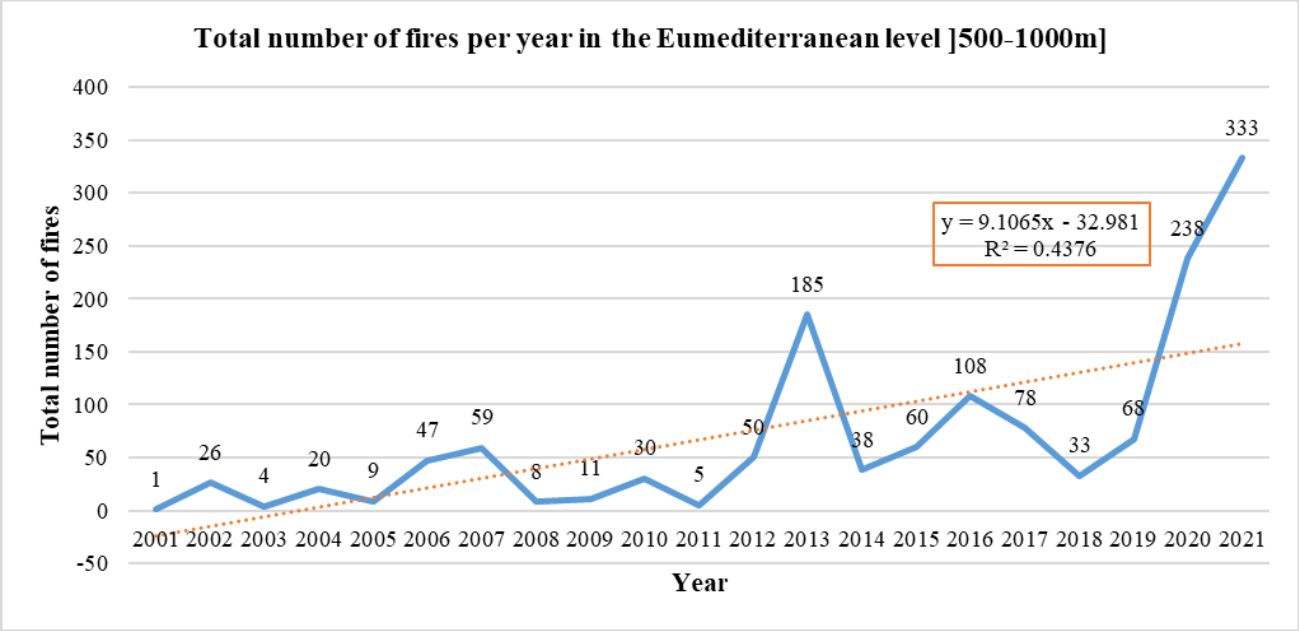

Figure 6-Total number of fires per year in the Eumediterranean level

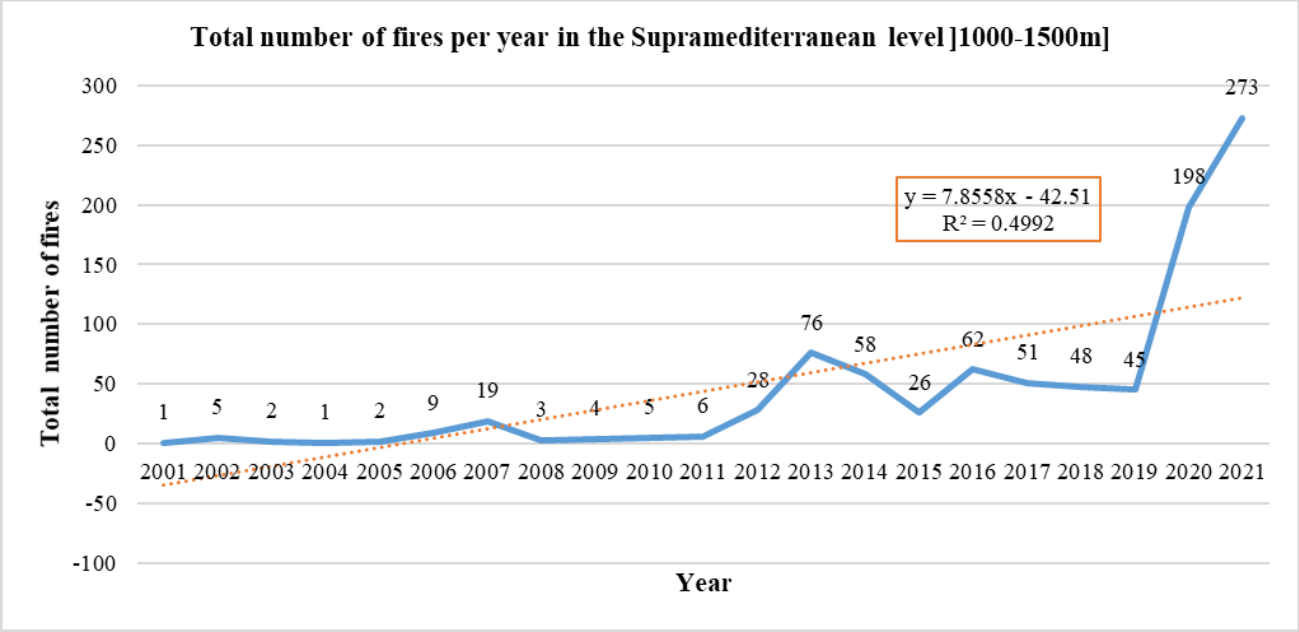

Figure 7-Total number of fires per year in the Supramediterranean level

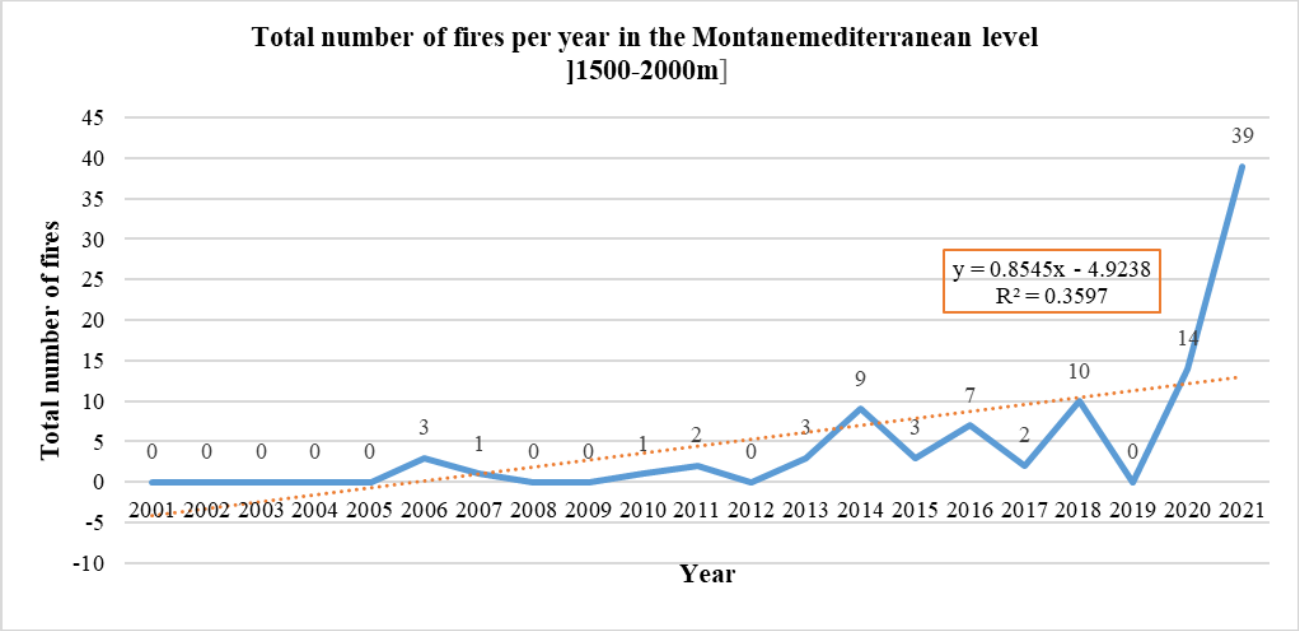

Figure 8-Total number of fires per year in the Montanemediterranean level

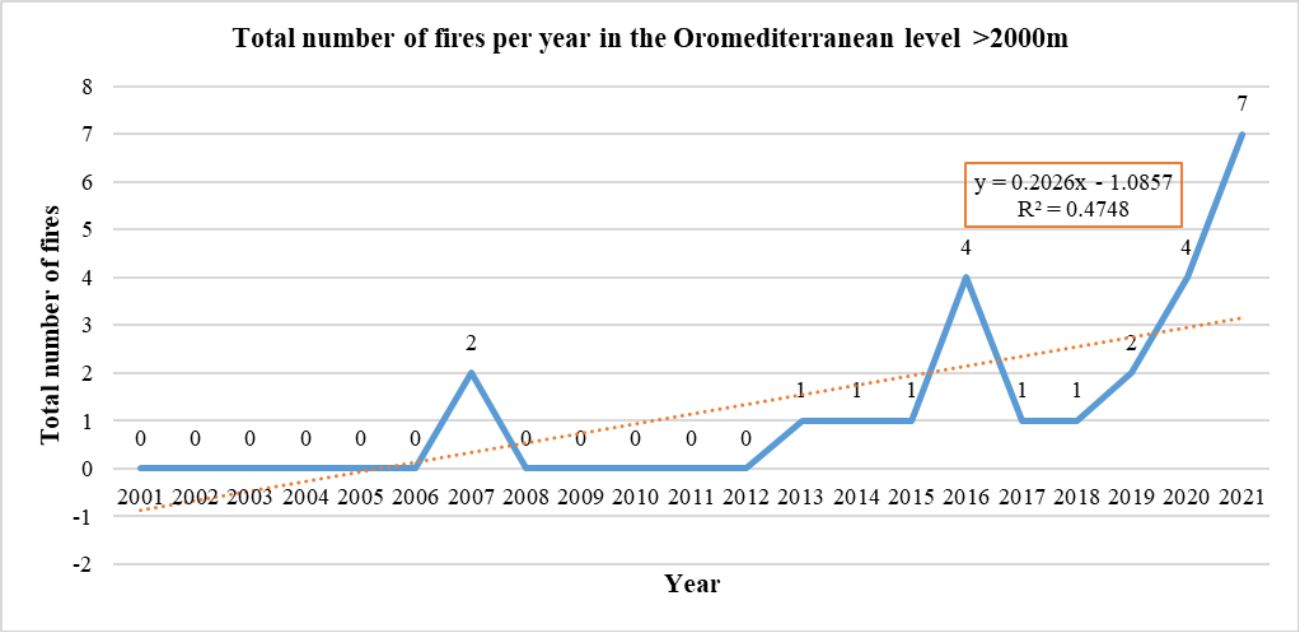

Figure 9-Total number of fires per year in the Oromediterranean level

Table 2-Correlation between total number of fires and years results

Vegetation levels	p value (Correlation between total number of fires and years)
Thermomediterranean [0-500]	p value = 0.000025 (Pearson correlation coefficient = 0.785)
Eumediterranean]500-1000m]	p value = 0.000035 (Spearman correlation coefficient = 0.777)
Supramediterranean]1000-1500m]	p value = 2.2227E-7 (Spearman correlation coefficient = 0.874)
Montanemediterranean]1500-2000m]	p value = 0.00036 (Spearman correlation coefficient = 0.704)
Oromediterranean >2000m	p value = 0.000018 (Spearman correlation coefficient = 0.794)

Overall, the results indicated a significant increase of drought conditions in high mountain lands across the high altitudinal ranges of vegetation levels simultaneously to obvious increase of fire events in those same areas. Accordingly, it was assumed that changing climatic conditions were expected to directly drive the increase of

fire occurrence in high country lands therefore pausing an increasing threat to vulnerable high mountain forest ecosystems such as cedar, fir and juniper forests and other types of natural landscape which comprise very often rare endemic species not adapted to fires. In fact, specific vulnerable mountainous ecosystems (i.e., cedar forests) experienced disastrous fire events for the first time in the recorded history of fires in Lebanon. As shown in **Figure 10**, there was a remarkable increase of fire events in high mountain forest ecosystem especially in the years of 2020 and 2021.

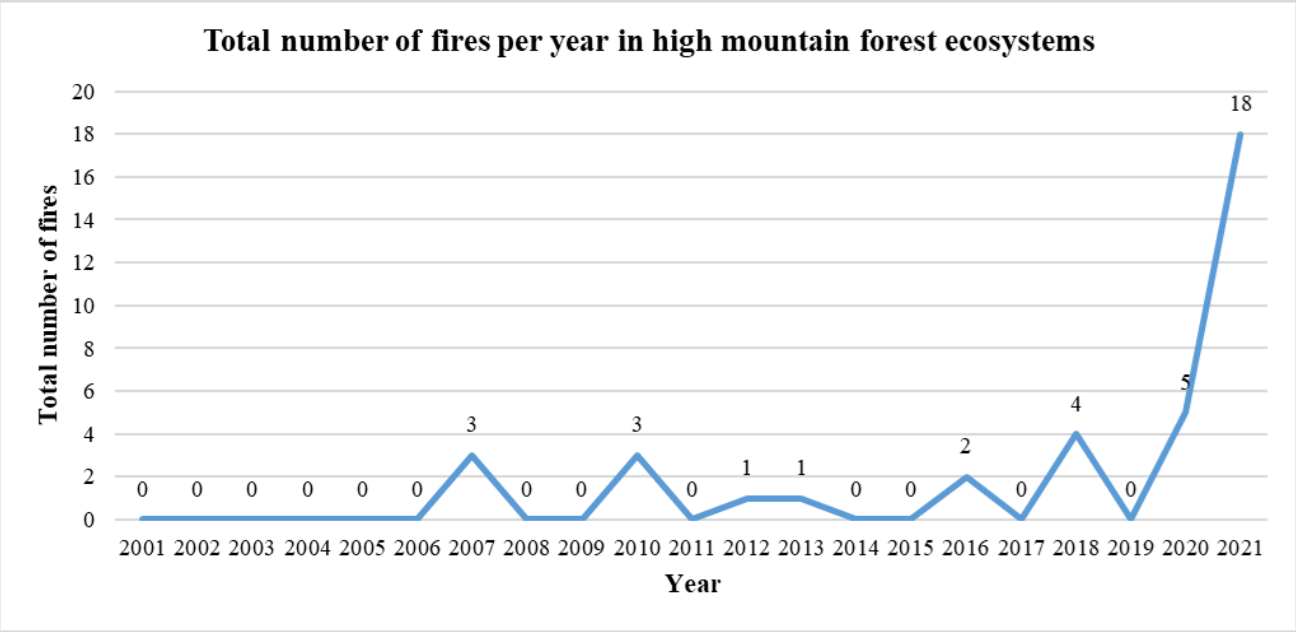

Figure 10-Total number of fires per year in high mountain forest ecosystems

5. Conclusions

As the climate science community sources a suite of global climate models to help decision makers understand the projections of future climate change and related impacts, the Coupled Model Intercomparison Project , Phase 5 (CMIP5) models, as included in the IPCC's Fifth Assessment Report (AR5) showed increase in fire weather conditions throughout the next 30 years with high confidence for the Mediterranean basin. Building on the results of this work, Lebanon is expected to face an increasing risk of fires, whether that's forest fires or grassland fires. More specifically, as the landscape becomes increasingly dry from multiple years of gradual change, an increase in the frequency and intensity of fires is expected. This necessitates developing and implementing all necessary adaptation measures to mitigate the impact of fires on both vulnerable community livelihood and the natural landscape.

Fire-adaptive communities, more-than-human theory, landscapes, contact zones

Abstract

With anthropogenic climate change already bringing more frequent and more intense wildfires, combined with significant human populations living in wildfire-prone landscapes, there are increased calls for adaptive approaches to fire. There is hope that by doing so, and by moving from a predominantly responsive 'war on wildfire' approach, humans can learn to 'thrive with fire' (Tedim et al. 2020).

Humans around the world have always shared their landscapes with fire – circumstances dictating the degree of comfort. Through these lived experiences, the stories of humans learning to live within their landscapes and therefore with fire have always been – and continue to be – stories of learning and innovation (Bowman et al. 2011; Pyne 2016). These adaptations, however, have been both enabled and constrained by how humans and their institutions have envisioned their relationships with the more-than-human actors and agents that share the landscape with them (Ruane 2018). These actors and agents include, amongst many other things, fire, vegetation and the weather.

There has been a great deal of focus on what can be learnt from Indigenous knowledges about fire on the landscape (i.e. Roos et al. 2016; Steffensen 2020). However, there has been less attention on how complex and often conflicting Western visions of the landscape and therefore of fire have contributed to particular adaptive approaches.

This paper explores how these visions – Aboriginal, as well as colonial, romantic, scientific, national and ecological – are a useful way of examining current narratives and adaptive approaches to fire in an Australian context. Examining these differing visions helps understand the range of fire management adaptions that have emerged in Australia.

Each vision has implications for how 'fire-adaptive' communities might act; what decisions they might make; who might be involved; and the processes that are used to take an adaptive approach to fire. They offer knowledges and practices that could complement the dominant colonial vision of 'war on wildfire', as well as reduce the effects of social and environmental 'slow emergencies' on human and more-than-human vulnerabilities. However, despite knowledge of these alternative visions in governments and communities, they are difficult to incorporate meaningfully into the dominant vision. Adaptive approaches to fire in more-than-human communities will require trade-offs across levels of society, scales of landscapes and of time.

1. Introduction

With anthropogenic climate change already bringing more frequent and more intense wildfires, combined with significant human populations living in wildfire-prone landscapes, there are increased calls for adaptive approaches to fire. There is hope that by doing so, and by moving from a predominantly responsive 'war on wildfire' approach, humans can learn to 'thrive with fire' (Tedim et al. 2020).

Humans around the world have always shared their landscapes with fire. Through these lived experiences, the stories of humans learning to live within their landscapes and therefore with fire have always been – and continue to be – stories of learning and innovation (Bowman et al. 2011; Pyne 2016). These adaptations, however, have been both enabled and constrained by how humans and their institutions have envisioned their relationships with the more-than-human actors and agents that share the landscape with them (Ruane 2018). These actors and agents include, amongst many other things, fire, vegetation and the weather.

There has been a great deal of focus on what can be learnt from Indigenous knowledges about fire on the landscape (i.e. Roos et al. 2016; Steffensen 2020). However, there has been less attention on how complex and often conflicting Western visions of the landscape, and therefore of fire, have contributed to particular adaptive approaches. Colonisation of the Australian landscape, which began in earnest with the establishment of the

British colony of New South Wales in 1788, provides an interesting example of how these Western visions inform narratives about, and therefore adaptions to, wildfire.

2. The Australian landscape: a more-than-human contact zone

When Donna Haraway wrote of contact zones in her book *When Species Meet* (2008), she used the concept to examine how separate species or systems, when 'forcibly brought together in relations of serious inequality' (Haraway and Reti 2007 p.33), can change and innovate through their encounters.

> *Contact zones are where the action is, and current interactions change interactions to follow. Probabilities alter, topologies morph, development is canalised by the fruit of reciprocal induction. Contact zones change the subject – all subjects – in surprising ways (Haraway 2008 p.219).*

Over a period of at least 60,000 years, as people have encountered and learnt about the effects of fire on the Australian continent, they have adapted their relationships with landscapes and fire to meet their needs. Adaptation through the encounters with wildfires – or 'bushfires' as the colonists began calling them – since colonisation has proved uncomfortable and difficult. In contemporary Australia, large populations of people are migrating into bushfire-prone semi-rural and peri-urban areas. Encounters with bushfires are inevitable, and problematic areas have been identified as: not people not 'properly' perceiving the risk that bushfire poses for them (e.g. Eriksen and Prior 2011); people not understanding the need to balance ecological fire with fire risk (e.g. Moskwa et al. 2018); and how negative public perception of prescribed fire puts a stop to prescribed ecological and hazard reduction burning (e.g. Morgan et al. 2020; Pyne 2020).

However, people's individual and collective innovation in fire management has been both aided and constrained by human perceptions, beliefs and values – visions – about their own role within their environment (Ruane 2018). These visions are in turn supported by specific narratives. Narratives are the stories told about humans, creating themes that inform ways of thinking, and therefore policies and actions (Moskwa et al. 2018). Examining and understanding narratives about how people position themselves and others in relation to complex environmental issues complements the modelled 'hard' sciences in developing policies for adaptative approaches regarding the landscape and fire (Bardsley, Wiseman, and Hugo 2016).

Examining these differing visions and narratives helps understand the range of fire management adaptions that have emerged from the human lived experiences of being a part of the contact zone of bushfire-prone landscapes. This in turn may help continue adaptive practices so that people can learn to thrice with fire – rather than simply letting human relationships with fire degenerate into border wars.

3. Envisioning human relationships to the landscape and fire

Several authors have identified a common pattern in how humans relate to the landscape in Australia. These range from an integral, symbiotic Aboriginal vision that was dominant for all but the last 240 years, to exploitative colonial and national development visions, and to more recent sustainable management and ecological visions (i.e. Heathcote 1972; Fien 1988; Ruane 2018). A useful categorisation is provided by geographer R.L. Heathcote (1972). He identifies six ways – visions – in how people perceived their relationships with the Australian landscape. Five of these are Western visions that dominated post-1770 – scientific, romantic, colonial, national, and ecological. He also discusses a sixth vision – Aboriginal, although not with the detail he gives the other visions.

Heathcote presented these visions as roughly sequential, and as arising from different 'eras' of thinking. However, these six visions overlap and aspects of all may be seen as present in the visions of Australians today. Heathcote's categorisations are very anthropocentric, viewing 'the environment' as being without agency and only having value if it is in economic terms for humans. Despite this, his categories offer a valuable way of examining complex more-than-human relationships in a non-binary way – and how they all both inform and contradict one another.

Table 1- Six visions of the Australian landscape that inform current fire narratives and adaptions. Adapted from Heathcote (1972).

Vision	Description
Colonial (dominant)	Survival and domination of the Australian landscape and Aboriginal peoples. Extraction of resources, transformation into a European space
Aboriginal	Cultural and spiritual connection to Country
Scientific	A curiosity about the Australian landscape (including its climate) and its uniqueness. A desire to categorise and therefore to perhaps understand it.
Romantic	Delight in the landscape as an 'untouched' wilderness. A sympathetic view of Aboriginal peoples.
National	Australian identity tied to the bush landscape, and to the hard-working people making a living in rural areas (successfully transforming the landscape with introduced flora and fauna)
Ecological	Concern about the impact that humans are having on the landscape. That European 'improvements'/adaptations have impoverished landscape conditions and facilitated extinctions.

This review of fire adaptive approaches for more-than-human communities contrasts these six visions. It identifies narratives that accompany each of these visions, as well as the fire-adaptive approaches that have arisen in Australia due to them.

3.1. Colonial (dominant) vision: narratives and adaptive approaches

Encounters with bushfires, especially the uncontrollable megafires that started to be experienced by colonists from the 1850s onwards (Morgan et al. 2020), shook perceptions of (white) human dominance, and enforced beliefs that the Australian environment posed a direct threat to European habitation (Collins 2006). The increasing frequency and intensity of megafires within Australia and globally (Morgan et al. 2020) continues to do so. As a result, 'we fear and suppress all of our unplanned fire' (Leonard 2017 p.1). This colonial adaptative approach is deeply entrenched in Australian language, legal system, government policies and practices, and built environment (Howitt 2014).

In Australia, narratives surrounding this colonial vision also take on moral undertones of blame and responsibility. Whittaker and Mercer (2004) point out that the 'aftermath of all major bushfire events in Australia invariably has been the apportioning of blame' (Whittaker and Mercer 2004, p. 263). Australian policy states that managing fire risk and fires as a 'shared responsibility' across governments, organisations and individuals. There is a strong legal framework around who, and under what conditions, can light fires (McLennan and Eburn 2015). Arsonists, people who deliberately light destructive fires, are particularly vilified (Hooper 2018).

Adaptive use of fire is limited to 'hazard reduction' burns that reduce the risk of fire damaging people and built infrastructure (Neale et al. 2019). 'Responsible' human adaptative actions informed by this colonial vision are those that mitigate fire risk (Bosomworth 2018), or plan how to survive a bushfire when it occurs (i.e. NSW Government 2020).

3.2. Aboriginal visions: narratives and adaptive approaches

Australia is one of many countries where colonisation has substantially displaced Indigenous peoples, as well as their fire and land management knowledge and practices (Bowman et al. 2011, Roos et al. 2016). For thousands of years, fire across the Australian continent has been used as a land and animal management tool (Neale et al. 2019, Gammage 2008). This knowledge has often been positioned by white researchers as historical (Eriksen and Hankins 2015), but there is growing contemporary use of Aboriginal fire knowledges – especially in northern Australia – as practice to promote the health and well-being of landscapes and human communities (Neale et al. 2019, McKemey et al. 2020, Russell-Smith et al. 2009). Indigenous writers such as Steffenson (2020) argue that putting cultural fire knowledges into practice on Country are integral to achieving social justice for marginalized peoples who have been enduring colonial rule.

3.3. Scientific vision: narratives and adaptive approaches

A scientific vision was behind the European exploration and colonisation of the Australian continent. The uniqueness of its flora, fauna and Aboriginal peoples were particularly valued, and science attempted to collect, categorise and therefore understand the landscape.

Narratives around fire in this vision are around experts gaining and applying their knowledge. Adaptation tends to be limited to fire management, rather than to local communities (Ruane 2019).

Adaptation is scientific approaches to use of fire – developed firstly through government-controlled forestry research (Pyne 2020). This has contributed enormously to knowledge about fire behaviour, which in turn has improved public safety through changes to building codes, fire danger indexes that create public warnings combining weather, soil and vegetation dryness data .

3.4. Romantic vision: narratives and adaptive approaches

A romantic vision is defined as people living in harmony with nature, and in harmony with diversity including with Aboriginal peoples. It can be linked to the 'co-existing with fire' narrative, which sees humans as a part of nature, and seeks to find a balance between fire and humans as parts of a social-ecological system (Bosomworth 2015).

One key adaptation as a result of this vision is seen in the National Parks in Australia, which are wilderness spaces, where people can only visit for approved recreation purposes. This approach has changed the landscape immeasurably since the 1770s and may have increased probability of fire in some areas. Whittaker and Mercer (2004) identified a 'wise use' narrative being used by timber, farming and mining industries after bushfires in 2003 bushfires to overstate fire risks of parks, and to demand the 'unlocking' of national parks.

3.5. National vision: narratives and adaptive approaches

National vision is defined as a celebration of the transformed bush, where European colonists could live a hard-working life free of the city and the industrial age/conditions. This vision underpins the Australian national identity - 'the bush became the synonym for Australia from the 1880s onwards' (Heathcote 1972, p.93). Its use supports colonial vision of the landscape and fire-suppression.

In national vision narratives, fighting bushfires (as well as the rest of the hostile Australian landscape) is the work of heroes, who work together showing egalitarian 'mateship' (Moore 2015). Arguably this narrative has also come to inform current Australian discourse around how communities do/should 'come together' in times of need, backed up by research into social capital (e.g. Aldrich 2012).

It is also perhaps this national vision which has underpinned recent shifts of populations from cities into bushfire-prone peri-urban and semi-rural landscapes (Eriksen and Prior 2011). In turn, this has meant that the dominant fire emphasis in Australia has to be community safety (Pyne 2020).

3.6. Ecological vision: narratives and adaptive approaches

Heathcote (1972) argues that the ecological vision of the Australian landscape arose from concerns that European 'improvements' to the landscape have actually made the landscape itself vulnerable. Western adaptations have not only limited farming successes, but also facilitated extinctions of native flora and fauna.

Ecological knowledge regarding optimal fire regimes for differing Australian ecologies has been growing (Bradstock 2010), and the narratives around this vision are that fire is natural and inevitable (Whittaker and Mercer 2004). At the same time, there is growing awareness that anthropogenic activities have impacted the Earth's climate, which is impacting the landscape – creating the conditions for more frequent and intense bushfires, as well as for more storms and floods (CSIRO and Bureau of Meteorology 2018).

Adaptation within this vision is about using prescribed fire to promote biodiversity. Some Australian researchers such as Leonard (2017) have suggested use of ecological fire could be 'democratised' out to people living in fire-prone landscapes. It is generally unclear how widespread this practice could be, given the level of bureaucracy that needs to be negotiated to light ecological fires legally.

4. Conclusion

Examining the relationships that Australian people have with their more-than-human communities through the categories of Heathcote's landscape visions exposes a range of narratives about fire. Each of these inform the adaptative approaches that have occurred as human and more-than-human actors/agents encounter one another – with obvious discomfort – in these contact zones.

Howitt (2014) argues that adaptation is not value-neutral, and successful adaptation requires trade-offs across levels of society, scales of landscapes and of time. Looking across these six human visions of the Australian landscape, it is not hard to see why. Which more-than-human actors/agents are the most vulnerable in encounters with which others in their community contact zones? Humans and their built environment encountering wildfire? The entire landscape itself encountering human activities? Marginalised Aboriginal peoples denied access to Country and fire? Ecologies that are no longer being burnt, or are being burnt too much? In the bushfire-prone contact zones, to borrow the words of researcher John Handmer, 'we are all vulnerable' (2003 p.55). The challenge is to identify and enact adaptive approaches to fire that reduce vulnerabilities for many actors/agents, rather than for only a few. Perhaps it is time to re-evaluate human relationships with the landscape and adjust our dominant colonial vision of domination. Perhaps then humans, and the landscapes they live in, can really thrive with fire.

Abstract

Fire regimes in Australian temperate forests have changed with the area burnt by bushfires having increased due to changing climate extremes every decade for the past 40 years. The Australian Capital Territory (ACT) has been heavily impacted with year-since-last-fire in forests being the shortest of all Australian jurisdictions due to large, intense bushfires during the droughts of 2003 and 2020.

The forested landscapes of the ACT are predominantly mountainous and scattered throughout are species and communities which are likely to be disadvantaged by an increase in the frequency of high intensity fire. Examples include alpine bogs, Alpine Ash (*Eucalyptus delegatensis*) and Mountain Plum Pine (*Podocarpus laurencei*). Many of these systems were severely burnt in 2003 and 2020.

Protection of these species and communities from bushfires is a high priority for conservation, but suppression operations are difficult due to inaccessibility and the danger to firefighters. A potential solution is to use prescribed burning to manipulate fire regimes to reduce risk. In this paper, we describe an approach designed to reduce bushfire risk while optimising land management workloads and total area burnt.

The approach has two key components: 1) development of a method for managing landscape bushfire risk in time; and 2) utilisation of landscape flammability mapping to design burn infrastructure to meet ecological objectives.

Bushfire risk planning is focused on space, but risk also changes in time with the effects of drought on fuel moisture accumulating and drying over multiple years. This time-scale offers an opportunity to intervene to reduce bushfire risk in fire sensitive ecosystems and influence fire regimes in favour of those ecosystems using prescribed burning. To do this, bushfire planners need to identify ecosystems at risk and develop burns which are to be implemented contingent on agreed climatic triggers.

Landscape flammability in mountainous landscapes in southeastern Australia during the autumn prescribed burning season is driven by solar radiation with north faces being drier and much more likely to burn than south faces. This imposes a critical constraint on prescribed burn planning. We conducted an assessment of the feasibility of designing burns to protect alpine bogs, Mountain Plum Pine and Alpine Ash. There appears to be some potential for reducing fuels around alpine bogs and good potential for emhancing protection of Mountain Plum Pine. On the other hand Alpine Ash stands largely occur on southern slopes and do not appear to be easily amenable to fire regime manipulation.

1. Changed Forest Fire Regimes

Fire regimes in Australian temperate forests have changed with the area burnt by bushfires having increased due to changing climate extremes every decade for the past 40 years (Canadell et al. 2021). The Australian Capital Territory (ACT) has been heavily impacted with year-since-last-fire in forests being the shortest of all Australian jurisdictions due to large, intense bushfires during the droughts of 2003 and 2020.

The forested landscapes of the ACT are predominantly mountainous and scattered throughout are species and communities which are likely to be disadvantaged by an increase in the frequency of high intensity fires

(Hawkins et al. 2021). Examples include alpine bogs, Alpine Ash (*Eucalyptus delegatensis*) and Mountain Plum Pine (*Podocarpus laurencei*). Alpine bogs are a product of the anaerobic decomposition of vegetation due to saturation in water. Fire is a fundamentally rare event and the ecological impacts of fires on bogs are overwhelmingly negative (DEWHA, 2009). Alpine Ash is a serotinuous species which is killed by high intensity fires and takes >10 years to mature (Doherty et al. 2017). High intensity fires at a frequency of <10 years present a threat to Alpine Ash populations which may be unable to produce seed. Mountain Plum Pine is a slow growing Gondwanan relic which occurs in high rocky mountain tops and is killed by fire of moderate intensity and greater (Tolsma et al. 2004). Discontinuous fuels on rocky mountain tops provide some protection from fire for this species but high intensity bushfires cause mortality (Figure 1). All of these systems were severely burnt in 2003 and 2020.

2. Limitations of Fire Suppression Operations

Protection of these species and communities from bushfires is a high priority for conservation (Hawkins et al. 2021), but suppression operations are difficult due to inaccessibility and the danger to firefighters. Even if suppression operations are technically feasible, for example by deploying helicopter-borne Remote Area Fire Teams (Cooper, 2020) resources must be prioritised to protection of human life and property. During the large fire events which are of most concern for conservation management, conservation-focussed suppression will almost certainly be restricted to small areas of the highest priority.

3. Prescribed Burning in the Australian Capital Territory

The ACT Parks and Conservation Service conducts a prescribed burning program which is evaluated annually using Normalised Burn Ratio (Leavesley et al. 2021). Analysis of the interaction between the Orroral fire in the ACT in 2020 found that burns which were <2 years old halted the spread of the bushfire, reducing its final extent. In addition, a burn which was four years old significantly reduced the severity of the bushfire. Burns which were seven years old were discernible in the landscape but appeared to have a limited effect on bushfire behaviour. The study concluded that the interaction between the burning program and the Orroral fire was positive for conservation and catchment values.

4. Concerns about Prescribed Burning

A criticism of prescribed burning is that in many ecosystems the leverage is low (Price et al. 2015). The leverage number represents the likelihood that a prescribed burn will intersect with a bushfire before fuel accumulates to the point that fire behaviour is affected. For example, in southern Australian forests, the leverage has been calculated to be 0.33 which means that to reduce the annual average area burnt in bushfires from 5 percent to 2.5 percent requires the annual area of prescribed burning to be 7 percent – an overall increase in total area burnt.

But this generalised analysis does not take into account conservation land management objectives or fire response traits of focal species. Species which are tolerant of low or moderate intensity fire but sensitive to high intensity fire can be advantaged by high frequency application of low intensity prescribed burning and this is well documented in ecosystems such as the northern Australian savannahs (Evans and Russell-Smith, 2020).

Similarly, where a species or ecosystem is identified to have exceptional conservation value, managers may make a judgement that a trade-off which advantages a high value ecosystem or species is justified, despite disadvantaging other effected species. To our knowledge, such trade-offs are relatively rare in southern Australian forests where the conservation policy focus is on ensuring that prescribed burning is applied at intervals determined to be consistent with the fire response traits of all of the species in a particular ecosystem or known to be present in a burn block. We suggest, that in the face of changed fire regimes, a greater focus on conservation priorities and a renewed consideration of trade-offs is warranted.

5. How can we adapt?

High-frequency, broad-scale application of low intensity prescribed burning to southern Australian forests is likely to change ecosystems and is difficult and costly to achieve. Can we be more judicious in the use of fire but still reduce the risk to high value species and communities? We think this could be achieved by prescribing burns at times when landscape bushfire risk is elevated and in places most likely to manipulate the conservation outcome positively, should a bushfire subsequently occur.

Our approach has two key components: 1) development of a method for managing landscape bushfire risk in time; and 2) utilisation of landscape flammability mapping to design a burn program to meet ecological objectives.

6. Managing bushfire risk in time

Best practice landscape bushfire risk planning is usually focused on space (eg Gazzard et al. 2020; Penman et al. 2020), but risk also changes in time with the effects of drought on fuel moisture accumulating and drying over multiple years (Nolan et al. 2016). This time-scale offers an opportunity to intervene to reduce bushfire risk to high value conservation assets by conducting burns aimed at manipulating fire regimes in the prescribed burning season, between summer fire seasons, at times when landscape dryness is elevated and the likelihood of large, intense landscape-scale bushfires is consequently also elevated. If applied successfully, the approach would increase the leverage of a burning program because the likelihood of intersection between burns and bushfires is greater. It is worth noting, that operational experience suggests that the risk of prescribed burn escape in the burning season, is not significantly affected by elevated landscape dryness during the burning season.

To be effective in southeastern Australia the approach requires a sound understanding of landscape fuel moisture dynamics and a robust predictive capability for landscape dryness in the coming fire season which exceeds present capability (Vinodkumar *et al*. 2021). The triggering metric would be needed in advance of the peak burning season in March and April, at least seven months before the usual commencement of the fire season on 1 November.

The next stage of the work would be to test some candidate prescriptions in a fire regime simulation. The main aim of the work would be to define a set of parameters which were effective and operationally achievable. If an effective prescription was identified, the results of the simulation would be critical in developing options for stakeholder consideration and ultimately for obtaining a social licence to implement the work.

7. Working with flammability gradients

A critical constraint on the autumn prescribed burning program in southeastern Australian mountain forests is the pattern of landscape flammability (Nyman et al. 2018). In autumn, the landscape transitions from mostly dry enough to burn, to mostly too wet (Nyman 2019). Flammability is driven by solar radiation and during the transition, the north faces are drier and much more likely to burn than south faces.

Prescribed burn planning for high value conservation assets must work within the landscape flammability constraints. Direct manipulation of fire regimes can only occur in the flammable parts of the landscape. Where Alpine Ash stands occurred on northern slopes, fuel could be reduced by low intensity prescribed burning to reduce the risk posed by high intensity bushfire the following summer. Similarly, prescribed burning could be deployed to enhance the topographic protection that Mountain Plum Pine derives from its rocky mountaintop habitat by removing connecting fuels. Alpine bogs present a greater challenge because they cannot be directly fuel-reduced. Nonetheless it may be possible to identify landscapes in which adjacent systems are flammable and which can be burnt to create a protection zone.

Our analyses show that burning to create a protection zone surrounding and directly adjacent the largest alpine bog in the ACT, Ginini Wetland, is not appear likely to be possible due to the large extent of non-flammable terrain adjacent, however an extended area encompassing other ecosystems, might be possible (Figure 2). The second largest alpine bog, Snowy Flat appears to be better situated for creation of a protection zone which is

directly adjacent (Figure 3). Mountain Plum Pine habitat on mountain tops appears to be generally amenable (Figure 4) with an important caveat that operational experience at that altitude is limited. Alpine Ash stands are almost exclusively located on southern slopes and cannot be burnt under prescribed burning conditions (Figure 5). Further thought and planning would be required to manipulate the fire regimes of that community.

Soil erosion, coevolution, landscape evolution, feedbacks, critical zone

Abstract

Climate drives the coevolution of vegetation and the soil that supports it. Wildfire dramatically affects many key eco-hydro-geomorphic processes, but its potential role in coevolution of soil-forest systems has been largely overlooked. The steep landscapes of southeastern Australia provide an excellent natural laboratory to study the role of fire in the coevolution of soil and forests, as they are characterized by temperate forest types, fire frequencies, and soil depths that vary systematically with aridity. The aims of this study were (i) to test the hypothesis that in Southeastern Australia, fire-related processes are critical to explain the variations in coevolved soil-forest system states across an aridity gradient and (ii) to identify the key processes and feedbacks involved. To achieve these aims, we developed a numerical model that simulates the coevolution of soil-forest systems which employ eco-hydro-geomorphic processes that are typical of the flammable forests of southeastern Australia. A stepwise model evaluation, using measurements and published data, confirms the robustness of the model to simulate eco-hydro-geomorphic processes across the aridity gradient. Simulations that included fire replicated patterns of observed soil depth and forest cover across an aridity gradient, supporting our hypothesis. The contribution of fire to coevolution increased in magnitude with aridity, mainly due to the higher fire frequency and lower post-fire infiltration capacity, increasing the rates of fire-related surface runoff and erosion. Our results show that critical feedbacks between soil depth, vegetation, and fire frequency dictate the trajectory and pace of the coevolution of flammable temperate forests and soils.

1. Introduction

Interactions and feedbacks between soil and vegetation are key factors in controlling catchment ecohydrological behavior (Donohue et al., 2007, 2012; Trancoso et al., 2016; Zhang et al., 2004). Thus, understanding how soil-vegetation systems coevolve can help explain observed variations in catchment responses and enable better predictions of change in response to future climate scenarios (Troch et al., 2015). Coevolution in this context is defined as a climatically driven process in which interactions and feedbacks between vegetation and its supporting soil causes ongoing changes in their properties (Berry et al., 2005; Porder, 2014; Troch et al., 2015; van Breemen, 1993). Due to its interdisciplinarity, complexity, and nonlinearity and because it operates outside of our observational time scales, studying the coevolution of soil-vegetation systems requires models that couple ecological, hydrological, and geomorphological processes and their drivers under one numerical framework (Istanbulluoglu, 2016).

Fire affects both vegetation and soil and is therefore likely to play a role in their coevolution. Fire changes the hydrological properties of the system by removing the canopy cover and changing the properties of the soil surface (DeBano, 2000; Inbar et al., 2014; Shakesby & Doerr, 2006), often making it more conducive to surface runoff (Nyman et al., 2010; Shakesby & Doerr, 2006) and more erodible (Noske et al., 2016; Nyman et al., 2013). These combined transient effects often result in a temporary increase in soil erosion of different magnitudes (Lane et al., 2006; Moody & Martin, 2001; Nyman et al., 2011; Prosser & Williams, 1998). Fire had also been shown to cause transient changes in the water and energy balance by altering the amount of water that infiltrates, is intercepted, and is transpired by the local forested systems (e.g., Nolan et al., 2014).

The role of fire in coevolution had been mainly investigated through its geomorphic effect on landform change (Benda & Dunne, 1997; Gabet & Dunne, 2003; Istanbulluoglu et al., 2004; Istanbulluoglu & Bras, 2005; Orem & Pelletier, 2016; Roering & Gerber, 2005). Here we point to an important feedback that is indirectly related to the geomorphic effects of fire that might have been overlooked. Soil depth holds an important role in controlling vegetation water holding capacity at a point by setting an upper limit to the plant available water capacity (Hahm et al., 2019). This implies that fire-driven erosion processes could potentially push soil-vegetation systems toward an alternative coevolved state by affecting its soil depth, if high fire-frequency is sustained over long time scales. Accounting for the processes that affect fire frequency is therefore necessary to fully untangle the role of fire in the development of the critical zone and landscape evolution.

In the landscape evolution literature, fire is often regarded as a "disturbance" and is modeled stochastically (Gabet & Dunne, 2003; Istanbulluoglu et al., 2004; Istanbulluoglu & Bras, 2005). However, evidence shows that long-term fire frequency depends on processes that control the availability of burnable fuel (Pausas & Bradstock, 2007) and their moisture state (Pausas & Bradstock, 2007; Taufik et al., 2017), making it a dynamic process that is coupled to the ecohydrological state of soil-vegetation systems. This implies that fire is tightly coupled within coevolutionary feedbacks both as a forcing and as a response variable. The modelling of a fire regime that is coupled to the hydrological state of the modeled systems has been explored in some dynamics vegetation models (e.g., Prentice et al., 2011; Thonicke et al., 2010, 2001; Yue et al., 2014). These models, however, do not include the geomorphic effect of fire and its consequences on processes and feedbacks in the coevolution of soil-vegetation systems. The full range of mechanisms by which fire can drive landscape change and coevolution therefore remains unclear. To address this limitation, a model is required that couples fire to both ecohydrological and geomorphic processes and enables the complex coevolution of vegetation and soil to be more robustly investigated.

The central highlands in southeastern (SE) Australia provide an ideal natural laboratory to investigate the role of fire in coevolution of soil-vegetation systems for several reasons: (i) It is home to some of the most flammable forests on earth; (ii) a gradient in temperate climate had resulted in a range of forest types with different fire regime (Cheal, 2010); and (iii) the lack of active uplift (Czarnota et al., 2014; Wellman, 1987) and the lack of glaciation below 1,200melevation during late Pleistocene (Barrows et al., 2001) narrow down the drivers and possible geomorphic processes that might have affected coevolution in the area.

The aims of this study were to (i) test the hypothesis that fire-related processes are critical to explain the variations in coevolved soil-forest systems across an aridity gradient in SE Australia and (ii) to identify key processes and feedbacks involved the coevolution process. To achieve the aims, we developed a numerical model (COevOLution of FLAMmable Systems—CoolFlameS) that simulates the coevolution of soil-forest systems and is underpinned by equations that couple fundamental ecohydrological, vegetation dynamics, and geomorphological processes. CoolFlameS was formulated, parameterized, and calibrated to simulate systems that are typical to SE Australia. The model was evaluated by comparing model outputs of system properties and process rates against observations, measurements, and published data.

2. Method

In systems where nutrient availability is not limiting plant growth, vegetation carrying capacity is driven by the supply and demand for water and the ability of the critical zone to store it (Hahm et al., 2019). While water supply and demand are often affected by climate and topography (Nyman, Sherwin, et al., 2014; Rasmussen et al., 2015), the ability of a system to store water depends on soil properties, primarily depth, but also texture, porosity, and organic matter content (Clapp & Hornberger, 1978; Saxton & Rawls, 2006). CoolFlameS is therefore based on the conceptual model whereby the structure of soil-forest systems at any point in time and space is controlled by the legacy of climatically driven feedbacks between vegetation, fire, and the ability of the system to hold moisture, which is dictated by soil depth (Hahm et al., 2019). In the proposed model (Figure 1a), soil moisture plays a central role in coevolution by controlling evapotranspiration (ET) and primary productivity (Montaldo et al., 2005; Rodriguez- Iturbe, 2000) and by ecohydrological control on the flammability of the system (Krueger et al., 2016). Soil water holding capacity in the model is determined primarily by soil depth and, together with climate (i.e., aridity), limits ET and biomass accumulation (Klein et al., 2015; Milodowski et al., 2015). Fire removes vegetation and causes changes to soil hydraulic properties (Certini, 2005; DeBano, 2000), which temporarily increases erosion potential (Nyman et al., 2013; Wagenbrenner et al., 2010). By this

approach, changes in climate and fire frequency can alter the depth of the soil and its water and biomass holding capacity and thereby drive coevolution.

In order to investigate the role of fire in the coevolution of soil-vegetation systems, it is necessary to couple fire with ecological, ecohydrological, and geomorphic processes. One of CoolFlameS major novelty is that it bridges the gap between landscape evolution, land surface models, and flammability through coupling ecohydrology, vegetation dynamics, and moisture deficits with geomorphic processes that control soil depth. This feature is missing from existing models. For this purpose, we employ a combination of new and well-established generic equations that represent ecohydrological, geomorphological, and forest dynamics processes as defined in existing literature. Moreover, in order to represent SE Australian systems appropriately, CoolFlameS was developed from deep ecohydrological and geomorphic understanding stemming from decades of intensive research and model development. Due to the long time scale and multitude of disciplines and processes involved in the coevolution of soil-vegetation systems, simplicity was prioritized over complexity during model development. To overcome this potential shortcoming, model components (i.e., ecohydrology, geomorphology, and fire) were evaluated by comparing simulation results with measurements and published values.

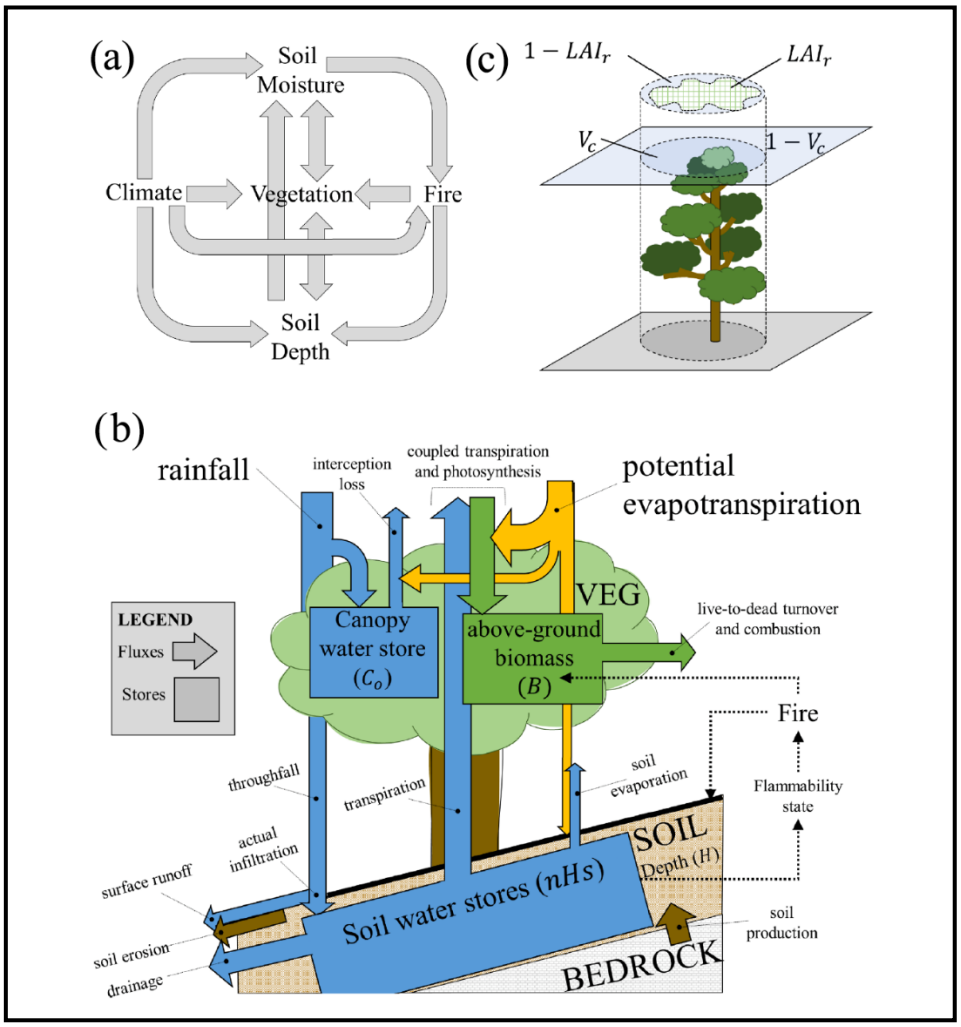

Figure 1-(a) A conceptual model that describes the coevolution of a coupled soil-vegetation system and (b) a schematic representation of what eco-hydrogeomorphic processes represented in CoolFlameS are, and the manner in which they are coupled. The dynamics of soil depth (H), soil moisture (nHs, where s is degree of saturation and n is porosity), and standing biomass (B) are expressed by a set of equations described in Inbar et al. (2020). Thick colored arrows represent fluxes of water (blue), energy (yellow), carbon (green), and minerals (brown). Thin dashed arrows point to the effects of soil moisture on fire and the effect of individual fire on forest cover and soil surface properties. An illustration of the spatial representation of the model system is presented in panel (c). The system surface area is divided horizontally into vegetated (Vc) and bare (1 − Vc) proportions. The vegetated area is further divided into covered (LAIr) and uncovered (1 − LAIr) proportions.

3. Results and Discussion

The performance of the model for the replicating observed patterns in soils, hydrology, fire and vegetation can be found in Inbar et al. (2020). A brief overview of the results and discussion is provided below.

3.1. Experiment 1—The Role of Fire in Coevolution (Evaluating the Hypothesis)

Our initial hypothesis that fire-related processes are critical to explain the variations in coevolved soil-forest system states across an aridity gradient is supported by the results (Figures 2a and 2b) showing that simulations with fire are more consistent with contemporary observation than simulations without fire. Model results show that the relative role of fire increases with aridity (Figures 2a and 2b). This can be explained by the more frequent fires and higher erosion rates as aridity increases. As aridity increases beyond the value of 1, so does the relative contribution of fluvial erosion rates, and this effect is further amplified by fire. The fact that the predicted projected canopy cover (Vc − ss) trends in a similar manner as soil depth (Hss) with respect to aridity can be explained by the change in biomass holding capacity of the soil, caused by the interaction between climate, fire, and the balance between soil production and erosion on soil depth (Hahm et al., 2019). The phenomenon that erosion controls vegetation patterns was observed by Milodowski et al. (2015) in the northern Californian Sierra Nevada, USA, where mean basin slope, a proxy of long term erosion rate, explained 32% of variance in above ground biomass, outweighing the effect of other factors, such as MAP, temperature, and lithology. The authors ascribed this effect to the reduction in water holding capacity due to the limitation dictated by thinner saprolite.

3.2. Experiment 2—The Role of Fire-Related Processes in Coevolution

Results indicates that among the three possible effects of fire that were explored, the role of post-fire reduction in Ic on Hss and Vc − ss was the largest (Figures 2c and 2d). Post-fire reduction in Ic can explain the increasing dominance of fluvial processes at aridity values >1, which result in shallower soils from simulations with fire beyond that point (Figures 2a and 2b). For aridity values <1, post-fire reduction in Ic is not sufficiently large to affect surface runoff. Consequently, on slopes supporting wet forest types, the relative role of diffusive processes is higher compared to that of fluvial processes. Post-fire erosion is often associated with loss of cover, increased hydrophobicity, and reduction in root cohesion (Istanbulluoglu & Bras, 2005). The latter process was not implemented explicitly in CoolFlameS but is implicit within the surface cohesiveness term. Our results indicate that long-term erosion is more sensitive to reduction in Ic (and consequential increase in surface runoff) than to the amount of sediment that is available to be transported after fire (−ΔCO; Figures 2e–2h). This can be explained by the interplay between the transport-limited nature of the non cohesive material and the time it is available for transport (Nyman et al., 2013).

The relative role of post-fire reduction in forest cover (−ΔLAI) was found to be lower than the two other processes examined (Figures 2). This result can be explained by the effect of the interaction between forest cover and infiltration capacity on fluvial erosion across the aridity gradient. At higher aridity values, background forest cover is always relatively low (Figure 2b), and the effect of the short-lived post-fire removal of vegetation cover on fluvial erosion is insignificant compared to the reduction in infiltration capacity during the same period. In wetter climates, vegetation density is higher and the effect of the temporary loss of cover on fluvial erosion rates can be significant. However, this effect is balanced by the high infiltration capacity, which keeps surface runoff rates low even after fire (Noske et al., 2016). These results indirectly suggest that the time to forest canopy recovery that explicitly depend on forest recovery trait has little impact on long-term coevolution of soil depth and vegetation in SE Australia.

In a study aggregating hundreds of post-fire infiltration and runoff measurements, Sheridan et al. (2015) found that post-fire runoff generation was highly correlated with aridity, such that more arid hillslopes, that often have younger and less developed soils, were associated with higher post-fire sediment yields. Our results indicate that the trend of Hss with aridity (Figure 2a) is determined mainly by the amount of surface runoff that is generated (which is controlled by the infiltration capacity) and how it affects post-fire fluvial erosion rates. Our model suggests that in a world without fire, the differences in soil depth and vegetation cover between dry and wet systems would have been significantly smaller to what is currently observed (Figures 2a and 2b). Other theoretical experiments had shown a significant increase in forest cover on the expense of grasslands in a world without fire (Bond et al., 2005). Our results highlight the possible role of fire-related changes in soil depth on global distribution of vegetation.

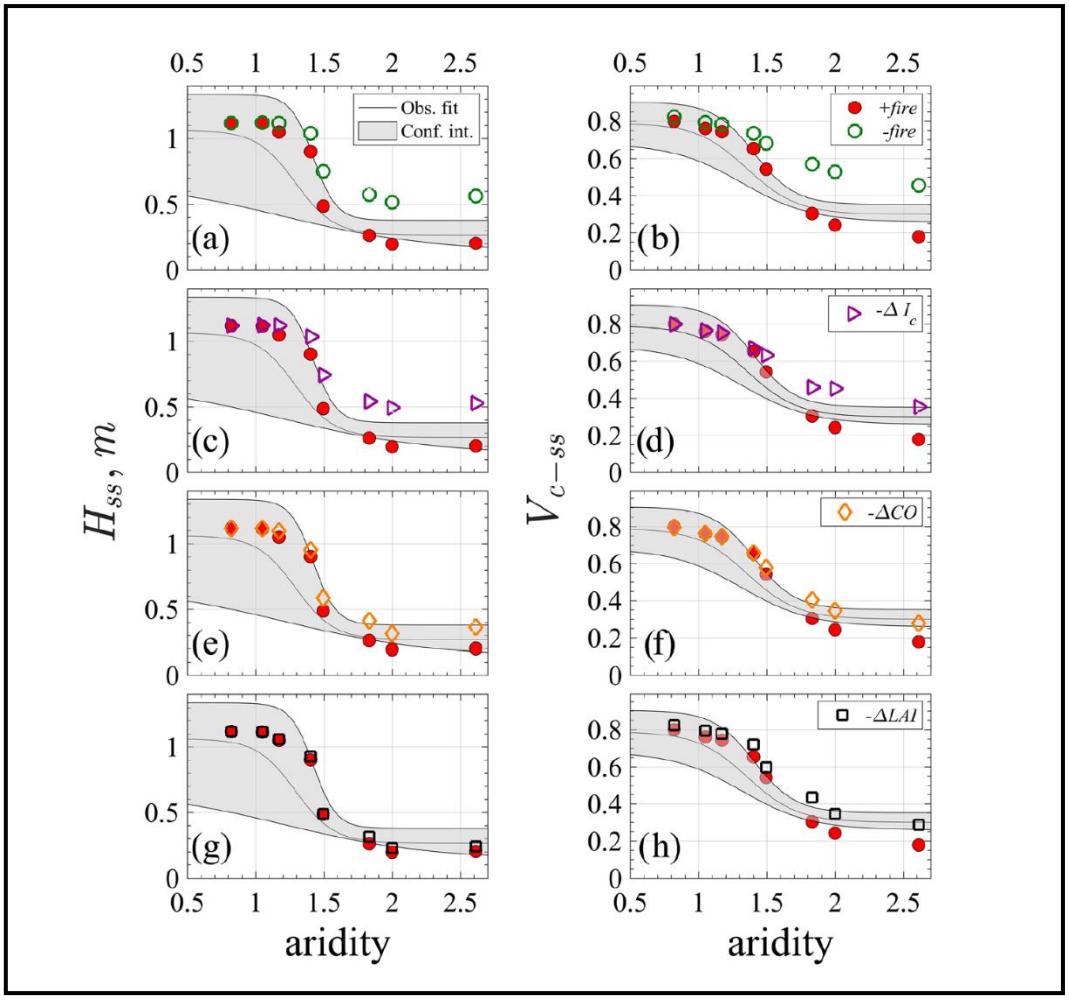

Figure 2-Modeled (Hss and Vc − ss) and observed soil depth and projected vegetation cover as a function of aridity for (a and b) simulations with (+fire) and without fire (−fire) and for simulations with fire but without post-fire changes in (c and d) infiltration capacity (−ΔIc); (e and f) soil cohesiveness (−ΔCO); and (g and h) canopy cover (−ΔLAI). The figure presents results for Experiments 1 (a and b) and 2 (c–h). Hss and Vc − ss values are plotted over functions and 95% confidence interval (gray area) fitted to soil depth measurements (Inbar et al., 2018) and remotely sensed vegetation cover using annual LANDSAT values (Tern AusCover, 2017) for areas near the three steepest sites (Table S5). Confidence interval for vegetation cover was generated for 1,000 randomly sampled values of remotely sensed vegetation cover.

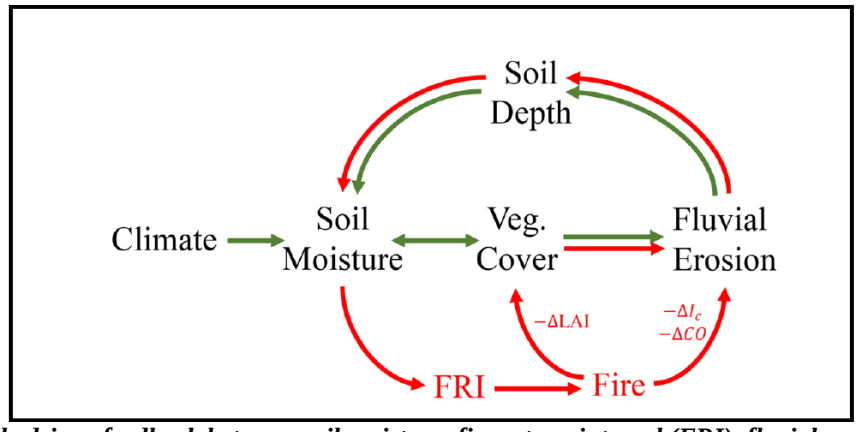

Figure 3-Climatically driven feedback between soil moisture, fire return interval (FRI), fluvial erosion, and soil depth. Red arrows represent effects that are related to fire and green arrows those that are not. In this feedback, long term change in climate affects soil moisture, vegetation cover, and fire frequency. This in-turn forces changes on soil depth and its water holding capacity by altering the rate of fluvial erosion, which feeds back to soil moisture, vegetation cover, and fire frequency. LAI is the leaf area index, Ic is the infiltration capacity of the soil (as affected by fire and water repellence), and CO is soil cohesiveness (altered by fire).

4. Conclusion

We used the flammable landscapes of SE Australia to evaluate the role of fire in the coevolution of soil-forest systems. Using a new numerical model (CoolFlameS) that represents the eco-hydro-geomorphic processes that are typical to SE Australian forests, we (i) tested the hypothesis that fire-related processes are critical to explain the variations in coevolved systems states across an aridity gradient; (ii) identified the dominant fire-related processes and feedbacks involved in the coevolution process. CoolFlameS showed good skill in predicting patterns of soil moisture thresholds ecohydrological partitioning, fire frequency distribution, surface runoff, and erosion and denudation rates across a gradient of aridity when compared to local measurements and published data (see Inbar et al. 20 for details). The validated model was then used to conduct numerical experiments to address the aims. The results showed that (i) the hypothesis was supported and that the relative role of fire in coevolution of soil depth and forests increased with aridity in the study area; (ii) among the three effects of fire examined, the relative role of post-fire reduction in infiltration capacity (and its effects of surface runoff and fluvial erosion rates) on coevolution of soil-vegetation systems was the largest, followed by post-fire reduction in soil cohesiveness and canopy cover; and the trajectory and magnitude of the coevolution of soil-vegetation systems are driven by a climatically driven feedback between soil, vegetation, and fire. For example, under a drying climate, long-term increase in post-fire erosion might contribute to more frequent fires and more erosion. We conclude that incorporating fire-related processes and feedbacks is essential when using models to investigate the critical zone and landscape evolution in fire-prone landscapes.

Wildfire risk prevention, fire resistant and resilient landscapes, fire smart, fuel management, EU Green Deal

Abstract

Pyrosilviculture and understory fuel management to reduce forest stand and landscape flammability represent loss-making interventions from an economic point of view. Consequently, prevention is carried out above all on public property and with public funds (e.g. Rural Development Programs), while the interest of the private individual for prevention interventions on aggregated areas is limited. These shortcomings do not allow to reach the distribution and the quantity of treated surface necessary to modify the fire regime and its impacts.

To solve this problem, we need initiatives that catalyse the interests of multiple stakeholders (economic actors, bodies responsible for territorial management and research, fire-fighter agencies) towards common goals. Moreover, we need to improve the cost-efficiency ratio of prevention through value-chains of products and services generated by preventive measures (e.g. payments for positive externalities and ecosystem services). Within the European project PREVAIL (PREVention Action Increases Large fire response preparedness) we analysed collaborative processes in the Mediterranean Basin between private and public actors that developed "smart solutions". Different sources of funding, including non-specific funds for prevention, offer additional economic resources to support preventive value-chains (e.g. RDP funds for agro-pastoral and forestry development, LIFE funds for habitat conservation, private investments, PES mechanisms). This paper analyses the key elements that characterise smart solutions for wildfire risk prevention in Southern EU: sustainability, cost-benefit ratio, synergies between sources of financing, inter-sectoral cooperation and integration between strategic prevention planning and multiple land governance objectives, innovation and knowledge transfer, and adaptive approach. A selection of solutions documented by the PREVAIL project and replicable in other contests will be presented and discussed.

1. Introduction

In recent decades in Europe there has been an increasing emphasis on multi-objective policies in fire risk management, integrating prevention, preparedness, response and recovery activities (Rego et al., 2010; Bacciu

et al., 2022). This allows for holistic territorial planning (Moreira et al., 2020), working more on the causes and promoting fire-smart territories (FST) (Tedim et al., 2016, Fernandes, 2013).

Fire risk prevention is pursued at European level with several strategies implemented by the European Commission, which contribute widely to building fire-smart territories by converging multiple objectives, e.g. Bioeconomy Strategy, LIFE programme, the EU Climate Change Adaptation Strategy and the Forestry Strategy. All of these are included in the Green Deal objectives, which allows for a synergistic approach to act on fire prevention in multiple aspects. Additional incentives for fire prevention can be provided through the Rural Development Programmes (RDPs). At the same time, active prevention have been promoted by an increasing number of local-scale initiatives especially in southern European countries. These noteworthy initiatives are characterised by the ability to adopt sustainable fuel management programmes and nature-based solution in a smart way, benefiting from policy instruments to functionally act on fire prevention with bottom up projects (Varela et al., 2020; Colonico et al., 2022). In this study, the most relevant initiatives based on management of fire prone territories were identified to define sustainable landscape-scale fuel management models for southern Europe and practical solutions for fire prevention at local level.

2. Selection and description of fire prevention initiatives

Noteworthy fire prevention initiatives were analysed in Greece, Italy, Portugal and Spain, given their particular susceptibility to fire (Moreira et al., 2020) and the high number of forest fire prevention programmes at local and regional scales (Varela et al., 2020). Data were collected through a survey filled in by the managers of the individual initiatives. The initiatives were analysed using five key criteria for the construction of FST (Tedim et al., 2016): (i) sustainability, (ii) cost efficiency in risk reduction, (iii) synergies and cooperation, (iv) knowledge exchange and transfer, and (v) adaptive management. Each initiative was assessed according to its "readiness degree" in the different fields of sustainable fire prevention, considering both its local potential and its ability to create synergies at European level. Finally, on a sub-sample of the initiatives, economic feasibility, stakeholder involvement, the legal framework and social and environmental awareness were assessed, showing strengths and weaknesses through a SWOT analysis.

Thirty-eight initiatives were identified in the four countries under analysis, distributed mainly in Spain (17 initiatives - 45%) and Portugal (11 initiatives - 29%), followed by Italy (7 initiatives - 18%) and Greece (3 initiatives - 8%). Most of these initiatives are implemented by public agencies (60%), financed largely by the Life Programme and Rural Development Programmes (RDPs), followed by initiatives with private investment. Most initiatives are characterised by being mainly related to Direct and Indirect fire prevention, with half of them focusing on Preparedness as an important step in disaster risk management. The initiatives were then evaluated according to their representativeness in each of the 5 evaluation criteria (from "Not at all represented" (0) to "Totally represented" (4)), creating a ranking that allowed for the identification of the most represented criteria and the most comprehensive solutions.

3. The fire-smart solution model

Through the analysed initiatives it is possible to build a general model for the creation of sustainable fire risk prevention programmes in southern European countries, based on some key elements useful for building smart solutions and planning fire resistant and resilient landscapes (Fig. 1).

Some of the fire smart solutions identified are based on the short supply chain as an added value to fire prevention, enhancing products through a label that certifies fire prevention activities. In fact, certification is a powerful tool at local, national and international level to recognise the multiple purposes of these initiatives, maximising cost-efficiency and producing socio-economic services (Varela et al., 2018). Fire prevention must also be recognised as a true ecosystem service, given its multiple roles in different social sectors and the importance of being integrated into territorial governance. Indeed, fire prevention is an essential tool for the creation of resilient and fire-resistant landscapes, which goes hand in hand with biodiversity conservation, water supply, mitigation of other natural hazards, landscape aesthetics, civil protection of infrastructure and local economic development. Another element that contributes to the fire smart solutions definition is the ability to create synergies between local development and international support, giving space for wide-ranging projects

(Proença, 2019). Finally, it is very important to consider the available knowledge on fire risk management at the time of planning functional local activities.

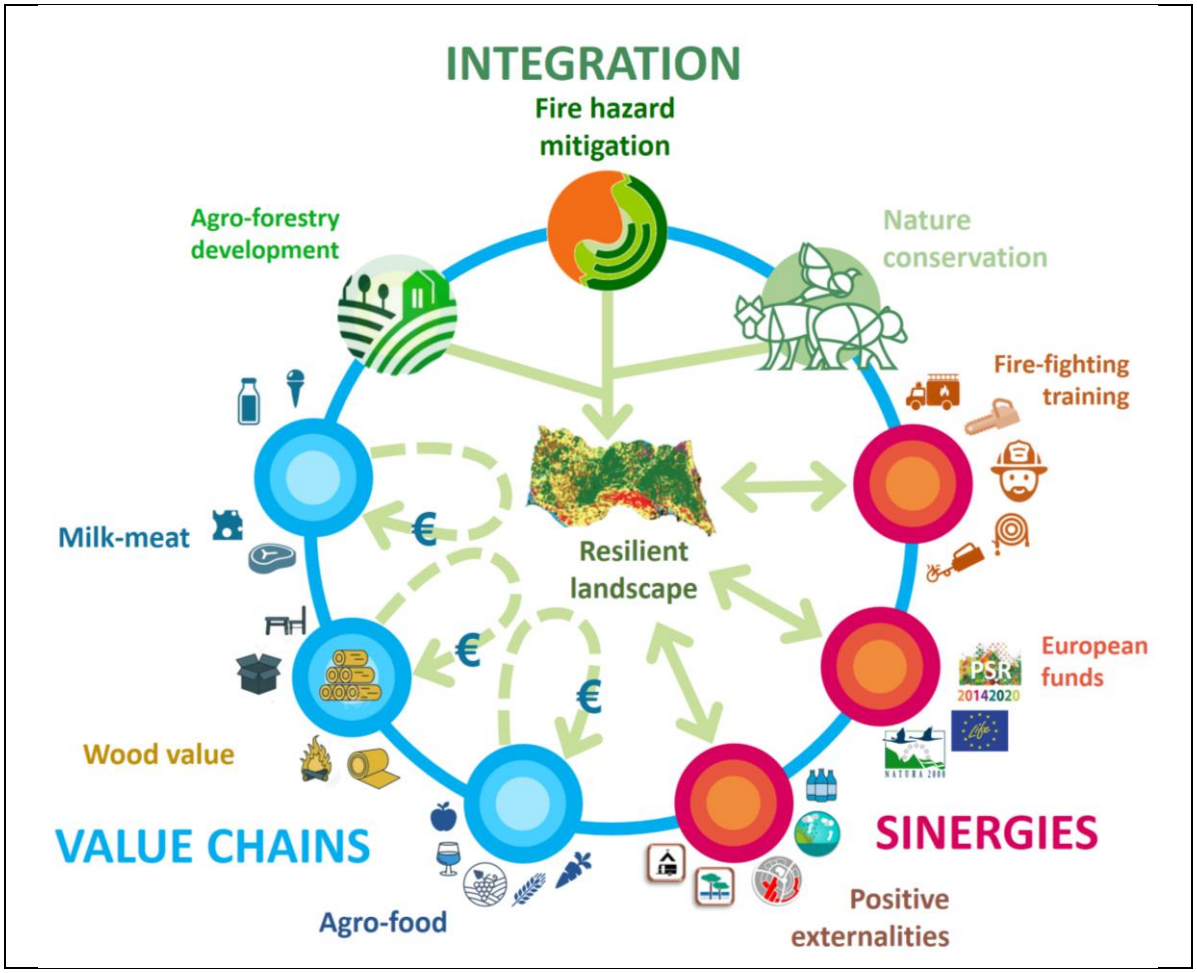

Figure 1 - Key emerging components that characterizes a smart-solution for wildfire risk prevention

4. Prospects for smart solutions replication under the EU Green Deal

The smart-solution model proposed here (Fig. 1) finds with the Green Deal the perfect opportunity to be implemented, acting on forest fire prevention at multiple levels to achieve objectives at the landscape and territory scale. The projects' continuity is also ensured by medium-long term incentives, being able to count on long-lasting projects to manage fire prone landscapes in the future. The ability to involve multiple actors and agencies is a further strength, addressing the European objectives of cooperation and transdisciplinarity and creating local networks essential for managing the territory as a whole (Rego et al., 2018). The fire smart solutions model we propose can also be of inspiration for the creation of calls and projects related to fire prevention funding at European level, being able to identify the key points of local interest, creating per example multi-measure calls for integrated territorial projects in high wildfire risk areas. These types of calls allow the convergence of multiple actors with different goals and objectives, which, with the right policy-management framework, can be able to create complex projects able to manage the territory in a holistic way and include fire risk mitigation.

5. Conclusions

Dealing with extreme fires requires interfacing with many areas simultaneously, such as the environmental and socio-economic factors (Ascoli et al., 2021; Fernandes, 2013; Tedim et al., 2018; Wunder et al., 2021). Indeed, to contain fire effects, it is necessary to adopt multi and transdisciplinary strategies that include the different components at stake (Tedim et al., 2016, Varela et al., 2020).

The smart-solution concept for fire risk management offers a framework to be applied at the local level by being able to take advantage of European tools to achieve its objectives. Their implementation at a local level and replication at a European scale is only possible through close communication between initiatives and institutions involved in fire risk and land management, including communities in a mutual exchange of good practices.

In conclusion, fire smart solutions are a concrete example of implementing the Green Deal locally in disaster risk management. The fundamental criteria of the fire smart solutions presented here derive from a direct exchange with local realities and define the most important aspects to create functional networks for fuel management. These criteria should be considered in the creation of future public funding calls for fire prevention projects, allowing a broad involvement of public and private actors to build solutions adapted to the real needs of marginal territories.

Fuel mapping, kriging, regression kriging, Rocky Mountains

Abstract

Forest fuel inventory, monitoring and mapping provide the basis for fuel management activities, including assessing wildfire hazards and risk, prescribed fire planning, designing silvicultural treatments, and predicting fire behaviour and effects at various scales. One of the most significant challenges in developing accurate surface fuel maps is capturing the spatial variability of fuel load within and between different fuel components. In this paper, we compare the performance of four spatial interpolation methods for estimating and mapping fine-scale fuel load in a dry mixed conifer forest in Colorado, USA. The four approaches are: classification, multiple linear regression, ordinary kriging, and regression kriging. We chose these methods because they are commonly used in ecological studies and cover a range of SIM including, non-geostatistical, geostatistical, and hybrid approaches. All SIM methods yielded unbiased fuel load estimates, with mean error within 3% of the observations with MAPE from 100% to 40%, depending on the specific fuel com-ponent and spatial interpolation method. Our results indicate that regression kriging was able to better capture the fine-scale spatial variability in fuel load compared to other spatial interpolation methods.

1. Introduction

Forest fuel inventory and monitoring provide the basis for fuel management activities, including assessing wildfire hazards and risk, prescribed fire planning, designing silvicultural treatments, and predicting fire behaviour and effects at various scales. The most commonly assessed attribute of the fuels complex is the load. Fuel load is a required input to nearly all fire behaviour and effects models and is a critical component of terrestrial carbon inventories and wildlife habitat assessment (Keane et al. 2013). Fuel inventory approaches have traditionally assumed that the spatial variability in fuel load is of little consequence for management decisions and thus focus on providing estimates of spatially averaged values for a given area. Yet, recent studies highlight that fine-scale variability in the fuels complex exerts considerable influence on many ecologically relevant fire behaviour and effects metrics (O'Brien et al. 2016). Directly mapping fine-scale fuel variability is costly and time-consuming, especially across large. To overcome these limitations, it is often necessary to utilize a spatial interpolation method (SIMs) to estimate the fuel load at unsampled locations and generate spatially continuous fuel load maps for wildfire hazard and risk assessments, prescribed fire planning, and silvicultural treatment design.

One of the most significant challenges in developing accurate surface fuel maps is capturing the spatial variability of fuel load within and between different fuel components. This variability arises due to interactions between the physical environment (e.g., climate, soils, and topography) and ecological processes (e.g., productivity, deposition, decomposition, and disturbances) that determine the balance between inputs and outputs of fuel across multiple spatial and temporal scales. One of the most commonly used approaches to capture this variability is to classify an area into unique groups using auxiliary, often remotely sensed data (e.g., vegetation type, topographic data, or land use classes) and then assign a fuel load to all areas of a given class based on the sampled data (e.g., Keane et al. 2013). A drawback of a classification approach is that the variability in the data is reduced to a few unique values. Other researchers have utilized regression-based approaches where the relationship between continuous auxiliary variables and the surface fuel load is used to predict values at

unmeasured locations. Previous studies have weak to nonexistent correlations between the surface fuel load and topographic and forest structural metrics (e.g., Lydersen et al. 2015; Hall et al. 2006) indicating that surface fuel maps developed based on these relationships may have limited accuracy. Recent studies have found that surface fuels exhibit strong fine-scale spatial autocorrelation, which, if taken into account, may increase fuel map accuracy (Keane et al. 2013; Vakili et al. 2016). Although previous research has acknowledged spatial autocorrelation in fuel load, only Pierce et al. (2009) have explicitly assessed the degree to which this improves spatial interpolation. Their results indicate that including spatial autocorrelation did not significantly improve fine-scale predictive accuracy compared to linear regression approaches. However, the scale of analysis used in this study was greater than the inherent spatial scale of surface fuel variability identified by Keane et al. (2013) and Vakili et al. (2016), which may have limited any potential improvements in predictive accuracy.

In this paper, we compare the performance of four SIMs for estimating and mapping fine-scale fuel load in a dry mixed conifer forest in Colorado, USA. The four approaches were: classification, multiple linear regression, ordinary kriging, and regression kriging. We chose these methods because they are commonly used in ecological studies and cover a range of SIM including, non-geostatistical, geostatistical, and hybrid approaches.

2. Methods

2.1. Study Area and Data Collection

We conducted this study on the 17.6-ha Pike Peak Forest Dynamics Plot (PFDP) located within the Pike and San Isabel National Forest of Colorado. PFDP was established in the summer of 2016 as a collaboration between Colorado State University and the USDA Forest Service for long-term forest dynamics monitoring. The PFDP is representative of mixed conifer forests in the southern Rocky Mountains with an elevation range from 2,781 to 2,833 m and a dry, continental climate with 660.7 mm of rain per year and a mean daily temperature ranging from -4.7° C in January to 14.0° C in August. Topographically, the PFDP is shaped by two significant ridges, one oriented west-east in the northern portion of the plot and another oriented northwest-southeast in the southwestern portion, and several smaller secondary ridges protruding from the two main ones. The dominant overstory vegetation for the study site includes ponderosa pine (Pinus ponderosa Lawson & C. Lawson) and quaking aspen (Populus tremuloides Michx.) on southern aspects, and mixtures of Engelmann spruce (Picea engelmannii Parry ex Engelm.), blue spruce (Picea pungens Engelm.), and Douglas-fir (Pseudotsuga menziesii (Mirb.) Franco) on northern aspects. The average density, basal area, and quadratic mean diameter at breast height for the site are 804 trees ha-1, 7.55 m2 ha-1, and 19.0 cm, respectively.

All trees in PFDP at least 1.37 m tall were mapped to the nearest 0.1 m and had their species, diameter at breast height, height, and crown base height recorded. To characterize the surface fuel load across the site, we double sampling procedure to estimate the fuel load of the 1-, 10-, and 100-hr dead down and woody fuels on 437 1-m2 irregularly located plots (Keane and Dickinson 2007, Tinkham et al. 2016). We estimated litter and duff fuel load using the depth-to-load method using locally derived bulk density estimates. Total fuel load was estimated by summing the individual component fuel loads (1- 10-, 100-hr dead, down and woody fuel, and litter and duff).

We used our stem-mapped overstory data along with remote sensing imagery to calculate two overstory (dominate species and basal area) and two topographic (percent slope and Beer's aspect) characteristics that we used as auxiliary information in spatial interpolation. Topographic auxiliary variables were calculated using a 10-m digital elevation model (DEM; available at nationalmap.gov; accessed 20 June 2022).

2.2. Spatial Interpolation Methods and Analysis

We compared the performance of four SIMs for estimating and mapping fine-scale fuel loads: classification (CL), multiple linear regression (LR), ordinary kriging (OK), and regression kriging (RK). For LR and RK, we included local basal area, cover type, aspect, and percent slope as auxiliary variables. The CL model was based solely on the predicted cover type. For OK and RK, we predicted each fuel component separately with fitted auto-semivariograms.

We assessed the comparative performance of each SIM with a k-folds cross-validation approach. We chose the following statistics to assess SIMs' performances: mean error (ME); mean absolute error (MAE); mean absolute percent error (MAPE); and Pearson's correlation coefficient between observed and predicted values.

3. Results and Discussion

All SIM methods yielded reasonably unbiased fuel load estimates, with mean error within 3% of the observations (Table 1, Fig. 1). Except for RK predictions for the total fuel load, all approaches resulted in a slight underprediction bias. Although a minimal bias was associated with all SIM, OK consistently resulted in the greatest bias.

Table 1. Summarization of cross-validation from spatially interpolating surface fuel components' loads in the Pike Forest Dynamics Plot.

Component	Method	ME	MAE	MAPE	$r_{obs,pred}$
1-hour	CL	0.001	0.192	67%	0.36
	LR	0.001	0.193	68%	0.40

The MAPE varied from over 100% to around 40%, depending on the specific fuel component and spatial interpolation method (Table 1). The two Kriging based approaches evaluated produced lower MAPE than either CL or LR, with RK producing the lowest MAPE across all fuel components. However, there were relatively small differences in MAPE among the SIM, with the best-performing SIM reducing MAPE between 2 and 8% compared to the worst-performing SIM. The Pearson Correlation coefficients ranged from 0.07 to 0.63, depending upon the fuel component and SIM. RK resulted in the greatest Pearson correlation coefficient of all SIM tested regardless of the fuel component.

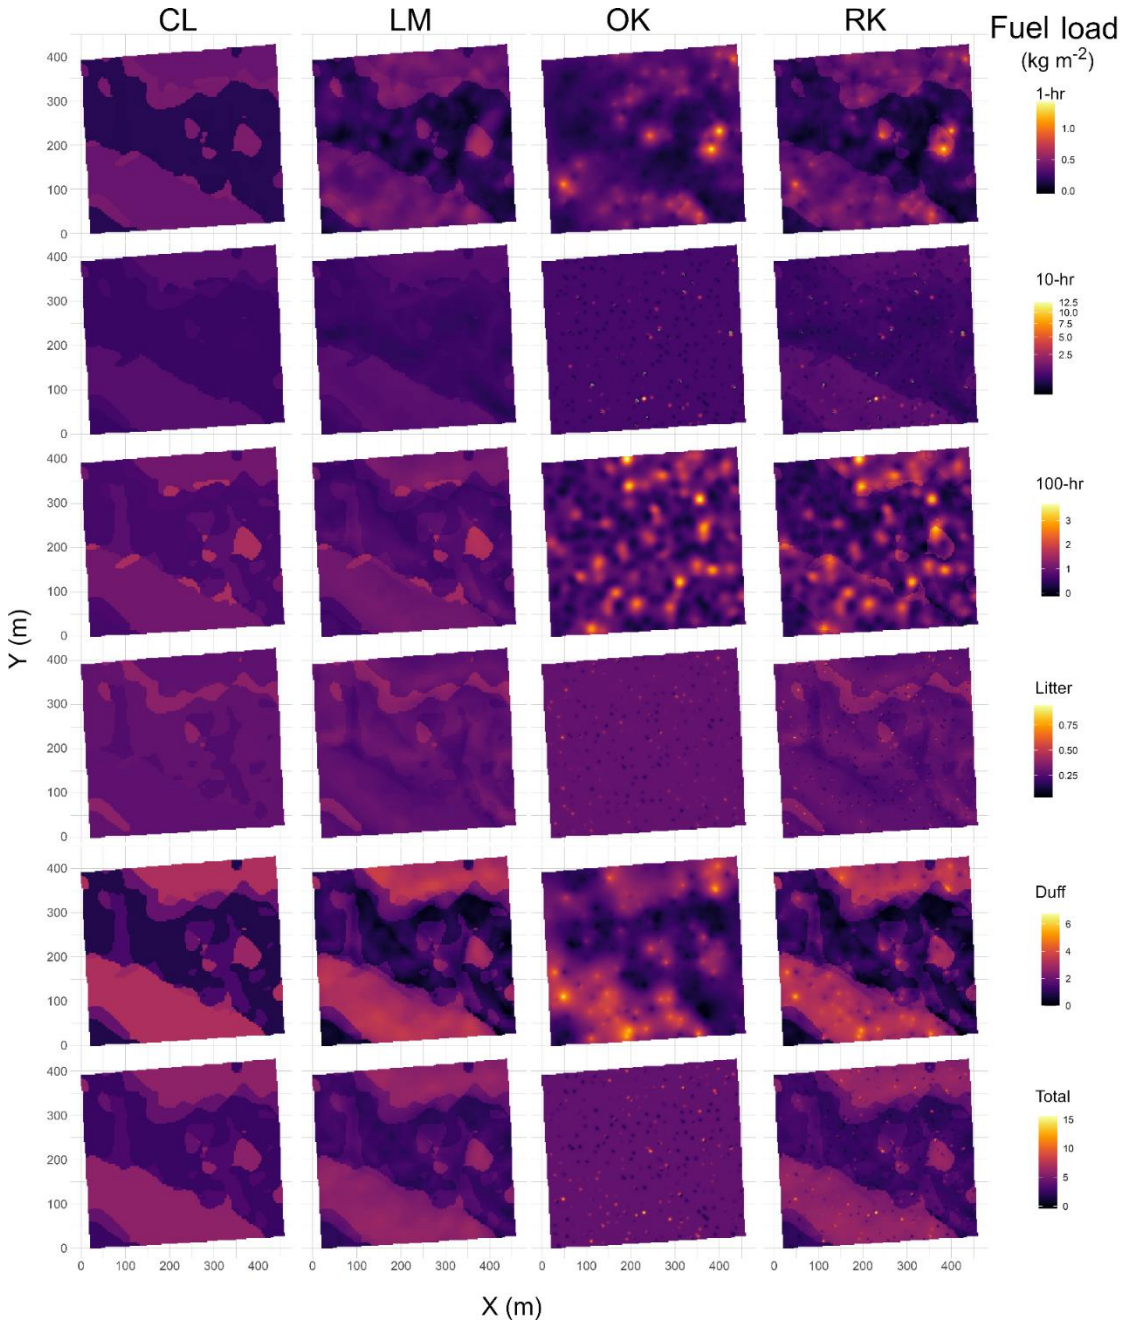

Fig. 1 Fuel load maps predicted in the Pike Forest Dynamics Plot by four spatial interpolation methods of 1-hour, 10-hour, and 100-hour woody fuels, litter, and duff surface fuel components, and total fuel load.

Fuel maps are commonly utilized by fire and land managers across a range of spatial scales to assist with fire suppression planning, locating and designing wildland fuel treatments, evaluating fire hazard and risk. Fine scale variation in fuel characteristics is increasingly recognized as important driver of fire behaviour and effects and as such, there is a growing demand for high-resolution maps of the wildland fuels. Of the four SIM evaluated, regression kriging provided the best overall estimation of surface fuel load for all fuel components. our findings indicate that RK was able to better capture the fine-scale spatial variability in fuel load and therefore is the preferred method to produce spatially interpolated fine-scale fuel maps.

Knowledge management – prevention – harmonized – fire – analysis.

Abstract

Faced with an increase in risks all over the the planet due to climate change and land management, scientists and operational staff are trying to find answers to adapt to "increased risks". Wildfires are a global problem that impact societies and the environment. Over the past decade, the number of wildfires has been unprecedented, creating great uncertainty for emergency responders.

The results of these events are catastrophic impacts on life, property and the environment, e.g. Portugal 2017, Greece 2018, Spain 2019 in Southern Europe and Sweden 2018, Germany 2019, United Kingdom 2019 in Central and Northern Europe. Science proves that the risk of forest fires is increasing across Europe and that climate change is making the situation worse.

Even countries that have never seen forest fires as a real threat to society and the environment will need to master firefighting. During a fire, European firefighting systems are exposed to demanding situations that help to understand fires and improve firefighting systems. Irrespective of the ability of some European emergency services to transfer acquired knowledge on wildfire management, extracting lessons learned and converting them into applicable knowledge for future events in the same or different countries is not sufficiently taken into consideration.

Some countries have created knowledge networks around fire behavior analysis that operate at regional and national level (e.g. the FAST team in Spain, the Wildfire Tactical Advisor group in the UK and specialist centers in the Council Europe such as the Global Fire Monitoring Center in Germany and the European Forest Fire Center in Greece). A European forest firefighting knowledge sharing network is needed to extend existing regional and national knowledge, translate it with the mission of two-way learning to generate improved overall European emergency response capabilities in case of fire. With expertise in knowledge management (1), ENSOSP has joined forces with other recognized partners to develop a knowledge network (2) specific to forest fires (3).

1. Expertise in knowledge management…

The National School of Fire Officers of France (ENSOSP) has been working for several years to formalize knowledge and skills in the fields of civil security for training, prevention, operational management, feedback … This is part of the development of knowledge management defined as a process that aims to optimize and develop skills by establishing a culture of learning. In other words, it consists of the accumulation and sharing of skills, knowledge resulting from training or experience. Since 2008, ENSOSP has created a platform for sharing knowledge and other resources such as feedback to enable all firefighters in France to optimize their knowledge, which is unified and standardized in order to learn continuously. Thus, PNRS[1] is a free accessible platform with an unprecedented collection and exchange of documents, knowledge and techniques for firefighters in France. This portal has gradually established itself in the civil security ecosystem, increasing from 40,500 visits in 2010 to 586,000 visits in 2021, an increase of 90%.

[1] http://pnrs.ensosp.fr/

2. …faced with the need for the emergence of a knowledge network…

In 2020, the European Commission launched a call[2] for EU proposals in the field of civil protection under the EU Civil Protection Knowledge Network. This call is launched in line with the Annual Work Program 2020. It aims to fund projects that support and enhance EU knowledge building, partnership building and knowledge networking on civil protection. This requires better and faster disaster risk management through consolidated prevention, preparedness and response activities which can only be achieved through enhanced cooperation and better coordination between a wide range of stakeholders across countries. The mission of the UCPM Knowledge Network is to bring together civil protection and disaster management actors and institutions in order to improve the overall knowledge situation and foster the EU's capacity to respond to disasters. The main objectives of the knowledge network are:

- act as a bridge between knowledge holders relevant to the UCPM;
- strengthen coordination, cooperation, compatibility and complementarity between capacities and improve the competence of experts;
- collect and share knowledge, experience, expertise, skills, lessons learned and best practices in close cooperation with civil protection authorities and disaster management authorities and knowledge centres;
- stimulate research and innovation and encourage the introduction and use of new appropriate technologies;
- strengthen links between civil protection and disaster risk management actors and develop a common understanding and culture of prevention, preparedness and response.

3. …at the service of the fight against forest fire.

Drawing on its experience in knowledge management, ENSOSP jointly with the Pau Costa Foundation put together a response to the call for projects by targeting the outcomes relating to the following objectives:

- To support civil protection and disaster risk management actors that promote and facilitate the development, dissemination and exchange of knowledge, good practices and expertise (specific objective n°1).
    - 1.1 Good practices, recommendations, and lessons in prevention, preparedness and response are collected, reviewed, shared and applied during exercises and real-time emergencies.
    - 1.2 Expertise in civil protection and risk disaster management is further developed and shared.
- To support new and consolidate existing partnerships in civil protection and disaster risk management that enhance cooperation and synergies in prevention, preparedness and response. These two objectives will be targeted in a specific operational field, the prevention and fight against fires in natural areas (specific objective n°2).
    - 2.1 Existing structures of relevant civil protection and disaster risk management actors are strengthened and expanded.
    - 2.2 New partnerships are established.

Initiated in January 2021 and ending in June 2022, the European project Advanced Fire Analysis Network (AFAN[3]) co-financed by the European Commission is conceived as the feasibility study of the future global structure, pooling the knowledge generated by the various centers of excellence and networks of existing actors in the analysis of vegetation fires. Forest fires are in fact the area illustrating the development, dissemination and exchange of knowledge, good practices and expertise identified (specific objective no. 1) while relying on existing partnerships, in order to strengthen and make them sustainable (objective no. 2). The consortium has been wisely designed to have complementary skills and geographical reach. For France, the mutual work between Ensosp and the Entente de Valabre makes it possible to combine expertise, training, research and innovation in the field of forest fires with knowledge network projects financed by the EU (DG HOME) such

[2] https://ec.europa.eu/info/funding-tenders/opportunities/portal/screen/opportunities/topic-details/ucpm-2020-kn-ag
[3] https://fireanalysisnetwork.eu/

as the FIRE-IN, MEDEA, Driver+ and other projects. The objective of the AFAN project is to strengthen existing regional, national and international knowledge and capacities, to transfer them with the aim of shared mutual learning and to create the basis of an operational network, based on trust and support to generate an overall improvement of the European Civil Protection Mechanism. This requires the development of a methodology, a process of knowledge capitalization in the field of forest fires, the multiplication and aggregation of partnerships of knowledge networks in the field of forest fires as well as the valuation of the results (experimentation with collaborative platforms and new technologies to prevent and fight forest fires).

Furthermore, the "new" discipline of fire analysis collects information about wildfires and transforms it into knowledge. This knowledge is used during emergencies to provide advice and guidance for decision-making at the strategic, tactical and operational levels of fire management. Six major themes are defined in the analysis of fires, namely, interpreting climate-meteorological data, establishing and monitoring the evolution of the fire, its behavior, the parameters influencing its spread, producing a tactical response and developing a strategic vision of the event.

To fill all these gaps, the AFAN project proposes the drafting of several guidelines[4] on the skills of a fire analyst, on the tools, sciences and good practices used for the analysis. In addition to these guidelines, a map[5] showing the existing expertise capacity across Europe was developed over questionnaire and dissemination during the project. The map, freely accessible on the AFAN website and updated each time a new answer is received, gather 24 structures over Europe. It gives from the address information to the fire analysis profile. To put the expert in touch and facilitate immediate content sharing, AFAN also created a Telegram group where experts could exchange on their situation and share data, information and knowledge.

The AFAN project has also created of a database[6], listing the tools and good practices on which fire analysis relies, depending on the countries of the consortium. The database is currently enriched, it must constantly evolve and it is supported by a guideline describing the different tools. Thus, in addition to being shared in the guidelines, the knowledge is integrated into a database which will eventually make it possible to identify the tools and best practices used by operational staff, by fire experts in Europe, facilitating interoperability between countries in the long term, but also the creation of working groups within the countries that will be most affected by the fires.

4. Conclusion

Through the AFAN project, this document describes how knowledge management can be a factor in improving the prevention and fight against wildfires. The operational network enables the transfer of specialist knowledge between countries, the sharing of experiences, science, new challenges and solutions, offers assessment for emergency management and proposes Europe-wide actions to face future challenges of forest fire fighting. More specifically, AFAN focuses on improving fire analysis skills and capabilities, sharing technological tools, science and best practices available for forest fire management. Finally, it permits to master remote assessment practice to be implemented across Europe and for external operations. Completion of the project would create a coherent network of forest fire analysis capabilities comprising actors from across Europe, with harmonized fire response capabilities and a set of tools (e.g. guidelines, training, tools, reports) for European fire managers and civil protection organizations wishing to strengthen their operational and analytical capacities in the field of forest fire management.

Risk, Vulnerability, Consequence, Probit, Wildland-Urban Interface

Abstract

This work describes a methodology to estimate the risk of a wildfire damaging an electrical substation operated by Chilquinta Distribución S.A. (a Chilean utility company) in the Wildland-Urban Interface (WUI) of Valparaiso, Chile. A Wildfire Quantitative Risk Analysis (WFQRA) framework is proposed for this purpose, where risk is defined as the product between the probability of a wildfire reaching the WUI and its consequences. The former is determined with an event tree, a tool where an outcome probability is calculated as the product between the frequency of an initiating event (ignition of a wildland fuel) and the probabilities of passing along a series of intermediate events between the initiating event and the outcome. The intermediate events are burned area > 1 ha, ambient temperature > 22°C, wind velocity > 4 m/s and burn probability > 0.01, for which this event tree anaylsis gives $7.36 \cdot 10^{-5}$ events/year as the probability of a wildfire reaching the WUI. On the other hand, the analysis of consequences requires determining asset vulnerability to a thermal insult, which is the quantitative relationship between thermal exposure of the asset and the damage experienced by it. This vulnerability is assessed by expressing it in terms of a probability of failure (ignition) for different doses of thermal radiation, i.e., a dose-response curve of sigmoid shape. To produce this curve, a probit equation is determined from flammability data of PMMA, a material that served as a proxy for the actual materials within the electrical substation. Thermal exposure of a target within the substation is calculated from fireline intensity and flame length results obtained with FlamMap simulations carried out on a simplified landscape representing the study area along with a simplified model for heat flux from the wildfire front to the target. Ignition probabilities are estimated with this vulnerability model for two wildfire scenarios in the substation. Wildfire risk is thus estimated as 10^{-6} to 10^{-5} events/year, or equivalently, one event every 100,000 to 1,000,000 years.

1. Introduction

Wildfires in Chile have caused significant human, ecological and economic damage to cities, protected areas, and the economy (Reszka and Fuentes 2014; Bowman et al. 2018). Climate change is expected to increase the occurrence and severity of these events (McWethy et al. 2018; Pausas and Keeley 2021; United Nations Environment Programme 2022). A need for tools to address wildfire risk quantitatively has been recognized, to support decision-making for wildfire safety in the Wildland-Urban Interface (WUI) (Finney 2005; Johnston et al. 2020; Miller and Ager 2013; Oliveira et al. 2021), following modern wildfire management paradigms (Moreira et al. 2020).

The goal of this work is to estimate wildfire risk to an electrical substation operated by Chilquinta Distribución S.A., a Chilean utility company. For this purpose, a methodology based on the Quantitative Risk Analysis (QRA) framework (Pasman and Reniers 2014; Center for Chemical Process Safety 2000) is proposed, where risks are defined as the product between the probability of incident outcomes and their consequences. The Wildfire Quantitative Risk Analysis (WFQRA) framework is illustrated in Fig. 1, based on the work by Johnston et al. (2020).

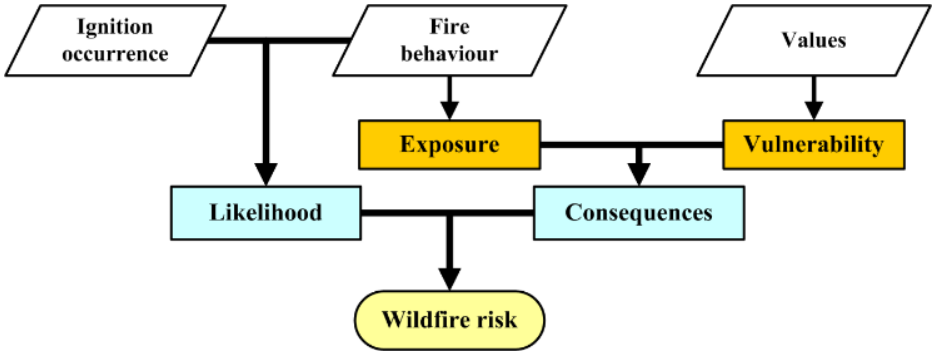

Figure 1- Relations between the definitions adopted for the WFQRA methodology (Johnston et al. 2020).

2. Methodology

The WFQRA can be used to estimate risk at any point of a study area but is used in this work to analyze a small segment of the WUI occupied by the electrical substation. The initiating event of any wildfire is a wildland fuel ignition that develops into sustained combustion of the surrounding fuels. The outcome is the arrival of the wildfire to the WUI. Risk is thus estimated as:

$$R_{x,y} = P_p P_d \tag{1}$$

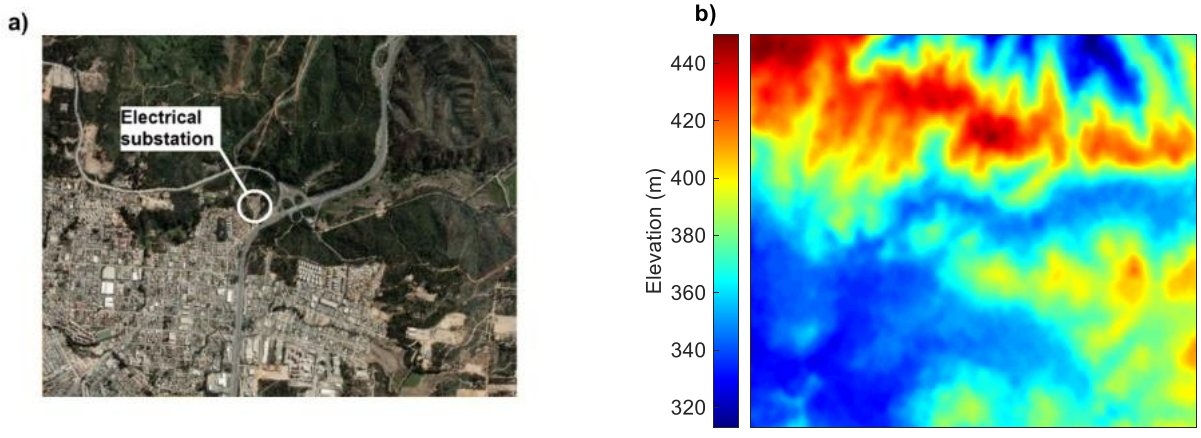
where P_p is the probability of a wildfire reaching point (x,y), and P_d is the probability of a target sustaining a damage, target ignition in this case.

The electrical substation is in the WUI that surrounds the cities of Valparaíso and Viña del Mar (33°06'30"S, 71°33'32"W; Fig. 2a). Fig. 2b shows a Digital Elevation Model (DEM) of the study area, acquired by the ALOS satellite with resolution of 12.5 m per pixel. Maps for slope and aspect (Figs. 2c and 2d) were produced with this DEM. Fig. 3 shows histograms from hourly data recorded by a weather station located near the study area during the entire year 2020. A survey made by the Chilean Forest Service (CONAF) indicates that *Eucalyptus globulus* plantations are the main fuel in the study area.

Calculating the likelihood of a wildfire reaching the WUI (P_p) requires estimating an historic ignition frequency (f_{ig}), and the conditional probability of a wildfire spreading to the WUI ($P_{p|ig}$), which is predicted with an event tree (Andrews and Dunnett 2000). Therefore:

$$P_p = f_{ig} P_{p|ig} = f_{ig} \prod_{j=1}^{N} P_{p|ig,j} \tag{2}$$

where $P_{p|ig,j}$ is the probability of an intermediate outcome after the j-th node in the event tree, and N is the number of nodes in the branch leading to the outcome of interest.



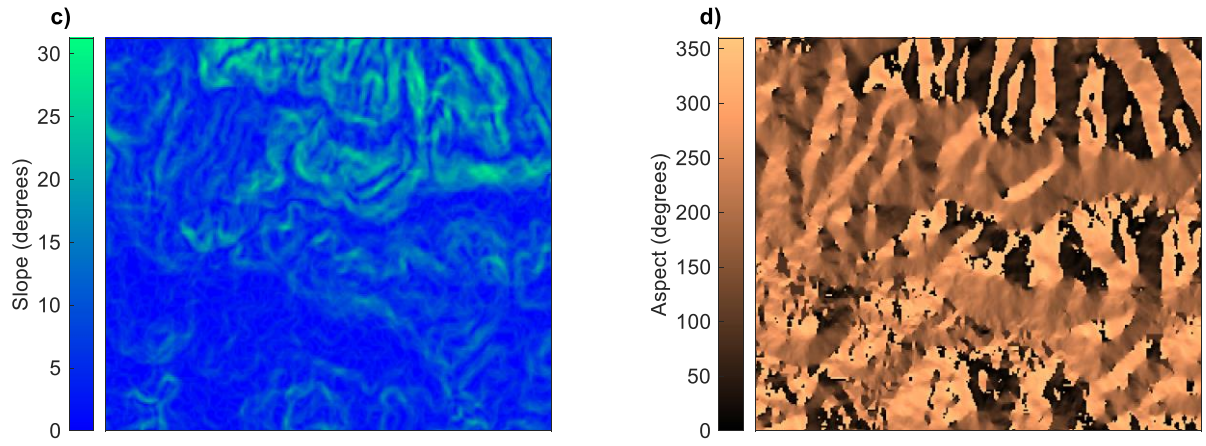


Figure 2- Study area: a) satellite image; b) DEM; c) slope, and; d) aspect map.

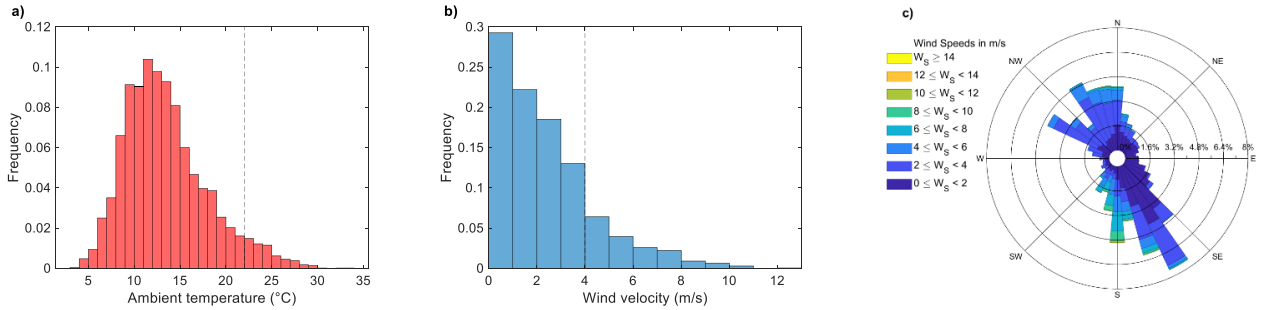

a) ***b)*** ***c)***

Figure 3- Histograms from hourly data recorded by a weather station near the study area during all year 2020: a) temperature; b) wind velocity, and; c) wind rose.

Wildfire consequences depend on both the exposure and the vulnerability of a target to a radiative heat insult. The vulnerability of the target is the quantitative relationship between thermal exposure and target damage. In fires, for damage to occur the target must ignite (a binary response: ignition/no ignition), thus a way of evaluating asset vulnerability is to express it in terms of an ignition probability P_d for different radiant heat fluxes, resulting in a dose-response curve that generally takes a sigmoidal form, which can be converted to a linear function with a probit analysis (Finney 1947). The probit function is the inverse of the cumulative distribution function (CDF) of the standard normal distribution. Therefore, if a dose-response curve is modelled as a normal CDF with mean μ and standard deviation σ, the relation between response P_d and probit variable Y is:

$$P_d(Y) = \frac{1}{\sigma\sqrt{2\pi}} \int_{-\infty}^{Y-5} \exp\left(-u^2/2\right) du \tag{3}$$

where $u = (D-\mu)/\sigma$ and D is a thermal dose. Note that Y is in the upper limit of the integral in the right-hand side of Eq. 3, where 5 is subtracted to Y so that the conversion gives $Y = 5$ when $P_d = 50\%$ (Finney 1947). Since the CDF and its inverse are not available in closed form, computing the probit function requires approximations, e.g.:

$$P_d(Y) = 50\left[1 + \frac{Y-5}{|Y-5|} \cdot \operatorname{erf}\left(\frac{|Y-5|}{\sqrt{2}}\right)\right] \tag{4}$$

By converting the measured cumulative responses into probit variables with Eq. 4, the dose-response curve in terms of the probit variable becomes linearly related to the logarithm of the dose:

$$Y = k_1 + k_2 \cdot \log(D) \tag{5}$$

where k_1 and k_2 are constants from a linear regression. This method is used to evaluate the vulnerability of people (Center for Chemical Process Safety 2000) and vessels (Cozzani et al. 2005) to thermal exposures, and

it is implemented in this work to develop a vulnerability model from flammability data. Considering that electrical equipment is usually manufactured in metallic alloys and polymers, and that the latter are most vulnerable to fires, PMMA is selected as a proxy fuel to develop this model from data available in the literature (Bal and Rein 2011).

For estimating exposure, a configuration consisting of a rectangular solid flame front at some distance from the target within the electrical substation is considered (Fig. 4). Assuming the flame front as a blackbody and neglecting atmospheric transmissivity, radiant heat flux on the target is:

$$\dot{q}_r'' = F\frac{X_r b I_f}{A_f} \tag{6}$$

where F is the view factor between the wildfire front and the target, estimated as described by Morandini et al. (2013), X_r is radiant fraction (assumed equal to 0.3, Pinto et al. 2020), b is rectangle width, H is flame length, A_f is rectangle surface ($A_f = b \cdot H$), and I_f is fireline intensity. Flame length and fireline intensity were determined from FlamMap 6.1 simulations (Finney 2006), using the topography, weather, and fuel models of the study area as inputs. A simplified landscape consisting only of an urban and a wildland area was used for these simulations, with fuel models 91 and 163 from the classification developed by Scott and Burgan (2004) being assigned to these areas. Simulations considered crown fire modeling with constant values for stand height (15 m), canopy base height (1 m) and canopy bulk density (0.2 kg m^{-3}), and a uniform wind field (5 m/s at 150°, cf. Figs. 6d and 3c). Burn probability was also estimated with FlamMap by simulating 1,000 fires ignited at random locations in the study area, considering the same resolution as in the DEM map, crown fire modeling with the same conditions described above, maximum simulation time of 50 min per ignition and spot probability set at 0.5. Although firebrand production is an important pathway for rapid wildfire propagation via spot fires (Fernandez-Pello 2017; Manzello et al. 2020), this phenomenon was not addressed with further detail, since the aim of this work is to demonstrate the usefulness of the WFQRA framework applied to the present case.

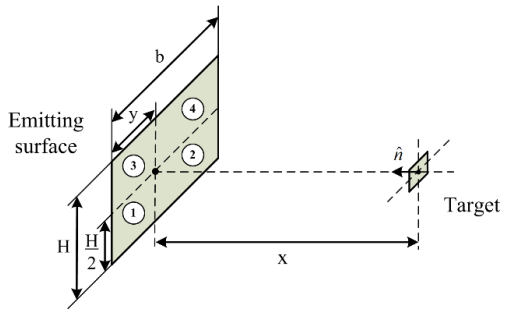

Figure 4- Configuration assumed to determine the view factor between the wildfire front and a differential target.

3. Results

3.1. Likelihood of a wildfire reaching the WUI

Figure 5 shows the event tree proposed to estimate the probability of a wildfire reaching the WUI, which gives P_p = 7.36·10^{-5} events/year. Ignition frequency is estimated at 239 events per year from CONAF historical ignition data circumscribed to the Valparaíso and Viña del Mar municipalities between 2002 and 2019 (Fig. 6a). As this estimation corresponds to the total area of the two cities (52,320 ha), this frequency is scaled down to the study area (996 ha), giving f_{ig} = 239·996/52,320 = 4.55 events per year. Additionally, CONAF has registered the resulting burned areas from these ignitions (Fig. 6b), along with ambient temperature and wind velocity recorded when these ignitions occurred (Figs. 6c and 6d). In the event tree, the probability of a fire resulting in burned area > 1 ha is 0.166 (calculated as 1 – 0.834 = 0.166, where 0.834 is the frequency of burned area between 0 and 1 ha in Fig. 6b), and the probabilities of having representative temperature and wind magnitudes during a wildfire are estimated by selecting their most frequent ranges in the 2002-2019 period (22 to 24°C in Fig. 6c and 4 to 6 m/s in Fig. 6d, respectively), and then summing the frequencies corresponding to temperatures and wind velocities higher than 22°C and 4 m/s in 2020 (Figs. 3a and 3b), giving 0.056 and 0.170, respectively. Figure 7 shows burn probability estimated with FlamMap, from which an average of 0.010 in the substation perimeter is considered for the event tree.

Initiating event	Is burned area > 1 ha	Is ambient temperature > 22°C?	Is wind velocity > 4 m/s?	Burn probability	Outcome
				Yes	Propagation to the WUI
			Yes	0.010	0.0000736
		Yes	0.170	No	No propagation to the WUI
	Yes	0.056		0.990	0.00714
Ignition of a wildland fuel	0.166		No		No propagation to the WUI
4.55			0.830		0.03521
(events/year)		No			No propagation to the WUI
		0.944			0.71239
	No				No propagation to the WUI
	0.834				3.79496

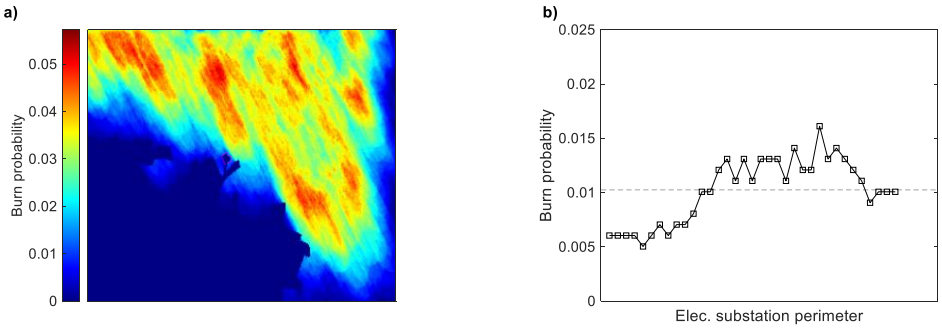

Figure 7- Burn probability: a) map; b) profile in the electrical substation perimeter.

3.2. Vulnerability

A probit equation for the vulnerability of PMMA is determined from the experimental data shown in Fig. 8a (Bal and Rein 2011), where no unique value of a critical heat flux is observed, because these data include results from several authors, heat losses from the specimens induce non-linearities (Sabi et al. 2018, 2021), and a critical heat flux criterion depends on the experimental configuration and procedure (Mindykowski et al. 2011). Instead, there is a transition from a low (~1%) to a high ignition probability (~99%). To estimate the heat fluxes corresponding to these ignition probabilities, it is assumed that data in Fig. 8a is bounded by two curves that tend to these heat fluxes when time to ignition increases:

$$t_{ig,lower} = C_{lower} \cdot (\dot{q}_e'')^{\gamma} \tag{7a}$$

$$t_{ig,upper} = C_{upper} \cdot (\dot{q}_e'')^{\gamma} \tag{7b}$$

where C_{lower} and C_{upper} are two constants, and γ is a common exponent (Sabi et al. 2021). By calculating the logarithm of each side in Eqs. 7a and 7b:

$$\log(t_{ig,lower}) = \log(C_{lower}) + \gamma \cdot \log(\dot{q}_e'') \tag{8a}$$

$$\log(t_{ig,upper}) = \log(C_{upper}) + \gamma \cdot \log(\dot{q}_e'') \tag{8b}$$

Exponent γ is determined with a linear fit to data in Fig. 8b, giving γ = -2.6044. Constants C_{lower} and C_{upper} are estimated by adjusting two bounding curves to the data and determining their intersections with the *y*-axis, giving C_{lower} = exp(12.5) = $2.68 \cdot 10^5$ and C_{upper} = exp(15.3) = $4.41 \cdot 10^6$. With these results, Fig. 8a shows the lower and upper fits to the data expressed by Eqs, 7a and 7b. By setting t_{ig} = 3000 s in Eqs. 7a and 7b, the limiting critical heat fluxes are 5.6 to 16.4 kW/m^2 (dashed lines in Fig. 8a): to the left of this range there is a no-ignition region, and to the right, ignition probability approaches 100%.

Since probit values corresponding to 1% and 99% are 2.67 and 7.33, respectively, a probit equation is obtained by applying a linear fit to these probits as a function of the logarithm of the two limiting heat fluxes (log(5.6) = 1.72 and log(16.4) = 2.80, Fig. 8c), resulting in:

$$Y = -4.8014 + 4.3368 \cdot \log(\dot{q}_e'') \tag{9}$$

Using Eq. 4, Fig. 8d shows ignition probability of PMMA in terms of the logarithm of heat flux.

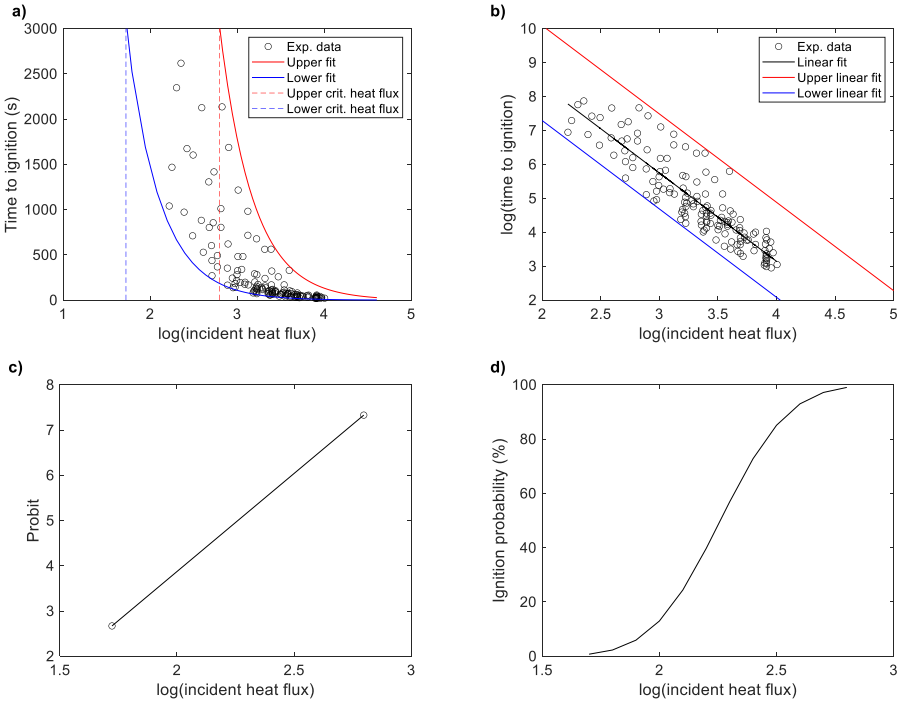

Figure 8- a) Flamambility data used for the PMMA vulnerability model; b) data in log-log scales; c) probit function, and; d) ignition probability.

3.3. Exposure

Fireline intensity and flame length maps from FlamMap simulations are shown in Fig. 9a and 9b. Homogeneous patterns are observed near the WUI, which is attributed to the species uniformity. Fig. 9c and 9d shows fireline intensity and flame length profiles for the substation perimeter, averaging 1832 kW/m and 3.98 m, respectively.

These results represent fire behavior in all the landscape pixels. This is equivalent to a wildfire engulfing the substation perimeter (Fig. 10). A more realistic scenario is a flame front attacking one side of the perimeter at the time. Hence two scenarios are considered (Fig. 10) for estimating view factor and incident heat flux on the target within the substation with Eq. 6, omitting the existence of a wall or fence around it to simplify the problem. Table 1 summarizes these results.

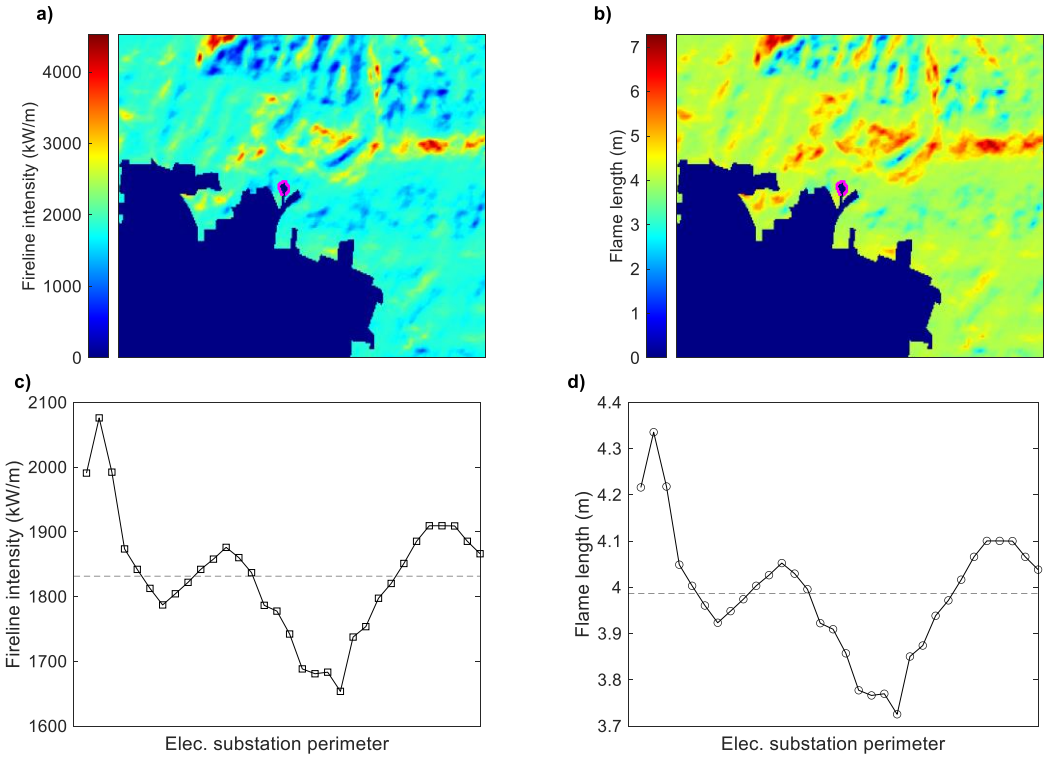

Figure 9- FlamMap outputs: a) fireline intensity; b) flame length; c) fireline intensity profile, and; d) flame length profile.

Figure 10- Scenarios for estimating incident heat flux on a target within the substation. Orange indicates a wildfire engulfing the substation perimeter; yellow rectangles represent the flame fronts considered.

3.4. Wildfire risk

Wildfire risk is calculated with Eq. 1, considering $P_p = 7.36 \cdot 10^{-5}$ events/year (cf. Section 3.1). Probit values are determined with Eq. 9 using the heat fluxes estimated from the fire behavior simulations (cf. Section 3.3), and these probits are used as inputs to Eq. 4 to determine asset ignition probabilities (cf. Table 1). Wildfire risk results are shown in Table 1. Their orders of magnitude are 10^{-6} to 10^{-5} events/year, i.e. one event every 100,000 to 1,000,000 years. It is observed that the probability of a wildfire reaching the electrical substation ($7.36 \cdot 10^{-5}$ events/year) and asset ignition probability (0.03 to 0.3) cannot be used as full risk metrics by themselves only. It is necessary to consider these two components into a wildfire risk estimate, and the definition of wildfire risk proposed in this work is thus more comprehensive than other ones found in the literature (Johnston et al. 2020).

Table 1- Results obtained with the WFQRA for two wildfire scenarios in the electrical substation.

Scenario	A	B
P_p (events/year)	$7.36 \cdot 10^{-5}$	$7.36 \cdot 10^{-5}$
I_f (kW/m)	1832	1832
H (m)	3.98	3.98
b (m)	40	45
A_f (m^2)	159	179
X_r	0.3	0.3
F	0.045	0.060
$\dot{q}_r''$ (kW/m^2)	6.2	8.3
log ($\dot{q}_r''$)	1.82	2.12
Y	3.11	4.38
P_d	0.029	0.269
$R_{x,y}$ (events/year)	$2.2 \cdot 10^{-6}$	$2.0 \cdot 10^{-5}$

4. Discussion

The WFQRA framework presented in this work enables analyzing wildfire risk in a systematic fashion. On one hand, the likelihood of a wildfire reaching the WUI depends on ignition frequency, whose anthropogenic component depends on human behavior and thus could be reduced by educational campaigns, law enforcement or other measures of such nature. This likelihood also depends on burn probability: since a patchy landscape typically hinders wildfire propagation, burn probability could be lowered by treating the wildland fuels and reducing the fuel load near the electrical substation. On the other hand, ignition probability of a target depends mostly on the incident heat flux, which can be lowered by establishing a wide and clear area between the substation and the wildland or blocking radiant heat transfer. Some observations concerning the assumptions, limitations and perspectives of the methodology are:

- Characterizing the study area requires defining a period and spatial delimitation for historical ignition data. Data availability can be an issue because historical records are imperative to estimate ignition frequency. Since climate/weather impacts on the propensity of wildland fuels to ignite, a period of analysis should be clearly and carefully defined so that the estimated ignition frequency be representative of current climatic conditions. Also, the study area may have a particular ignition pattern different to that of the territory in which it is located, hence varying its boundaries for ignition data may also impact on ignition frequency.
- Only two fuel models are considered in this work for simplicity, but a detailed risk analysis requires dividing the study area into several subareas depending on the wildland fuels distribution. This fuel mapping is a challenging task, since it needs a territorial division in terms of plant species, forest type (native or plantation), canopy cover, stand height, fuel load, etc.
- Estimations of flame length and fireline intensity depend on the models incorporated in the fire behavior modeling tool. For example, flame length is usually correlated to fireline intensity via power-law relationships that require two empirical constants, thus flame length might vary one order of magnitude for a given fireline intensity depending on the pair of constants used (Egorova et al. 2022).
- Using a dose-response curve assumes a binary response for the target (ignition/no ignition), in line with a theoretical approach that considers ignition as a phase transition problem where time to ignition either diverges or vanishes according to a universal power-law formula when incident heat flux tends to a critical

value (Sabi et al. 2018, 2021). This approach suits well to understand the sigmoid nature of the dose-response curve for flammability data expressed as ignition probability.

- When the wildfire front arrives to the WUI, firebrands impacting on the target represent a crucial ignition mechanism. Direct thermal radiation and spotting work in parallel, hence the risk posed by them to an asset should be addressed separately, and then summed. Incorporating spotting into the WFQRA framework requires a more extensive database not yet compiled, considering the complex ignition characteristics of structural fuels (Manzello et al. 2020).
- The WFQRA methodology could be used to discriminate between catastrophic and regular wildfires by adding a branch in the event tree to distinguish weather conditions that are prone to extreme fire events from those that are not, leading to two risk estimates, one for regular fires and another for extreme wildfires, which can be directly summed to estimate wildfire risk on the asset.
- In the absence of a tolerability criterion for wildfires, the results obtained with the WFQRA could be compared with risk estimates for other activities. For example, maximum tolerable risks in Canada and the UK are between 10^{-3} and 10^{-6} per year for land-use planning, worker safety and other industries (Muhlbauer 2004).

5. Conclusion

A quantitative methodology for estimating the risk posed by wildfires is proposed and applied to an electrical substation in the WUI of Valparaiso, Chile. Simulations were carried out with FlamMap to estimate burn probability, flame length and fireline intensity in the substation perimeter, but the methodology is independent of the modelling software employed. Wildfire consequences for a proxy fuel within the substation were estimated from a dose-response curve determined with a probit analysis that links incident heat flux on the target with its ignition probability. This comprehensive definition of wildfire risk considers both wildfire occurrence probability (via an event tree analysis) and asset vulnerability, thus potentially enabling a systematic analysis of wildfire risk evolution in time due to climate changes and a quantitative assessment of risk mitigation measures. Due to this, the WFQRA framework is well suited to analyze risk at critical infrastructure located at the WUI.

Global fire activity; Fire macroregimes; Fire Radiative Power; Truncated lognormal distribution with generalized Pareto tails

Abstract

Characterization of large-scale fire regimes associated to patterns of fire activity is especially relevant because they reflect the complex interplay of meteorological, landscape, and human factors. We present a statistical model with 8 parameters that adequately describes satellite derived fire radiative power (FRP) at the global scale and over large areas with given fire regimes. The statistical model combines three components, namely a truncated lognormal distribution central body with a lower and an upper tail, both consisting of Generalized Pareto (GP) distributions. The model is fitted to four samples of 1 000 000 values of $\log_{10} FRP$ randomly selected from a dataset consisting of observations by the MODIS instrument on-board Terra and Aqua satellites covering the 19-year period spanning from 4 July 2002 to 3 July 2021. The four samples are extracted from observations worldwide and from regions characterized by three fire macroregimes, respectively Wild, Tamed and Domesticated fires. For all four cases, the very high quality of the fit translates into the agreement between the cumulative distribution function and the respective empirical cumulative distribution function obtained from the sample. When going from the Domesticated fire macroregime to the Tamed and then to the Wild fire macroregimes, there is a progressive displacement towards the right of the respective probability distribution functions that indicates a progressive tendency for the occurrence of extreme events with a high release of radiative power that is associated with a decrease in human actions that translates into lower landscape fragmentation and lower fire suppression. Statistical model of FRP of the type here presented are a useful tool that allows characterizing in an economic way fire behaviour in a given region and monitor changes in time associated to climate change or to changes in landscape or in land occupation.

1. Introduction

The large spatiotemporal patterns of fire activity reflect on the one hand, the control exerted by climate on vegetation productivity and on fuel accumulation and respective moist content (Andela et al., 2019), and on the other hand, the effect of human actions that account for most ignitions in burnable ecosystems as well for the decrease in fire size due to landscape fragmentation and fire suppression (Bowman et al., 2009).

The identification and characterization of the large-scale fire regimes associated to patterns of fire activity as well as of the factors that condition the spatiotemporal variability of fire activity are especially important, not only because fires result from a complex interplay of meteorological, landscape, and human factors, but also because they are a source of greenhouse gases.

The characterization of fire regimes is performed by means of a set of parameters describing which fires occur in each place and time, and Earth Observation by means of satellites plays a crucial role because it represents the only means to get systematic information at the global scale during sufficiently long periods of time. Besides providing the location and date of hotspots, satellites allow estimating fire radiative power (FRP) that is a measure of combustion rate, and therefore of consumed biomass (Wooster et al., 2005).

The aim of this work is to show that satellite derived FRP, at the global scale and over large areas with given fire regimes, can be described by means of a universal statistical model with 8 parameters. This is a useful tool that allows characterizing in an economic way fire behavior in a given region and monitor changes in time associated to climate change or to changes in landscape or in land occupation.

2. Data and Methods

Information about FRP was obtained from NASA's Fire Information for Resource Management System (FIRMS) that provides location, date and hour, FRP estimates and confidence for hotspots detected by the Moderate Resolution Imaging Spectroradiometer (MODIS) on-board Terra and Aqua satellites. Extracted data consist of 85 412 052 estimates of FRP associated to all hotspots (identified as active vegetation fires) during the 19-year period spanning from 4 July 2002 to 3 July 2021. The starting date of the period is that when observations become available for both MODIS instruments on-board Terra and Aqua.

Following Pereira et al. (2022), global fires were stratified into three fire macroregimes that are interpreted according to climate type (Köppen classification) and to ecological patterns created by sustained interactions between ecosytems and humans (anthromes) (Figure 1). The three regimes (each one subdivided into a prototypical and a transitional regime) are as follows; the Wild fire macroregime predominates in cold wildlands, and is characterized by sporadic burning and short fire seasons; the Tamed fire macroregime mostly occurs in rangeland and croplands of dry tropical climate and is characterized by high fire incidence; and the Domesticated fire macroregime that is characteristic of croplands and villages in humid, warm temperate and tropical climates and is characterized by low fire incidence. Results from the stratification into the three fire macroregimes were 67 324 278 Tamed fires, 9 768 127 Domesticated fires, and 8 319 647 Wild fires, respectively representing 79%, 11% and 10% of the active fires observed worldwide.

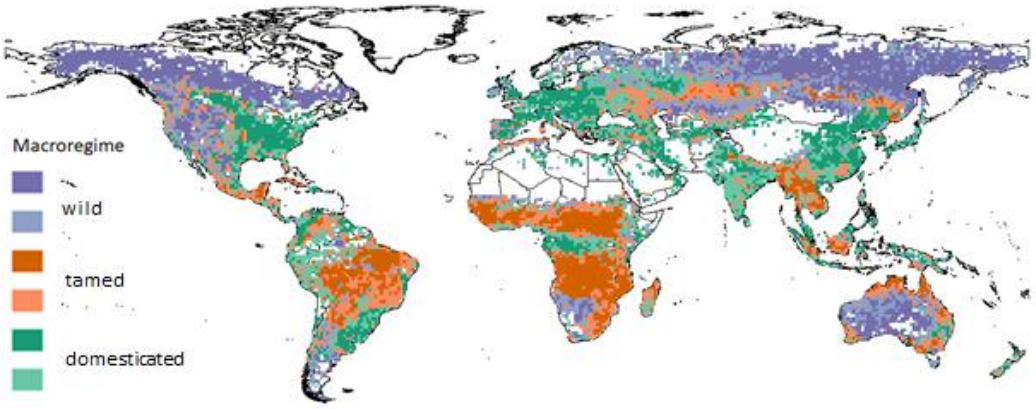

Figure 1- Global distribution of fire macroregimes; wild (violet), tamed (orange) and domesticated (green). For each macroregime, dark and light colors identify subdivision into prototypical and transitional regimes. The map was generated using information from Pereira et al. (2022).

Statistical models used in this study combine three components, namely a truncated lognormal distribution central body, f_b, with a lower and an upper tail, both consisting of Generalized Pareto (GP) distributions, f_l and f_u, respectively. The probability density function (pdf), h, for a generic random variable x is accordingly of the form:

$$h(x;\kappa_l,\sigma_l,x_l,\mu,\sigma_b,\kappa_u,\sigma_u,x_u) = \begin{cases} cbf_l(x;\kappa_l,\sigma_l,x_l), & x < x_l \\ bf_b(x;\mu_b,\sigma_b), & x_l \le x \le x_u \\ abf_u(x;\kappa_u,\sigma_u,x_u), & x > x_u \end{cases} \quad (1)$$

The lower tail GP distribution is:

$$f_l(x;\kappa_l,\sigma_l,x_l) = (1/\sigma_l)[1+\kappa_l\,(x_l-x)/\sigma_l]^{-1-1/\kappa_l}$$

where κ_l and σ_l denote the shape and the scale parameters of f_l, and where x_l is the transition point from the lower tail GP distribution to the truncated lognormal distribution body. When $\kappa_l < 0$, the distribution has a bounded support, $x_{min} < x < x_l$, with $x_{min} = x_l + \sigma_l/\kappa_l$.

The upper tail GP distribution is:

$$f_u(x; \kappa_u, \sigma_u, x_u) = (1/\sigma_u)[1 + \kappa_u\,(x - x_u)/\sigma_u]^{-1-1/\kappa_u}$$

where κ_u and σ_u denote the shape and the scale parameters of f_u, and where x_u is the transition point from the lognormal distribution body to the upper tail GP distribution. When $\kappa_u < 0$, the distribution has a bounded support, $x_u < x < x_{max}$, with $x_{max} = x_u - \sigma_u/\kappa_u$.

Finally, the lognormal distribution central body is:

$$f_b(x; \mu_b, \sigma_b, x_l, x_u) = \exp\left[-\frac{(\ln x - \mu)^2}{2\,(\sigma_b)^2}\right] \Big/ \left[\sqrt{2\pi}\; x\; \sigma\; C(\mu, \sigma_b, x_l, x_u)\right]$$

with

$$C(\mu_b, \sigma_b, x_l, x_u) = \frac{1}{2}\left[\mathrm{erf}\left(\frac{(\ln x_u - \mu_b}{\sqrt{2}\;\sigma_b}\right) - \mathrm{erf}\left(\frac{(\ln x_l - \mu_b}{\sqrt{2}\;\sigma_b}\right)\right]$$

and where μ_b and σ_b are the location and scale parameters of f_b.

Normalization constants a, b, and c in equation (1) must verify the relation:

$$cb + b + ab = 1 \Rightarrow b = (a + c + 1)^{-1}$$

On the other hand, continuity of h at $x = x_l$ and at $x = x_u$ implies that:

$$cbf_l(x_l) = bf_b(x_l) \Rightarrow c = \sigma_l f_b(x_l)$$
$$abf_u(x_u) = bf_b(x_u) \Rightarrow a = \sigma_u f_u(x_u)$$

The eight parameters $(\kappa_l, \sigma_l, x_l, \mu_b, \sigma_b, \kappa_u, \sigma_u, x_u)$ of h in equation (1) are obtained by maximizing the joint log-likelihood of an i.i.d. sample of x. The rationale for the procedure consists of three steps; 1) sample values of $\ln x$ are plotted against a theoretical lognormal distribution, and first guesses of x_l and x_u are obtained by identifying the lower and upper values of x that roughly delimit the inner domain of h, where points closely form a straight line, therefore following a lognormal distribution (Chambers et al., 2017); 2) first guesses of pairs (κ_l, σ_l), (μ_b, σ_b) and (κ_u, σ_u) are then obtained using the maximum likelihood method to fit, respectively, a GP distribution to sampled values $x < x_l$, a truncated lognormal distribution to sampled values $x_l \leq x \leq x_u$, and a GP distribution to sampled values $x > x_u$; 3) finally, first guesses obtained in the previous two steps are used to obtain maximum likelihood estimates of the eight parameters of h.

3. Results and discussion

Since the total number of recorded events is very large (85 412 052 hot spots), a sample of 1 000 000 events was randomly selected, and the statistical model was fitted to the logarithm of FRP (i.e., $x = \log_{10} FRP$) of selected events following the procedure described in the preceding section. Results obtained are presented in Figure 2, and the very high quality of the fit is worth being emphasized; the cumulative distribution function (cdf) virtually coincides with the empirical cumulative distribution function (ecdf) obtained from the sample (Figure 2, left panel) and the probability distribution function (pdf) closely follows the histogram obtained from the sample (Figure 2, right panel).

The same procedure was applied to the recorded events belonging to the three fire macroregimes. Results obtained are presented in Figure 3, and again the very high quality of the fit for each macroregime translates into the agreement between the cdf and the respective ecdf (Figure 3, left panel). It is worth noting that when going from the Domesticated fire macroregime to the Tamed and then to the Wild fire macroregimes, there is a progressive displacement towards the right of the respective pdfs that indicates a progressive tendency for the occurrence of extreme events with a high release of radiative power that is associated with a decrease in human actions that translates into lower landscape fragmentation and lower fire suppression.

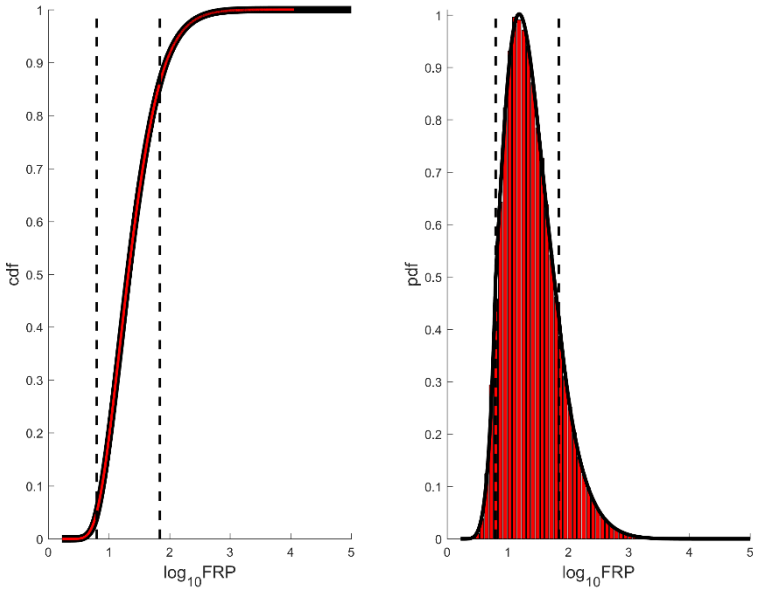

Figure 2 – Distribution of log_{10} FRP as obtained from the randomly selected sample of 1 000 000 hotspots observed worldwide during the period 04/07/2002 – 03/07/2021. Left panel: cumulated distribution function (cdf) of the fitted model (thick black curve) and empirical cumulative distribution function (ecdf) as obtained from the sample (thin red curve); right panel: probability density function (pdf) of the fitted model (thick black curve) and histogram obtained from the sample (red bars)). The two vertical dashed lines delimit the central body of the distribution.

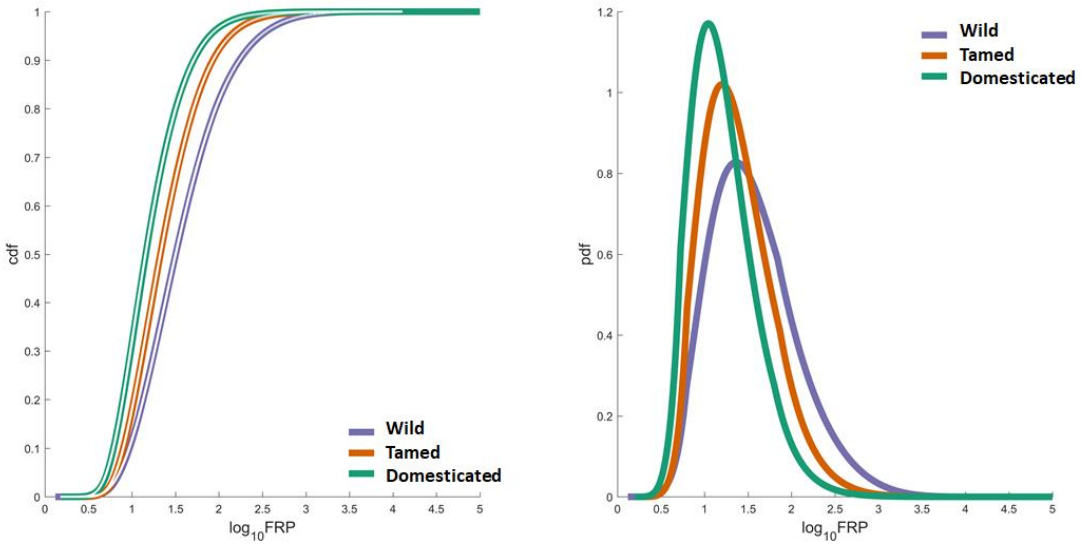

Figure 3 – Distribution of log_{10} FRP as obtained from the randomly selected sample of 1 000 000 hotspots for the Wild (violet), Tamed (orange) and Domesticated fire macroregimes during the period 04/07/2002 – 03/07/2021. Left panel: cumulated distribution function (cdf) of the fitted model (thick colored curves) and empirical cumulative distribution function (ecdf) as obtained from the sample (thin white curves); right panel: probability density function (pdf) of the fitted models.

4. Conclusion

Based on a 19-year record of satellite observations, we showed that the logarithm of FRP released by vegetation fires at the global scale closely follows a two generalized Pareto tail lognormal body distribution. The model showed to be especially useful to characterize fire macroregimes defined according to climate type and ecological patterns created by sustained interactions. Besides condensing information to a reduced number of parameters, models such as those proposed in this study allow comparing fire behavior for different periods and identifying changes in the distribution. Model of this type can be also used to calibrate meteorological indices of fire danger (DaCamara, 2014; Pinto et al. 2018) that provide operational support to decision makers on fire prevention and firefighting of rural and forest fires (DaCamara et al., 2018).

Abstract (237/500 words)

Since near-surface wind is the main influential parameter governing the rate of fire spread (ROS), its characterization remains key to simulate wildland fire behavior. The correct representation of the intensity and variability of the near-surface wind under complex terrain and vegetation remains an open problem but is essential to make a coupled atmosphere-fire model applicable to actual wildfires. In this work, we study the impact of canopy drag effects on the near-surface flow and the fire behavior simulated by the coupled Meso-NH/BLAZE model in the context of the FireFlux I experimental grass fire for which trees were located upstream and on the flanks. Drag effects can be activated in Meso-NH run in large-eddy simulation (LES) mode following work by Aumond et al. (2013) using SURFEX land surface platform. The drag approach formulation consists of adding drag terms to the momentum equation and subgrid turbulent kinetic energy dissipation as a function of the foliage density. This approach is compared to the standard roughness approach, where a different surface roughness coefficient is applied for the grass and tree areas. Results show the dynamical influence of the surrounding trees on the incoming atmospheric flow that is known to have a significant impact on the fire front propagation in the FireFLux I experiment following work by Costes et al. (2021). Results also indicate that the choice of drag effect parameterization, due to the difference in the represented physics, induces differences on the simulated fire front propagation. This encourages us to explore different options to accurately represent the surface boundary layer in presence of complex vegetation for coupled atmosphere-fire modeling in future work.

1. Introduction

Coupled atmosphere-fire models (Kochanski et al. 2013; Filippi et al. 2018; Costes et al. 2021) are both an efficient and representative way to simulate wildland fire behavior at landscape-to-meteorological scales. They can predict the fire front propagation at the land surface, the fire plume dynamics, and the different interactions they can have. The complex plume dynamics coming from the thermo-convective instability and its retroactive feedback can significantly modify the near-surface wind, enhancing the fire front propagation during a wildland fire event. In coupled atmosphere-fire models, the atmospheric model is run in large- eddy simulation (LES) mode at very high resolution (<100 m) and is coupled with a fire spread model that typically includes a rate of spread (ROS) parameterization and a 2-D front-tracking numerical scheme: see WRF/SFIRE (Mandel et al. 2011), WRF/FIRE (Cohen et al. 2013; Muñoz- Esparza et al. 2018), Meso-NH/FOREFIRE (Filippi et al. 2009) and more recently Meso-NH/Blaze (Costes et al. 2021). In a two-way coupling mode, the fire model requires from the atmospheric model the near-surface wind at a given height to evaluate the ROS and propagate the fire front. In return, it provides surface heat fluxes as surface boundary conditions to the atmospheric model. The counterpart is that parameterization of both the ROS (Rothermel et al. 1972; Balbi et al. 2009) and the surface heat fluxes is required and takes as input a large number of environmental factors related to biomass fuel properties, near-surface wind and terrain slope conditions. These input parameters are partially known (Jimenez et al. 2008) and thereby introduce uncertainties in the coupled model simulations. One way to deal with complex vegetation through these parameters would be either to adopt a stochastic viewpoint (i.e. to run an ensemble of coupled simulations), or to use a land cover database (e.g. ECOCLIMAP, (Masson et al. 2003)) to have a detailed description of the vegetation types and take advantage of the high-resolution simulations. The latter

would allow us to represent both the influence of the vegetation on the wildland fire and on the atmosphere. The main issue addressed in this work is to integrate a land surface modeling approach to the already-existing coupled atmosphere/fire modeling framework so as to represent the dynamical effects of forest canopy on the atmospheric flow and their impacts on wildland fire spread. This is of first importance to extend the applicability of coupled atmosphere/fire models to forest environment and pursue their validation for different types of vegetation.

2. Coupled Atmosphere/Fire Modeling Framework

In the present study, we use the coupled Meso-NH/BLAZE model to simulate the FireFlux I experimental grass fire (Clements et al. 2007). We briefly present Meso-NH/BLAZE in this section. More details can be found in Costes et al. (2021).

2.1. Description of the coupled Meso-NH/Blaze model

Meso-NH (Lac et al. 2018) is a non-hydrostatic anelastic atmospheric model of the French research community, jointly developed by CNRM (Météo-France/CNRS) and Laboratoire d'Aérologie (Université de Toulouse/CNRS). It is used to simulate meso-scale (few kilometers to less than thousand kilometers) up to micro-scale (less than hundred meters) atmospheric flows. For the present wildland fire application, Meso-NH is run in LES mode to simulate the atmospheric flow in the surface layer at decametric horizontal resolution (Δx = 25m resolution in the present study as in Costes et al. (2021)). BLAZE (Costes et al. 2021) is a fire spread model that relies on i) Balbi's ROS parameterization adapted for landscape-scale wildland fires (Santoni et al. 2011); ii) a two-dimensional level-set front-tracking numerical approach to propagate the fire front at the land surface; and iii) surface heat flux parameterization including flaming and smoldering contributions. A subgrid-scale fire front reconstruction is implemented in BLAZE to have a good localization of the surface heat fluxes without significantly constraining the fire model resolution (Δxf = 5m resolution in the present study as in Costes et al. (2021). In a two-way coupling mode, Meso-NH and BLAZE interact as follows: the near-surface wind simulated by Meso-NH at a given reference height (2 m above ground level as in Costes et al. (2021) is interpolated at BLAZE resolution, and is projected along the normal direction to the fire front; it is then given as input to the ROS parameterization. The surface heat fluxes simulated by BLAZE are given as surface boundary conditions to Meso-NH with a vertical distribution following an exponential decay over the first 30 m above the ground level as in Costes et al. (2021).

Figure 1 – Illustration of a coupled Meso-NH/BLAZE simulation of the FireFlux I experiment (without considering the trees near the burn plot).

2.2. Validation of the fire-atmosphere coupled modeling

The FireFlux I experiment (Clements et al. 2007) has been used to provide a first evaluation step of the coupled Meso-NH/BLAZE model. It corresponds to an experimental prescribed burn of 15 min on a flat terrain with tall grass. The burn plot of approximately 30 ha was instrumented with two towers equipped with thermocouples and anemometers at different heights (within the first 50 m above the ground level). In previous work, Costes et al. (2021) have simulated the FireFlux I experiment using the coupled Meso-NH/BLAZE model without considering the trees near the burn plot, i.e. the vegetation was considered as homogeneous tall grass for the whole computational domain and the impact of tall grass on the surrounding atmosphere was represented using the standard roughness approach (Figure 1). Simulation results (in terms of fire front positions and near-surface atmospheric variables such as the horizontal and vertical wind components at different heights) showed good agreement with the experimental measurements. In complement, Costes et al. (2021) have verified the validity of the anelastic approximation by developing a compressible version of Meso-NH to account for the three-dimensional density gradients in the vicinity of the fire front and by comparing results in anelastic and compressible modes for the FireFlux I experiment. Results in the two-way coupled mode have shown that the anelastic approximation for Meso-NH is suitable to represent wildland fire behavior, except for details of the plume if the atmospheric model horizontal resolution is of 10 m or finer. The anelastic approximation is therefore relevant to study canopy drag effects on wildland fire behavior at decametric resolution in the present study. Even though coupled simulations were reduced to a simple flat terrain with uniform vegetation in previous work, Costes et al. (2021) demonstrated the importance of atmospheric variability due to turbulence on the fire front propagation. This is a key result, which motivates the further development of the coupled Meso-NH/BLAZE model towards a more complex representation of the terrain surface and in particular of the vegetation. The objective in the present study is to account for the presence of trees upstream and on the sides of the burn plot (Figure 1), and to evaluate its impact on the near-surface flow and subsequently on the fire front propagation

3. Coupled MesoNH/Blaze/SURFEX simulations including canopy drag effects

To consider a more realistic fuel in the coupled atmosphere/fire simulations, it is of primary importance to have a better representation of the fuel behavior in response to the development of the fire but also of the fuel influence on the atmospheric flow. This implementation will be done via SURFEX (Masson et al. 2013), a surface modeling platform also developed by CNRM (Météo-France/CNRS). This model was originally aimed to better simulate energy and water exchanges between the land surface and the atmosphere to be integrated into Météo-France's operational products. It is also of significant interest in research mode to study surface/atmosphere interactions. In the present study, we mainly use the ISBA (Interaction Soil Biosphere Atmosphere) vegetation scheme (Noilhan et al. 1996; Boone et al. 1999; Decharme et al. 2006) in SURFEX to have a more detailed description of the vegetation (grass and forest areas in the FireFlux I case study). Integrating the ISBA scheme into the already existing coupled atmosphere/fire modeling framework (Figure 2) will allow us to go one step further towards simulating actual cases of large-scale wildfires. To account here for the dynamical effect of the vegetation on the atmospheric flow, we first recreated the immediate vegetation close to the field experiment forming some kind of shelter from the atmospheric flow. We then implemented two different methods to account for the canopy's drag effect on the the fire spread, namely, a roughness approach and a momentum/TKE drag approach.

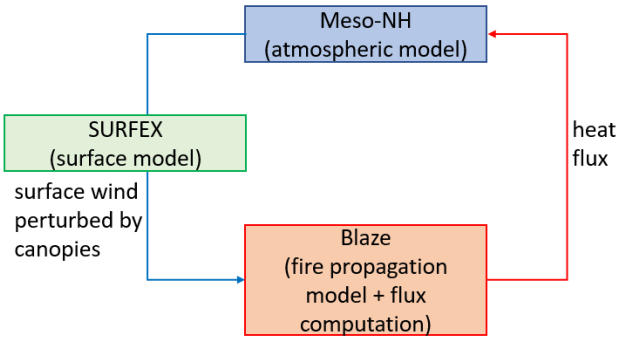

Figure 2 – Schematic of the coupling between Meso-NH, BLAZE and SURFEX with the additional component SURFEX to account for the tree's drag on the the fire spread.

3.1. Classical log-law parameterization

The classical approach, referred to as the standard roughness approach, in large-scale atmospheric models is to have a log-law with characteristics such as roughness length and zero plane displacement that depend on the surface type. This approach, initiated by Von Kármán (1930), revisited by Monin and Obukhov (1954) to take stability into consideration, supposes that the wind profile starts at a given height with a logarithmic profile. However, for LES, the fine horizontal resolution would allow us to represent the wake circulation behind obstacles (a tree barrier for example). Such complex flow feature cannot be fully accounted for using the classical log-law parameterization.

3.2. TKE and conservation of momentum parametrization

To include more physics into the LES, an alternative approach consists in incorporating a drag force directly into the atmospheric model dynamic equations. Using Kanda and Hino's (1994) parameterizations and following Aumond et al. (2013), an additional term is introduced to the momentum equation as follows:

$$\frac{\partial u_i}{\partial t} = A_{dv} + C_{or} + P_{res} + T_{urb}(u_i) - C_d A_f(z) u_i (u_1^2 + u_2^2)^{\frac{1}{2}} \quad i \in \{1,2\} \qquad (1)$$

where (u_1, u_2) corresponds to the two horizontal wind components $[m/s]$, A_{dv} is the advection term, C_{or} is the Coriolis force term, P_{res} is the the pressure gradient term, T_{urb} is the turbulence term, C_d is the canopy drag coefficient [-], and A_f (z) is the canopy area density $[m^{-1}]$ (this is a combination of the leaf area index (LAI), the fraction of vegetation in the grid cell and a function that represents the shape of the trees). To account for the subgrid-scale effect of trees on small-scale turbulence (trees have elements much smaller than the atmospheric grid mesh), additional dissipation is added into the turbulent kinetic energy (TKE) equation:

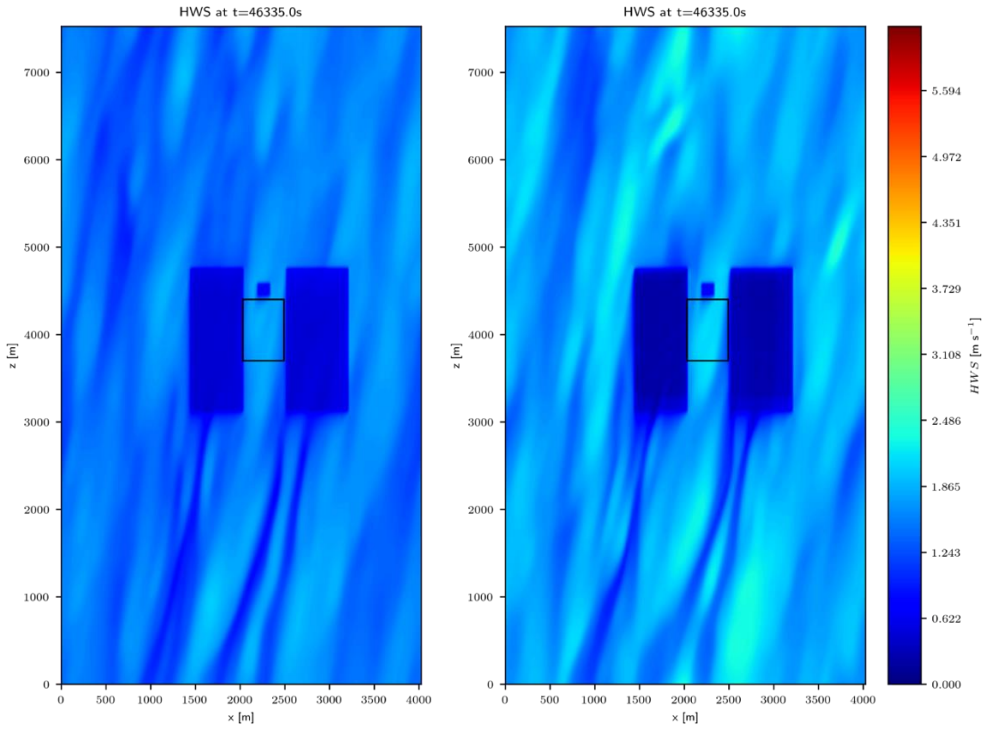
$$\frac{\partial e}{\partial t} = A_{dv} + D_{ynProd} + T_{hermProd} + T_{urbT}(u_i) - D_{iss-} C_d A_f(z) e (u_1^2 + u_2^2)^{\frac{1}{2}} \qquad (2)$$

where e is the subgrid TKE $[m^2/s^2]$, D_{ynProd} and T_{hermProd} are the dynamic and thermal productions, T_{urbT} denotes the turbulent transport and D_{iss} is the dissipation. This approach, referred to as the TKE/momentum drag approach, is particularly interesting for our wildland fire application since it directly links vegetation parameters, which can be inputs from a database, to drag force through the Cd and Af coefficients.

3.3. Results

We present a first comparison of the coupled Meso-NH/SURFEX simulations of the spin-up step of the FireFlux I case study that account for the forest canopy effect through either the standard roughness approach or the TKE/momentum drag approach (Figure 3). In Figure 3, the dark blue areas correspond to trees, while the rest of the domain is covered by tall grass. The burn plot is delimited by the empty black rectangle. It is worth mentioning that this spin-up step is required prior to the fire ignition to have realistic inflow conditions that correspond to in situ observation measurement statistics (Costes et al. 2021). This is a preliminary step before running the coupled Meso-NH/BLAZE/SURFEX simulations. The two approaches seemed to lead to very similar flow structures at first although the physics involved is very different but several differences can be

spotted. The first main difference is that the momentum/TKE approach dissipates less compared to the standard roughness approach, leading to higher near-surface wind speed. This is of particular interest in the context of wildland fire behavior simulations. The second main difference in the case of the momentum/TKE approach, is the presence of more coherent structures coming from the wake of canopies, possibly due to a slightly better representation of the porosity of the vegetation than in the case of the classical log-law parameterization.



a) Roughness approach (b) Momentum/TKE parametrization

Figure 3 – Simulation of the horizontal wind speed [m/s] for the spin up step of the FireFlux I experimental grass fire, taking into account the immediate tree canopies around the burn plot with the two different approaches: (a) standard roughness approach; and (b) TKE/momentum drag approach. The burn plot is delimited by the black solid lines, and the trees are located in the dark blue areas (the rest of the vegetation, including the burn plot, is set as grass.

4. Conclusions

This study presents a prototype of a coupled atmosphere/fire model based on the coupled Meso-NH/BLAZE/SURFEX system, in which a vegetation scheme capable of representing the drag of forest canopies is integrated through the ISBA scheme of SURFEX. This study assumes that the immediate trees next to the FireFlux I experimental burn plot account for most of the vegetation dynamical influence on the incoming atmospheric flow. The results obtained for the spin-up step of the coupled simulations indicate that the canopy drag affects the overall regime of the atmospheric flow surrounding the burn plot. The canopy drag will therefore have an influence on the fire spread but the choice of parameterization for the turbulent boundary layer may also be decisive. In the short term, future work aims at extending the analysis of the canopy drag effects for the FireFlux I experimental grass fire and at investigating if the sensitivity of the fire spread to the inflow variability is stronger when considering canopy drag effects or not. In the long term, future work aims at enhancing the representation of the wake due to complex vegetation and shifting towards the simulation of large-scale wildland fire in forest environment. Other methods, such as the promising immersed boundary layer (IBM), recently implemented in Meso-NH (Auguste et al. 2019), could also be investigated.

Abstract

The FireCCI project has developed, during the last decade, a suite of burned area (BA) products based on remote sensing tailored to the climate researchers and also useful for different fire applications. The different products span from 1982 to 2020, and include global products at coarse spatial resolution (FireCCILT11, at 0.05-degrees) and medium resolution (FireCCI51 and FireCCIS310, at 250 m and 300 m respectively), with derived grid products at 0.25-degree resolution. An additional burned area product at 20 m spatial resolution is also available for Sub-Saharan Africa for the years 2016 and 2019, with an accompanying grid product at 0.05-degrees. All products include ancillary information related to the uncertainty of the detection, the observational limitations, and the land cover burned.

The grid products, in NetCDF format, are specifically developed for climate researchers and those studying global vegetation dynamics, which usually use coarse resolution datasets as input for their models. The pixel products, on the other hand, provide the best possible spatial resolution based on the inputs of the BA algorithms, and are intended for researchers working on fire dynamics, land cover change, or focused on regional study areas, among other applications.

The latest product developed, FireCCIS310, represents the next generation of medium-resolution global burned area products. With an improved algorithm and taking advantage of the SWIR bands of the Sentinel-3 SYN product and the VIIRS active fires, it detected almost 5 Mkm2 of BA during the year 2019. This is expected to result in changes in the global estimation of fire emissions.

1. Remote sensing for burned area detection: FireCCI

Remote sensing data is a widely used and very advantageous source of information for burned area (BA) detection, as it provides global information in a systematic way (Chuvieco et al., 2019). The available sensors deliver images at diverse spatial and temporal resolutions, and in different spectral regions. This makes them suitable for the detection of burned scars with the use of infrared data at different wavelengths (near (NIR), short-wave (SWIR) and thermal).

Within the European Space Agency (ESA) Climate Change Initiative (CCI), the FireCCI project has the objective to develop and validate burned area algorithms to meet, as far as possible, GCOS (Global Climate Observing System) Essential Climate Variable (ECV) requirements for consistent, stable, and error-characterized global satellite data products from multi-sensor data archives. Since the start of the CCI Programme, FireCCI has developed different BA products based on surface reflectance and active fire information from a variety of ESA and NASA sensors.

2. The FireCCI burned area products

The current suite of products obtained from the FireCCI algorithms spans from 1982 to 2020, with plans to expand it to the present and future. These products, apart from providing information on burned area, also include ancillary information related to the uncertainty of the detection, the land cover affected (extracted from the CCI Land Cover product), and the observational limitations of the input data. All products supply information in monthly files, and are delivered at two spatial resolutions: pixel (at the original resolution of the surface reflectance input data) and grid (at a coarser resolution and specifically tailored for climate researchers). Figure 1 shows the total burned area obtained from the aggregation of the monthly grid files of FireCCIS310 for the year 2019.

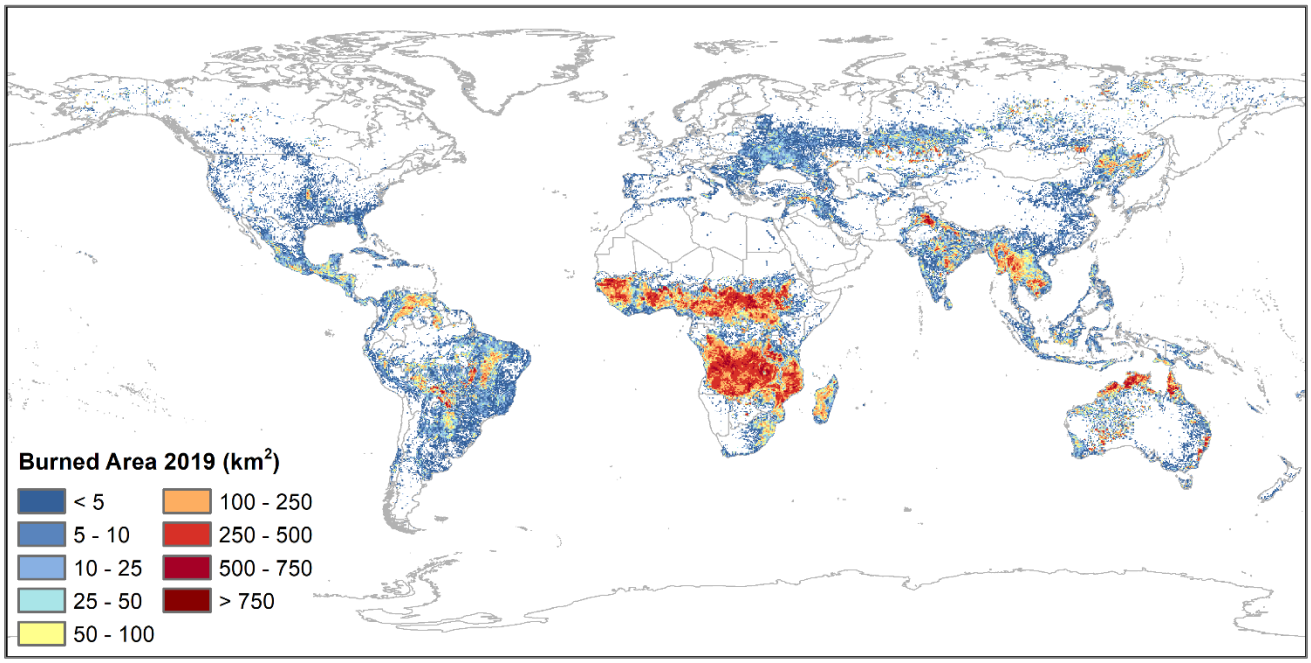

Figure 1- Total burned area of the year 2019 obtained from the FireCCIS310 grid product.

The current products include:

2.1. FireCCILT11

The dataset with the longest time series is the FireCCILT11 product, based on AVHRR information obtained from the Land Long-Term Data Record (LTDR) version 5 (https://ladsweb.modaps.eosdis.nasa.gov/missions-and-measurements/applications/ltdr/#project-documentation, accessed on March 2022), and spanning from 1982 to 2018 at a global scale (Otón et al. 2021). The pixel product has a spatial resolution of 0.05 degrees (approx. 5 km at the Equator), and provides information on the date of the fire detection, the confidence level of that detection, the burned area in each pixel, and an ancillary layer with the number of observations available for the detection. The grid product, at a resolution of 0.25 degrees, summarizes the data of the pixel product for each grid cell, and includes layers corresponding to the sum of burned area, the standard error, and the fraction of burnable area and observed area in each cell. FireCCILT11 is the global BA product with the longest time-series to date, although it presents high uncertainties related to the coarse resolution of input images (0.05 degrees) and stability of the LTDR series. It is especially intended for climate researchers working at global or continental scales and needing long BA time series.

2.2. FireCCI51

Another global product, but with a higher spatial resolution than FireCCILT11, is FireCCI51, whose algorithm uses as input MODIS NIR surface reflectance at 250 m and 1 km-resolution active fires (Lizundia-Loiola et al. 2020). This product covers a 20-year time series (2001 to 2020). It is the product providing global monthly BA information with the highest resolution currently available. The pixel product includes layers corresponding to the date of detection, the confidence level and the land cover burned, while the grid product, at 0.25-degree resolution, contains the same information as FireCCILT11, and also includes layers with the amount of BA for each land cover class.

2.3. FireCCIS310

As part of our effort to extend the BA information into the coming years, the FireCCI project has recently developed a new algorithm to detect BA using the 300 m-resolution SWIR bands of the Sentinel-3 SLSTR (Sea and Land Surface Temperature Radiometer) sensor, extracted from the Synergy (SYN) products developed by ESA (https://sentinels.copernicus.eu/web/sentinel/technical-guides/sentinel-3-synergy, accessed on March 2022). This input is complemented by VIIRS (Visible Infrared Imaging Radiometer Suite) active fire information at 375 m resolution, obtained from the S-NPP (Suomi National Polar-Orbiting Partnership) satellite. The resulting BA product, called FireCCIS310, takes advantage of the improved BA detection capacity of the SWIR bands and the higher resolution of the VIIRS thermal information, apart from including improvements in the detection algorithm. The first assessment of the product for 2019 data shows that it detects more BA than previous global BA datasets (4.99 Mkm^2, 28% more than FireCCI51), and with an increased spatial and temporal accuracy (Lizundia-Loiola et al. 2022). FireCCIS310 supplies the same layers as FireCCI51, but at a spatial resolution of 300 m for the pixel product. This product will continue to be processed for subsequent years.

Figure 2 shows the comparison between the BA detected by FireCCI51, FireCCIS310 and FireCCISFD20 (see section 2.4) in a small region in the border between Tanzania and Mozambique.

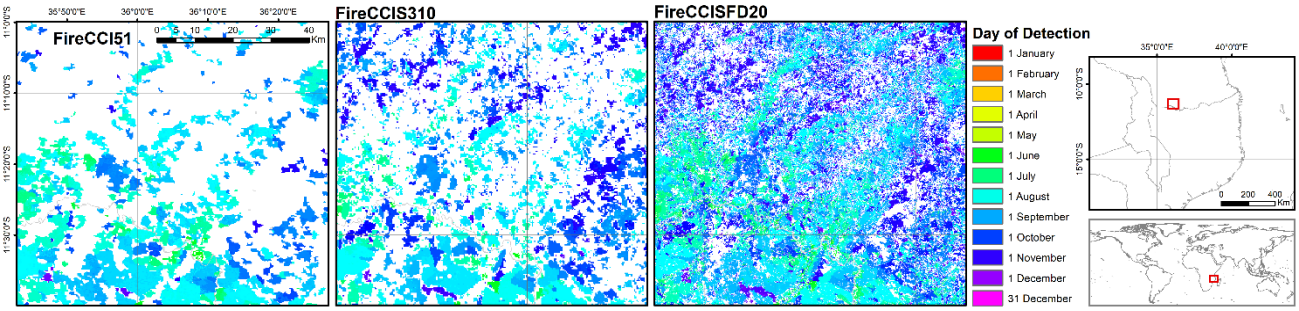

***Figure 2*- Comparison of burned area detection between FireCCI51, FireCCIS310 and FireCCISFD20 during 2019 for a region in Southern Tanzania.**

2.4. FireCCISFD

Finally, a specific dataset has been created for sub-Saharan Africa, where more than 70% of the total global burned area occurs (Chuvieco et al., 2019). This product, called FireCCISFD (SFD comes from Small Fire Dataset), uses surface reflectance from the Sentinel-2 MSI (MultiSpectral Instrument) sensor at 20 m spatial resolution, complemented with active fire information (Roteta et al. 2019). Version 1.1 of this dataset (FireCCISFD11) covers the year 2016 and is based on Sentinel-2A data + MODIS active fires, while the newer version (FireCCISFD20) has been processed for the year 2019, and takes advantage of the additional data provided by Sentinel-2B, duplicating the input data amount and temporal resolution, and the improved spatial resolution of the VIIRS active fire detection (Chuvieco et al. 2022). The grid version of this product has a spatial resolution of 0.05 degrees, as requested by climate researchers. Due to the much higher spatial resolution of the input data (Sentinel-2 MSI versus MODIS or Sentinel-3 SYN), this product detected 58% more BA than FireCCI51 for 2016, and 82% in 2019. The vast majority of this additional BA is due to the improved detection of small burned patches, not detectable with moderate resolution sensors (Ramo et al. 2021, and see also Figure 2). This dataset is especially useful for researchers working at regional level in Africa, and for studies dealing with greenhouse gasses emissions estimations.

2.5. Access to the products

All FireCCI products are available from the CCI Open Data Portal (https://climate.esa.int/en/odp/#/dashboard) and in the CEDA Catalogue (https://catalogue.ceda.ac.uk/uuid/6c3584d985bd484e8beb23ff0df91292), and the documentation of the products can be downloaded from the FireCCI website (https://climate.esa.int/en/projects/fire/about/).

Fire regime; carbon emission; cropland; MODIS; rangeland

Abstract

Introduction
- Even if the agricultural fires can affect a high proportion of burned areas, their inventory is insufficient.
- Considering the importance of agriculture in France, understanding agricultural fire regimes appears to be central to the objective of food security.
- Most cropland or rangeland fires are directly or indirectly related to human activities, facilitating their control.

Material and methods
- A data mining analysis of non-scientific literature was conducted between 2000 and 2021 to study the temporal and spatial evolution of agricultural fires.
- This database is compared to MODIS hotspots in order to validate this active detection method and to define its limits.

Results
- The data mining study allowed the inventory of more than 500 fire events per year.
- The national heterogeneity of agricultural fires is mostly explained by the variation of crop types across the territory as well as by climatic conditions.
- Crop fires occur primarily during the summer months when weather and fuel conditions are most favorable. Pasture fires, mainly prescribed fires, occur before and after winter to limit their spread. Fires in infrastructures occur throughout the year.

Discussion
- This first attempt at inventorying agricultural fires in France allowed us to describe spatial and temporal patterns specific to these types of fires.
- Remote sensing data only partially capture these small fires.
- Carbon emissions from these fires are currently largely underestimated.

1. Introduction

Agricultural fires account for a significant proportion of the annual burned area under temperate and Mediterranean climates (van der Werf et al., 2010).However, these cropland and rangeland fires are generally not included in current fire inventories and their consequences are severely underestimated (Shi et al., 2015). The characterization of these fires in terms of temporal and spatial variability as well as the associated carbon emissions are therefore largely unknown (Hunter and Robles, 2020). This lack of knowledge is partly attributed to the limitation of remote sensing technologies to capture agricultural fires for three main reasons: (1) Many harvested or ploughed croplands have similar spectral characteristics to burned areas. (2) The temporal behavior of harvested or burned cropland is similar to that of grassland fires (sudden decline followed by gradual recovery in NDVI, interannual variation in NBR) (Alonso-Canas and Chuvieco, 2015). (3) Many agricultural fires are human-caused and are generally small and short-lived, making them difficult to capture by satellite sensors (Vilar et al., 2015).

In France, where usable agricultural areas represent 30 million hectares (i.e., 52% of the country), and although croplands and rangelands have relatively lower biomass density than forests, the fire risk of these ecosystems

should not be underestimated ("World development indicators," n.d.). First, current climate change is increasing the number of days when climate-fuel conditions are critical for fire ignition and spread, increasing the vulnerability of these environments (Bowman et al., 2020). Second, because these ecosystems are central to the agri-food production system, the lack of knowledge about the behavior of these fires may pose a threat to food security (O'Mara, 2012). Third, lack of monitoring of these fires can lead to uncontrolled spread of fire to adjacent forests and even to human infrastructure (Dether and Black, 2006).

Most agricultural fires are human-induced, although their ignition may or may not be deliberate. Deliberate fires, called "prescribed fires," are intended to provide many benefits to ecosystems and human society: transforming arable land, cleaning crop residus, providing pasture production, providing habitat for wildlife, reducing hazardous fuels (Hunter and Robles, 2020; McLauchlan et al., 2020; Pausas and Ribeiro, 2017). In order to change land use and improve agricultural production, humans have therefore developed fire control techniques such as "burn-beating" or "stubble burning" approaches (Bowman et al., 2011; Prichard et al., 2017). In contrast, unintentional fires, called "wildfires," are caused by unauthorized ignitions, escaped prescribed fires, arson, or technological malfunctions (McLauchlan et al., 2020). Agricultural fires can also, less frequently, be caused by natural causes such as lightning (Amatulli et al., 2007; Coughlan et al., 2021).

Active detection of thermal anomalies during combustion by remote sensing is the primary source of information used to capture agricultural fire occurrence (Giglio, Louis, 2000), but suffer from a return time interval (6hrs) longer than most small-fire durations. It is therefore essential to assess the accuracy of these hotspots, based on reference data that we performed with datamining in national newspapers.

2. Materiel and Methods

A data mining analysis of the non-scientific literature was carried out for the period 2000-2021 over the whole France. This study was based on a systematic screening of regional and national online newspapers with keywords such as "fire", "agriculture", "fields", "residue", aiming at obtaining an overview of fires occurring on croplands or rangelands. For each fire event, the date and the location of the administrative unit are identified. Depending on the quality of the information source, vegetation type (crop type and status as residue or whole plant) is referenced. Where information is available, the estimated area of pasture or crop burned is recorded. In addition, fires in agricultural storage buildings are also considered, some of which provide a mass of burned dry matter.

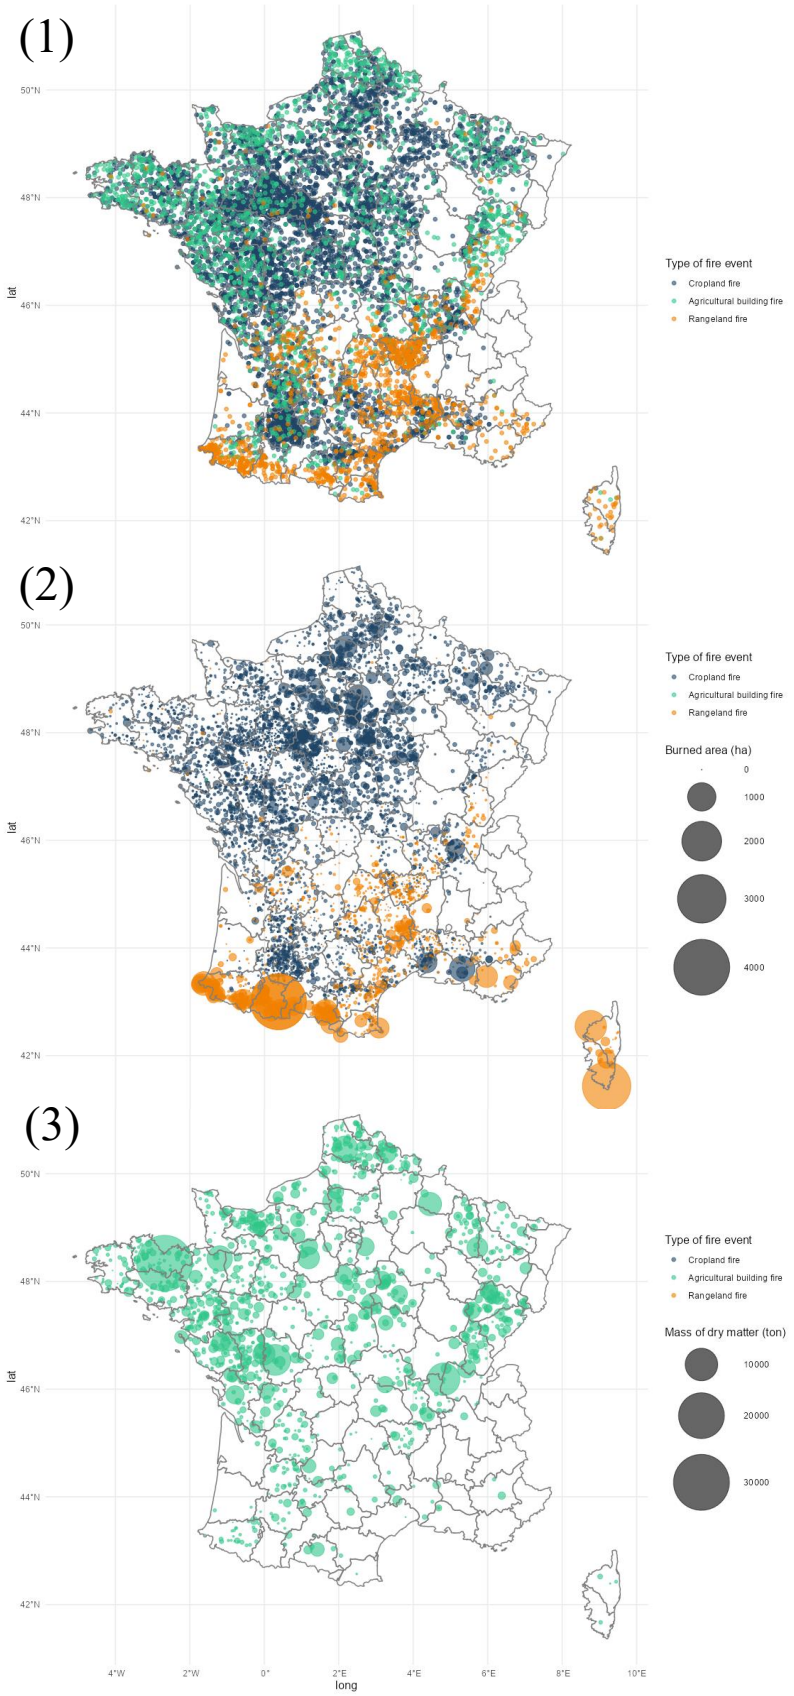
This database was then analyzed to describe the temporal evolution, seasonality, and spatial heterogeneity of agricultural fires. This analysis provides an understanding of the spatial and temporal fire patterns associated with cropland and pasture.

This database was then compared with VIIRS-SNPP hotspots (Schroeder et al., 2014) over the 2012-2021 time period. To do this, the VIIRS-SNPP hotspots were filtered out on cropland, grassland and pastures vegetation types (Corine Land Cover), and matched with referenced fires, in order to estimate the accuracy produced by this observation technique, as well identifying potential local or temporal caveats in fire reporting by the litterature. We estimated the fraction of fire events captured by hotspots as a function of fire size, and the relationship between fire events burned area and hotspot numbers. A final model relying hostspots to burned area, and omission errors allowed to provide an objective burned area data base for agricultural fires in France with its associated uncertainty for carbon emission studies.Current results and discussion

The database from the literature review identified 10453 agricultural fire occurrences between 2000 and 2021, i.e. more than 500 per year. These data correspond to 6808 crop fires, 2068 infrastructure fires and 1577 rangeland fires.

2.1. Spatial distribution

Figure 1.1 shows the spatial distribution of agricultural fires, which are present over almost the entire territory, including temperate and mediterranean environments. The least affected regions may correspond to the large French wine-growing regions, whose flammability is very low (Bordeaux, Burgundy and Alsace regions). High altitude regions (Alps) and those largely covered by forests (Landes) seem also less affected by agricultural fires.



Crop fires seem to be concentrated in the major French rainfed agricultural production areas, namely the Beauce plain south of Paris and Brittany to the west. Fire size (Figure 1.2) appears to be particularly large in the agricultural regions surrounding Paris, mainly composed of large cereal fields.

Fires in agricultural infrastructures largely follow the distribution of crop fires. The mass of dry matter burned seems to be particularly important in the West of France, a region where livestock and therefore fodder storage are important. As storage buildings are generally located close to livestock buildings (e.g. piggeries), these fires can lead to the death of a large part of the livestock and have severe economic consequences.

Rangeland fires particularly affect the high plateaus, especially in the Pyrenees, Corsica and the Massif Central. This distribution corresponds to the continuation of the practice of "stubble burning" in the south of France. This government-regulated practice involves the burning of standing plants to fertilize the soil and facilitate grazing. The fires that are particularly widespread in the Pyrenees are probably mixed fires (partly affecting the forest), probably escaped prescribed fires or involuntary fires.

Figure 1: (1) Distribution of agricultural fire occurrences in France between 2000 and 2021. (2) Spatial variability of cropland and rangeland burned areas (ha). (3) Spatial variability of dry matter mass (ton) burned in agricultural building fires. (Blue = Cropland fire, Green = Agricultural building fire, Orange = Rangeland fire).

2.2. Temporal trend

Figure 2 shows the evolution of agricultural fires over time. There is a strong seasonality and the appearance of particularly extreme years. Specifically, the years 2015 and 2019 for crop fires and the years 2012 and 2019 for rangeland fires show a very high number of fires. These years are characterized by particularly high temperatures related to heat waves early in the season. These climatic conditions lead to early droughts, reducing the moisture content of vegetation and increasing its flammability.

The amount of information available over the study period appears to vary. Indeed, the data available before 2006 do not seem to match the occurrence of agricultural fires in France after this date. The bibliographic review seems to be temporally biased, when there is a strong coverage of fire events by the local media. Our data do not allow us to conclude on a potential increase in agricultural fire events.

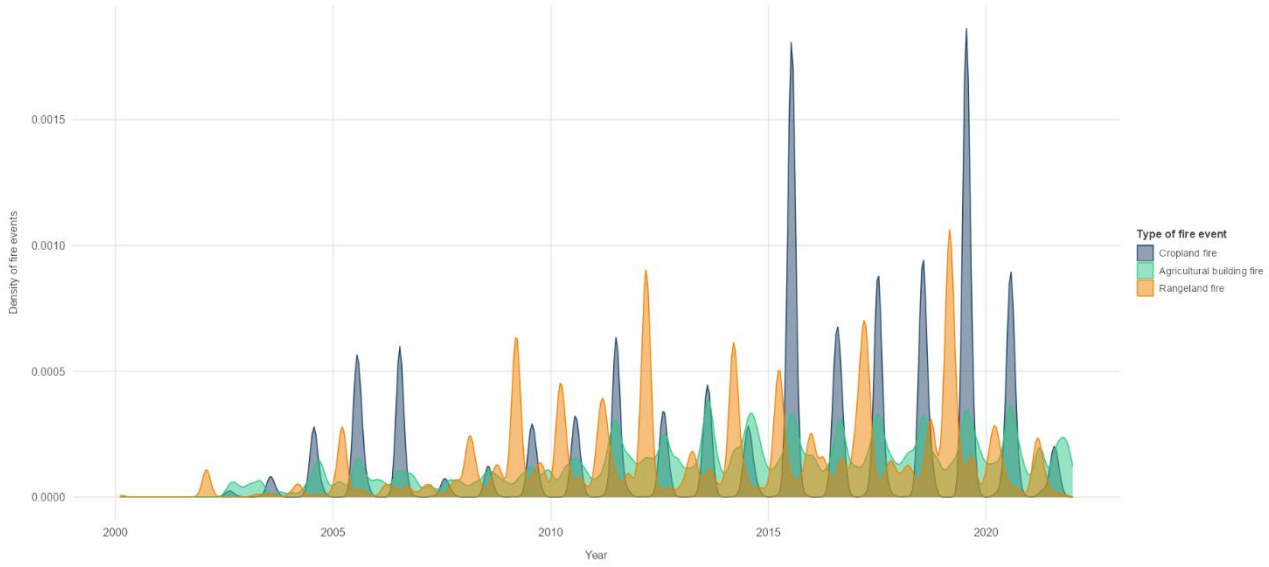


Figure 2 : Temporal evolution of agricultural fire occurrence over the period 2000-2021 in France. (Blue = Cropland fire, Green = Agricultural building fire, Orange = Rangeland fire).

2.3. Seasonality

Agricultural fires are marked by strong seasonality, with the peak occurrence in July with an average of over 200 agricultural fires per month (Figure 3.1). This peak is mainly due to the sharp increase in crop fires from June to August. This period is characterized by a strong increase in temperatures and a decrease in precipitation, particularly around the Mediterranean basin. These climatic conditions favor the burning of plots whose biomass has accumulated since early spring.

Fires in infrastructures occur almost uniformly throughout the year. While climatic conditions may account for their occurrence during the rest of the year, winter building fires can probably be attributed to mechanical and technological malfunctions leading to fire ignition.

The rangeland fires occur particularly in February-March, but also in September-October, especially for the years 2007, 2016, 2018 (Figure 3.2). These fires correspond largely to prescribed fires subject to authorization delivered only during this period when fire weather is less conductive to fire spreading.

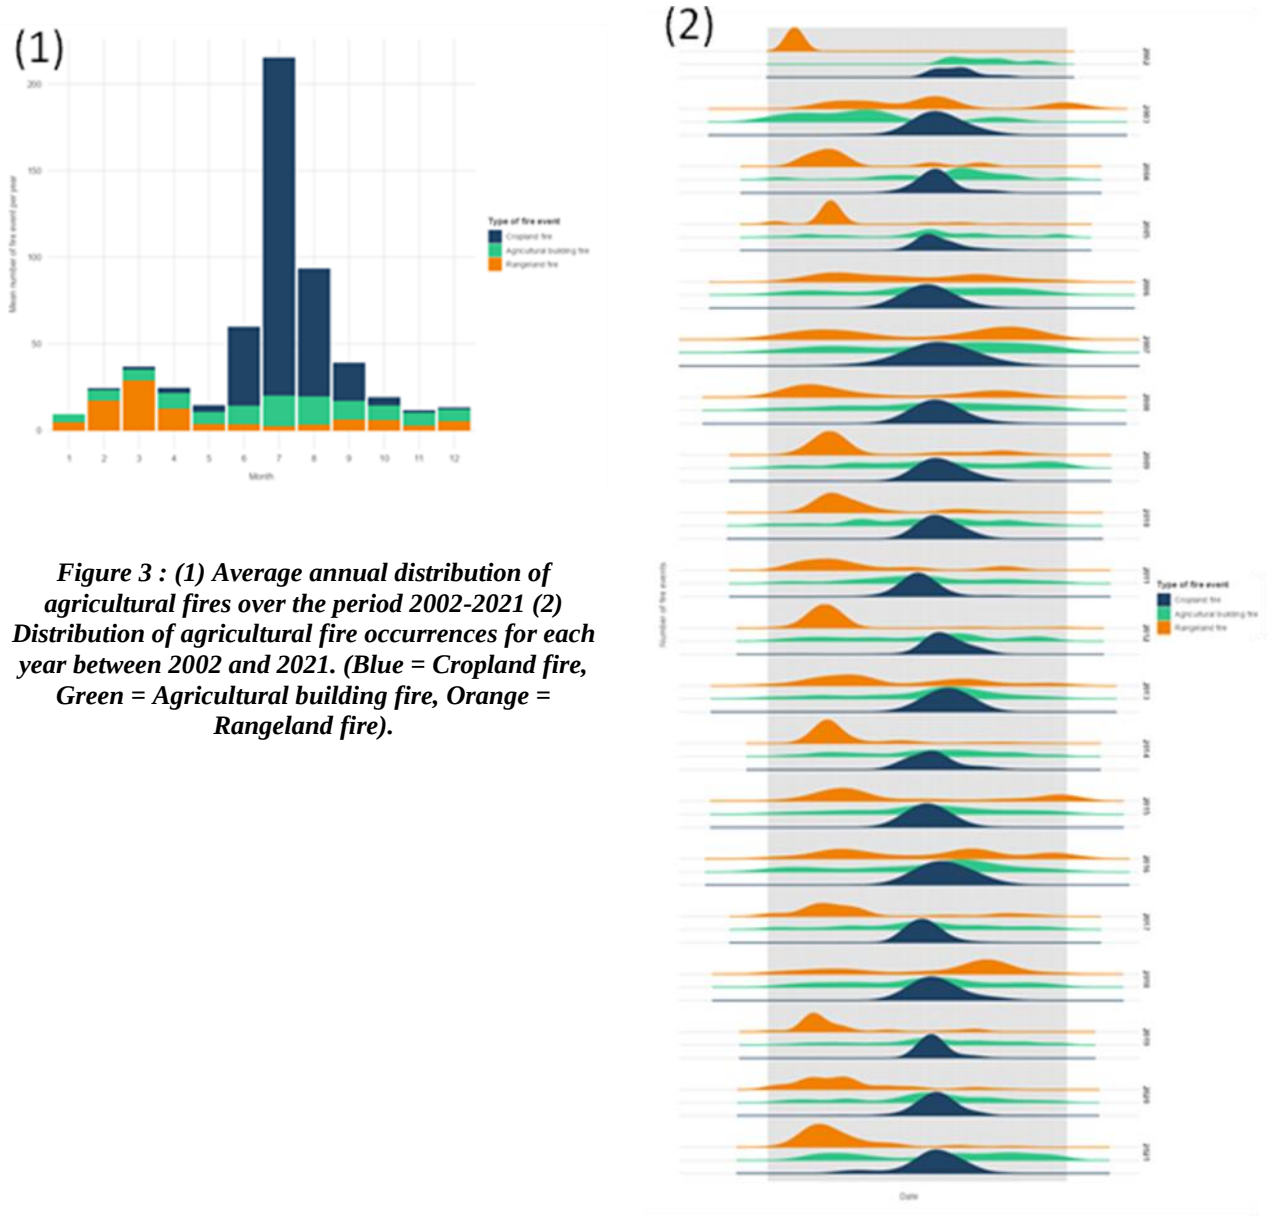

Figure 3 : (1) Average annual distribution of agricultural fires over the period 2002-2021 (2) Distribution of agricultural fire occurrences for each year between 2002 and 2021. (Blue = Cropland fire, Green = Agricultural building fire, Orange = Rangeland fire).

2.4. Remote Sensing

Figure 4 represents the hotspot density map over croplands/pastures in France from VIIRS S-NPP over the 2012-2020 period. We observe a similar national pattern as from datamining, with high fire activity captured where the largest fires are referenced, and the highest fire activity in the southwest mountainous pastures fires. Fires smaller than 100ha and 50ha were however only captured respectively at 50% and 25% (Figure 5), leaving a high uncertainty in small fires detection from remote sensing compared to datamining. The relationship between hotspot number and fire size for each fire event followed a logarithmic increase (figure 6) with remaining high uncertainty in large burned areas estimates (Liu et al., 2019).

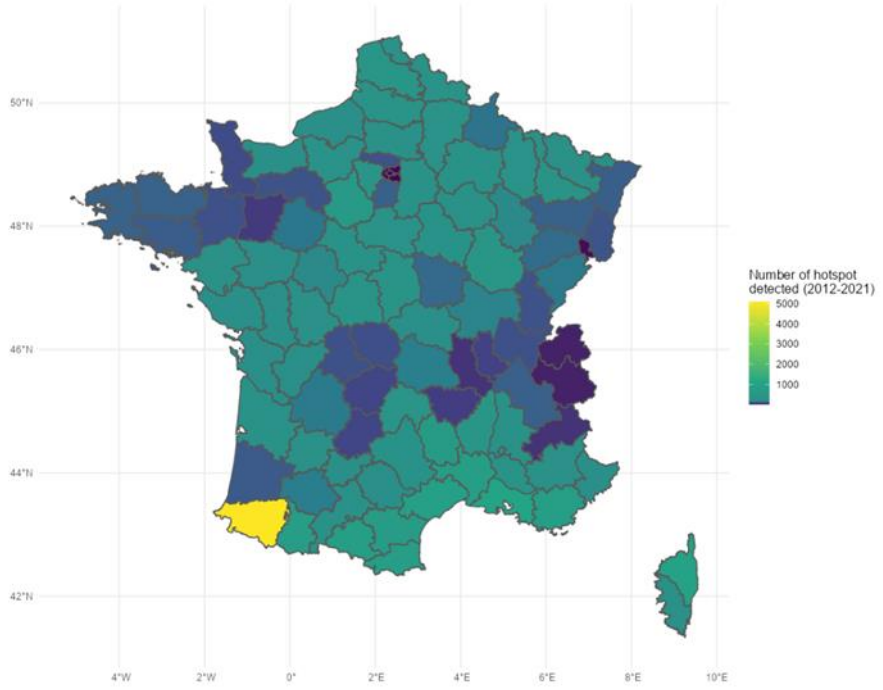

Figure 4 : Number of hotspots detected in croplands by VIIRS Suomi NPP from 2012 to 2021 for each department in France

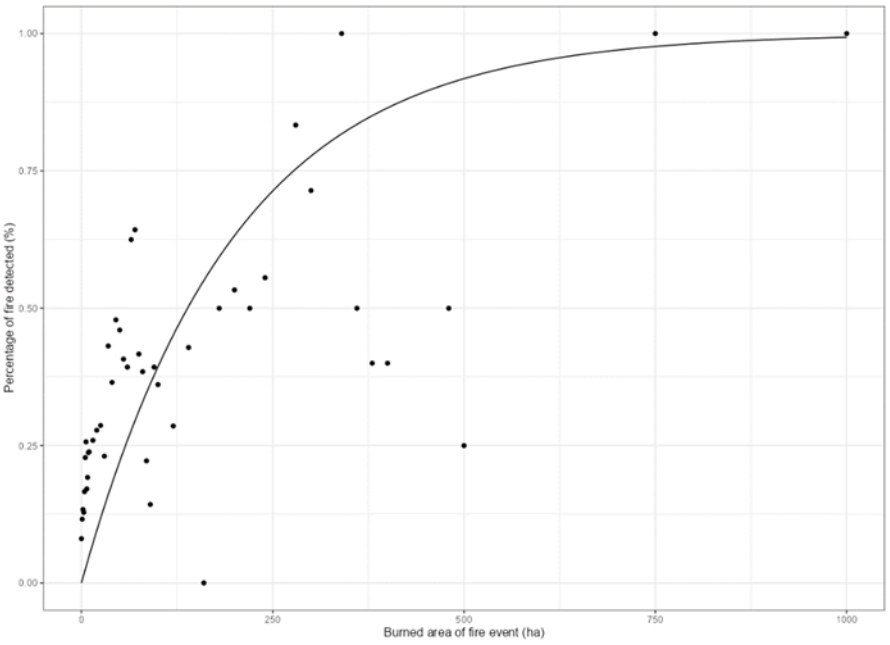

Figure 5 : Fire detection rate (%) with at least one hotspot from VIIRS S-NPP for burned area of fire events (ha) referenced in the datamining References

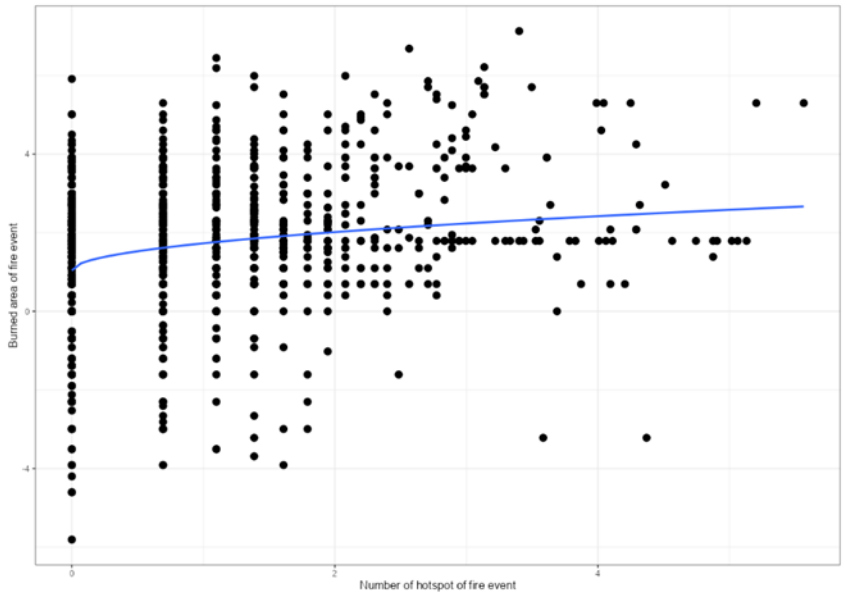

Figure 6 : Relationship between the number of hotspots (log scale) detected and the burned area (log scale) for each fire event (n=1620)

3. Conclusion

This study represents the first attempt to inventory agricultural fires in France. The data mining analysis allowed to highlight spatial and temporal patterns specific to cropland and rangeland fires. Remote sensing data provided a poor improvement for these small, low intensity fires, highlighting the need for better referencing of cropland fires and methodological developments from new sensors (Deshpande et al., 2022).

Large wildland fires, Fire Weather Index, fire risk assessment

Abstract

Wildland fires, especially the large ones, are becoming a growing problem in the climate-changing world. More frequent and long-lasting drought conditions accompanied by high temperatures and heat waves significantly increase fuel flammability, particularly during summer.

The wildland fire occurrence and behaviour are to a large degree weather driven and thus strongly depend on the meteorological parameters such as humidity, temperature, precipitation, and wind speed as well as on the amount of fuel load. The relationship between weather and fire occurrence and behaviour is included in the Canadian Fire Weather Index System (FWI), which has been used in Croatia for fire risk assessment since 1982.

This paper analyses the characteristics of the Fire Weather Index components for large fires in the Adriatic region of Croatia. Fire weather indices were evaluated for 103 wildland fires with a burned area of over 400 ha that occurred during summer fire seasons from 2003 to 2021. Obtained median values of the moisture indices, as well as the fire behaviour indices (FFMC 93, DMC 139, DC 649, ISI 13, BUI 182 and FWI 45) showed values designated as high and very high in the available literature. Compared to daily frequency distribution of indices for fire seasons from 2003 to 2021, the indices during large fire days belong primarily in their upper percentile categories (>75 percentile).

Climate change will continue to increase the fire risk and thus the possibility of large fires so this analysis can provide a baseline for improvements and recalibration of the fire danger classes in the Adriatic area of Croatia. Along with the improved fire weather warnings, this will give better and more accurate information about the increased wildland fire risk and the possibility of large fires.

1. Introduction

The Mediterranean region is the most prominent climate response hot spot (Giorgi, 2006), and Croatia is no exception. Climate analysis of the last 30 years shows noticeable trends in mean temperature rise and the more frequent occurrence and longer duration of extreme meteorological events such as dry spells and heat waves (Gajić-Čapka et al., 2010). These conditions contribute to the increase of fire risk and lengthening of the fire seasons, which tend to start earlier, in May, and extend until October, sometimes even until November. As a result, meteorological fire weather indices also show a rising trend, indicating a growing risk of large fires.

Weather is one of the main drivers of the wildland fires and the most variable one, both spatially and temporally. Long-lasting droughts and high temperatures provide favourable conditions for ignition by dehydration of fuel, and the wind is one of the main factors of fire propagation. Thus, weather parameters such as temperature, relative humidity, precipitation, and wind speed are considered when assessing the risk and behaviour of wildland fires. The Canadian Fire Weather Index (FWI) and its components - fuel moisture codes (FFMC, DMC and DC) and fire behaviour indices (ISI, BUI) represent the cumulative effect of the weather on fuel and thus allow the assessment of fire risk (Van Wagner, 1987).

For the past 40 years, the Canadian Fire Weather Index System has been used in Croatia for fire risk assessment. The index was calibrated for the Adriatic based on the statistical analysis of the burned area and the number of fires. Also, the fire danger classes were derived through a combination of FWI and BUI (Dimitrov, 1987).

At the peak of the fire season, the fire danger classes are predominantly high and very high. Therefore, they do not provide additional information about the fire risk, especially the conditions favourable for large fires.

2. Method and Data

The study area is the Croatian Adriatic, characterized by the Mediterranean climate. It is covered with agricultural land and Mediterranean vegetation, which are particularly conducive to wildland fires. The area can also be considered the wildland-urban interface zone, with many settlements integrated into the wilderness.

Information on the large fires between 2003 and 2021 was obtained from the Croatian Fire Fighting Association. They contain data about fire location, ignition and extinction date and time, and the total burned area.

In the literature, different thresholds of burned area for large fires can be found. Since the purpose is to evaluate indices for the conditions when the extreme fire spread and erratic fire behaviour were present, the wildland fires with a burned area bigger than 400 ha were referred to as large fires (Heilman and Bian, 2010).

For the analysis, the daily values of the Fire Weather Index components were used, calculated at 12 UTC, for 24 meteorological stations of the Croatian Meteorological and Hydrological Service. The values from the stations closest to the fires were relevant to the investigation and used in the analysis (Figure 1).

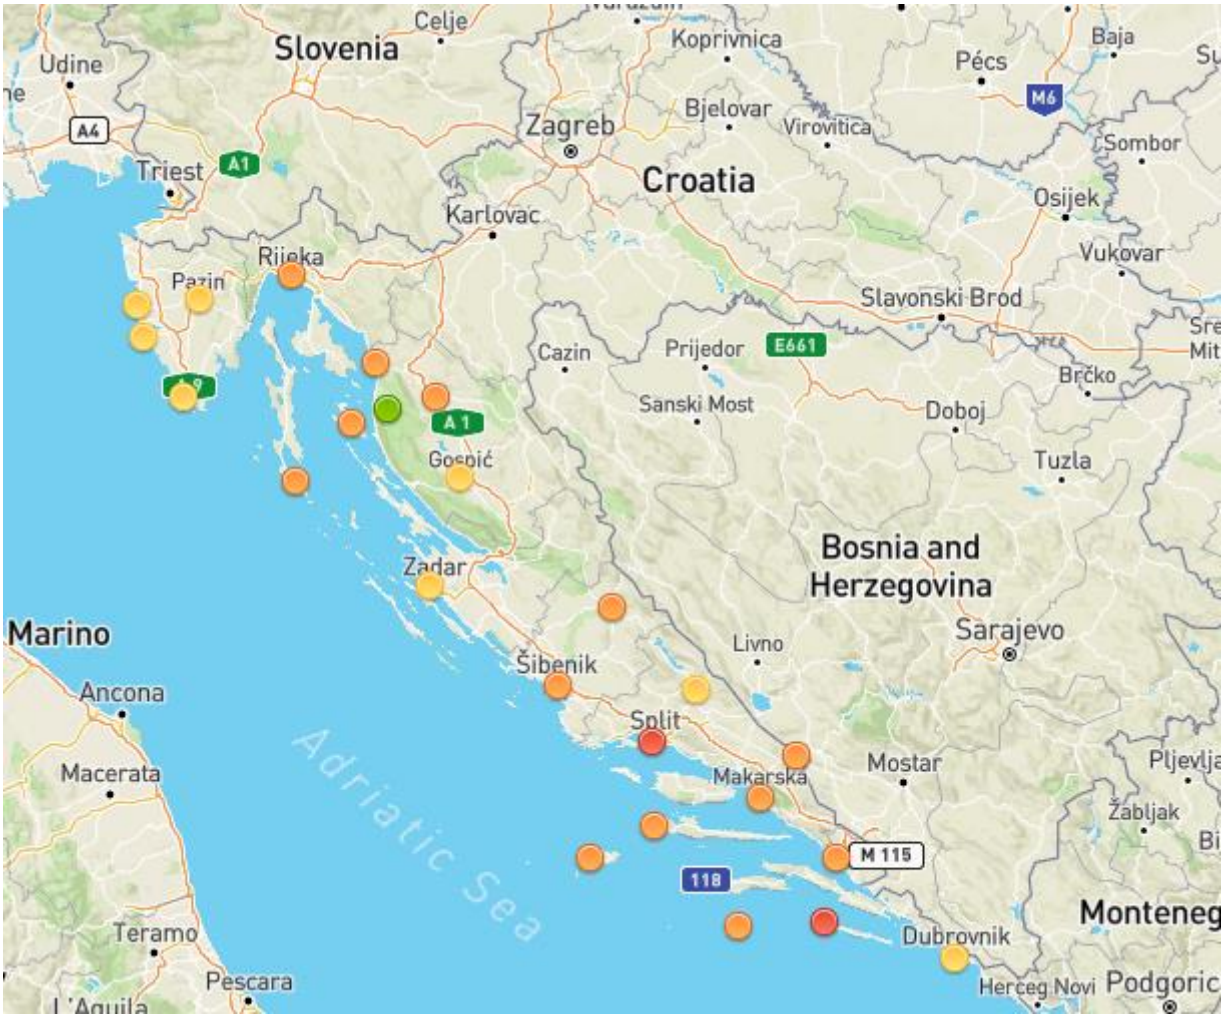

Figure 1 – Location of DHMZ weather stations, source DHMZ.

Empirical cumulative distribution frequency analysis and median and percentile categories were calculated for each FWI component. For comparison, daily distributions of indices for fire seasons (May to September) from 2003 to 2021 were also calculated. The objective of the analysis was to obtain estimates of the index values commonly present during the large wildland fires.

3. Results and Discussion

Statistics for each FWI component is given in Table 1, which summarises the median and percentiles (10, 25, 75 and 90) for FFMC, DMC, DC, BUI, ISI and FWI for days with large fires and fire seasons for a period from 2003 to 2021. Additionally, minimum and maximum values and average and standard deviation are displayed. Related cumulative frequency distributions are shown in Figures 2 to 7.

Table 1 - Statistical values for FWI components (median and percentiles, minimum and maximum value, average and standard deviation) for large fires and daily distribution for fire seasons from 2003 to 2021.

Parameters	Percentiles					Min	Max	Average	Standard deviaton
	10	25	Median	75	90				
FFMC large fires	88	90	93	94	96	73	98	92	3.8
daily distribution	72	85	89	91	93	4.1	98	85	11
DMC large fires	86.4	110	139	184.5	233.2	40	367	150.3	56.4
daily distribution	14.8	28.8	55.8	94.7	143.5	0.4	454.8	70	56.1
DC large fires	487	552.5	649	783.5	874	106	986	662.8	153.2
daily distribution	86.5	174.6	335.7	515.3	681	3.8	1138.7	361	225.1
ISI large fires	6	9	13	19	24.6	1	55	14.6	8.2
daily distribution	1.3	3.9	6.7	10.3	15.2	0	115.2	7.9	6.4
BUI large fires	125	146	182	221.5	262	66	367	187.5	53.2
daily distribution	21.2	40.1	75.5	122.8	176	0.7	454.7	89.2	63.8
FWI large fires	26	34	45	57	67.6	6	108	46	17.2
daily distribution	2.6	10.2	20.7	32.1	44	0	166.5	22.6	16.3

3.1. Fine Fuel Moisture Code – FFMC

The median of FFMC during large fires has a relatively high value of 93, as shown in Table 1. 10-90th percentile interval indicates closely clustered data around the median, with 50% of FFMC values for large fires between 90 and 94, situated above daily frequency median (89).

The FFMC is a numeric rating of the moisture content of fine fuels on forest surface and an indicator of ease of ignition (Van Wagner, 1987). Small spread around the mean as well as the steep slope of both cumulative frequency distributions (Figure 2) point to very low moisture content in fine fuels during most of the days, which can be expected in summer, especially in the environment favourable for large fires. An FFMC of 92 or more points to a high probability of the onset of extreme fire behaviour, depending on the wind and BUI level (Alexander and Cole, 2001). According to the FFMC analysis, these values have been observed in the 50% of large fire data set, and only in 10% of daily distribution (Figure 2).

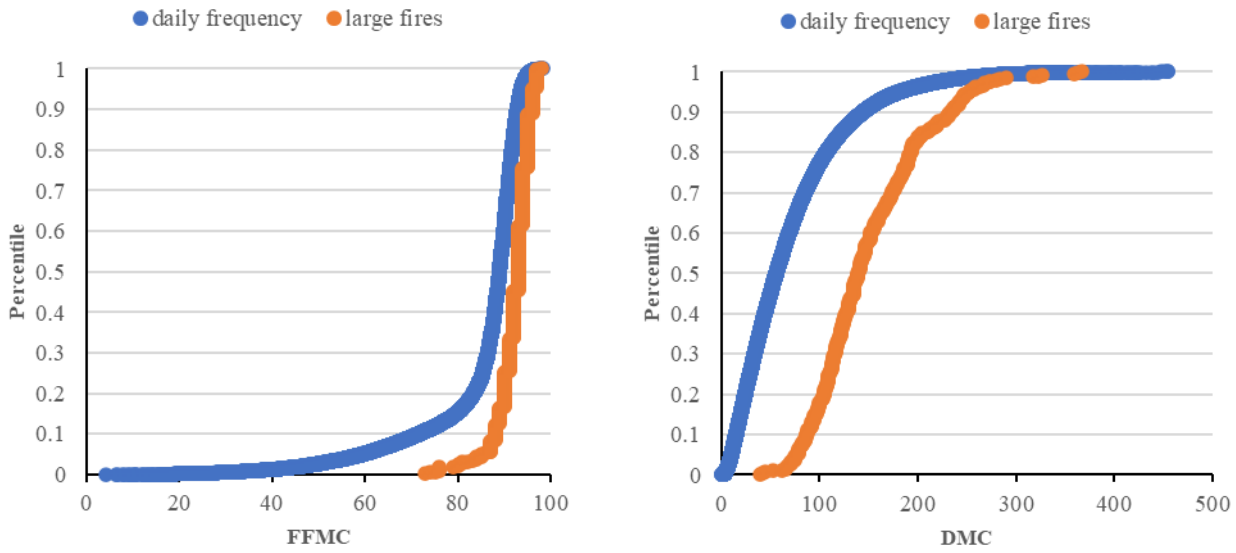

Figure 2 and 3 - Cumulative distribution of Fine Fuel Moisture Code (FFMC) and Duff Moisture Code (DMC) for large fires (red) and daily distribution (blue)

3.2. Duff Moisture Code - DMC

The cumulative frequency analysis for the DMC (Figure 3) shows a median of 139 for large fires and a significantly lower value of 56 for daily distribution (Table 1). Most large fire values are higher than the daily median.

The DMC indicates fuel consumption in moderate duff layers and medium-size woody material, and a value of 150 to 200 indicates that the duff will have lost most of its moisture (Van Wagner, 1987, Canadian Forest Service, 1996). While this is the case in 43% of large fire values, only 10% of daily distribution values indicates moisture loss in duff layers. The DMC analysis could suggest that large wildland fires in the Adriatic occurred even in cases of duff layers not completely dried out.

3.3. Drought Code - DC

According to percentile values (Table 1), for most days with large fires, the DC index was between 487 and 874, with a median of around 650. This value range is situated in the upper 70% of daily distribution values. However, the daily median is much lower, around 335.

The DC index is a numeric rating of the moisture content of a deep layer of organic matter (Van Wagner, 1987) and an indicator of seasonal drought. At a value of 300, the moisture content starts to decrease with depth (De Groot, 1987), so 99% of DC data (Figure 4) show drought conditions were present during large wildland fires, while 55% of daily values were above 300.

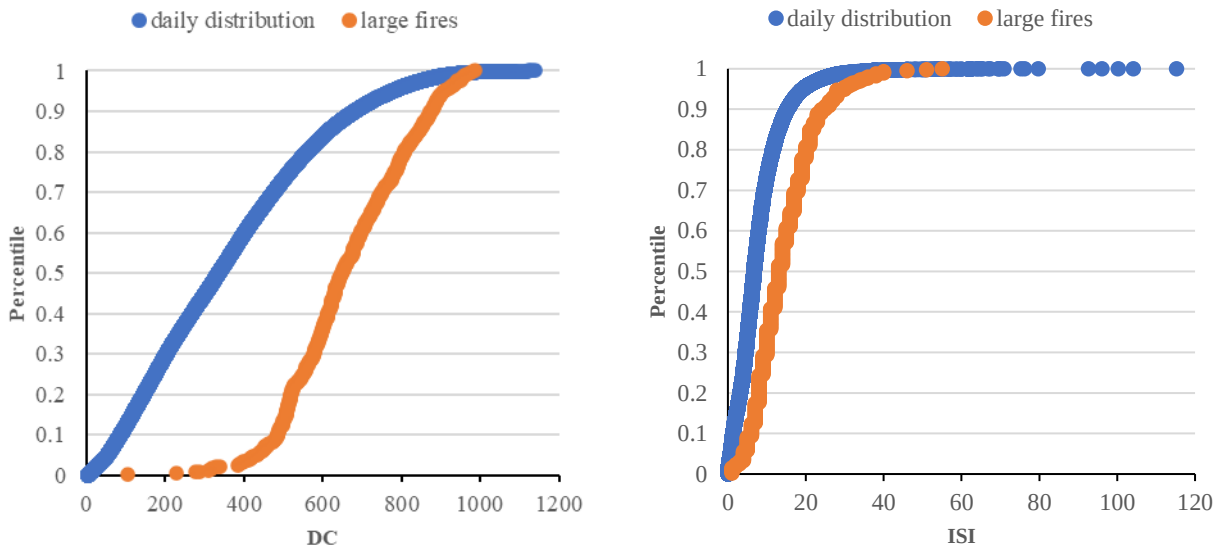

Figure 3 and 4 - Cumulative distribution of Drought Code (DC) and Initial Spread Index (ISI) for large fires (red) and daily distribution (blue)

3.4. Initial Spread Index - ISI

ISI for large fires showed a much larger spread around the median than other indices (Table 1, Figure 4), which is understandable considering its dependence on wind speed. The median for large fires was around 13, with data ranging mostly from 6 to relatively high 25, values that correspond to the 10th and 90th percentile. Compared to daily distribution, about 80% of large fire values were higher than the daily distribution mean. The highest ISI value for large fires was 55, while from 2003 to 2021, values up to 115 were recorded.

Combining the effects of wind and FFMC, the ISI is a numeric rating of the expected rate of fire spread (Van Wagner, 1987). The ISI is used in association with the BUI (or with the degree of curing, in the case of grass fuel types) in the FBP System (Forestry Canada Fire Danger Group 1992) to provide numeric values for fire behaviour for predetermined forest and slash fuel types.

3.5. Buildup Index - BUI

According to the cumulative frequency, BUI mean for large fires (Figure 6, Table 1) is 182, while 90% of the values (125 to 262) are above the 75th percentile of the daily distribution.

The BUI index is a numeric rating of the amount of fuel available for combustion (Van Wagner, 1987) and represents the fire potential. The statistical analysis done by Dimitrov (1987), currently used for fire danger assessment, classified BUI values as very low (0-48), low (49-85), moderate (86-118), high (119-158) and very high (159+). Therefore, around 70% of the large fire values and less than 15% of daily distribution can be placed in very high Dimitrov's class.

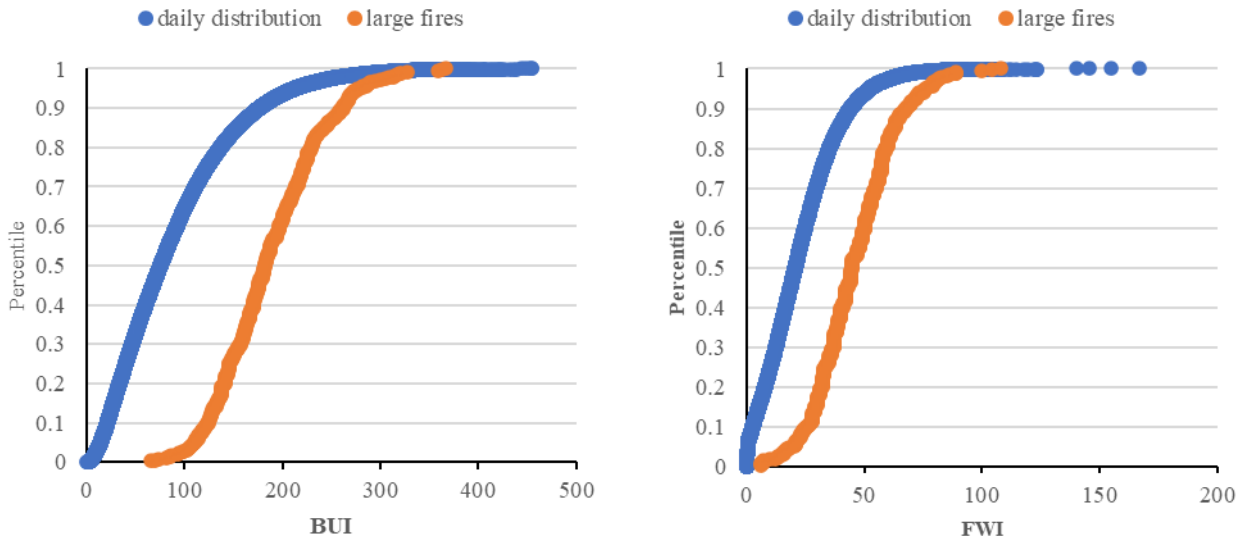

Figure 6 and 7 - Cumulative distribution of Buildup Index (BUI) and Fire Weather Index (FWI) for large fires (red) and daily distribution (blue)

3.6. Fire Weather Index - FWI

Analysis shows that 80% of FWI values for the large fires, ranging between 26 and 68 (Table 1, Figure 7), are situated above the daily frequency median (21). The large fire median of 45 is above the 90th percentile of the daily distribution.

The FWI is a general index of fire danger and a numeric rating of fire intensity calculated from ISI and BUI (Van Wagner, 1987). The FWI values used in Croatia, according to Dimitrov (1987), are considered very low (less than 4), low (5-8), moderate (9-16), high (17-32) and very high (33+). The 25th percentile of the large fire distribution is on the lower boundary of the very high Dimitrov's class, meaning that 75% of FWI data fall in the very high fire danger class.

4. Conclusion

Climate change scenarios suggest extreme weather events such as long dry periods and heatwaves will be more frequent and stronger in the future (Branković et al., 2012). As a result, the conditions conducive to fire will be more common in Croatia, particularly on the Adriatic.

The analysis of the FWI indices during large wildland fires provides an insight into the range of values that typically appear when weather conditions are favourable for extreme fire spread and behaviour. Median values of indices (FFMC 93, DMC 139, DC 649, ISI 13, BUI 182 and FWI 45) showed values designated as high and very high in the cited literature, particularly in Dimitrov (1982), and generally fall in the upper percentile categories (> 75th percentile) of daily frequency distribution for fire seasons from 2003 to 2021. Moreover, 70% of BUI and 75% of FWI fall into the very high Dimitrov's class. So, the median values and upper percentiles, e.g., 90th obtained for large fires and fire weather warnings, can be used as additional information for forecasters and fire managers when assessing the possibility of large fire occurrence.

The climatology of the FWI indices for the Adriatic is long overdue, along with the new calibration of the Index. Dimitrov's fire danger classes have proven inadequate during the peak of fire season when values are predominantly high and very high. However, there are some efforts to calculate the most recent climatology. Results obtained in this paper together with the new FWI climatology could provide a baseline for recalibration of the fire danger classes.

Abstract

The present paper provides an overview of the research carried out by the Institute of International Sociology of Gorizia (ISIG) in the framework of three EU funded projects (ECOSTRESS – DG ECHO, RESILOC – H2020, and FirEUrisk – H2020). Throughout these three research projects, a relevant corpus of literature has been analysed and re-elaborated, allowing for the development of methodologies and instruments for the assessment of social vulnerability at a local/community level. This paper provides, first, a theoretical overview on the issue, second, the results and potentialities of such instruments stemming from recent field applications, and third, the potential outline for operational approaches in the field of wildfire resilience-building strategies for local communities.

By addressing the complexity of vulnerability, both as a concept and as a phenomenon, the paper focuses on social vulnerability to wildfire, intended as the magnitude of social impact deriving from wildfires, and the (in)ability of local communities to cope with wildfire as a stressor.

In the absence of standard assessment benchmarks and thresholds for (social) vulnerability, the paper argues for a relative perspective of analysis, within which the 'vulnerability' of a community is analysed in comparison with other similar units of analysis.

Furthermore, the paper argues for participatory approaches towards such assessments, that would allow for an increased level of integration of local knowledge within the analysis. Moreover, building on the results of recent research projects, the paper promotes participatory approaches to vulnerability assessment as a preliminary 'needs assessment' by means of which end users/communities may identify 'areas of vulnerability', as well as well as existing resources/adaptive capacities, to be considered in the elaboration of resilience strengthening strategies or equivalent development/strategic planning processes at local level.

1. Introduction – a research framework for social vulnerability

The paper provides an overview of the research carried out by the Institute of International Sociology of Gorizia (ISIG) in the framework of three EU funded projects[1], namely summarising the relevant corpus of literature that has been analysed and re-elaborated to develop instruments for the assessment of social vulnerability at a local level.

This paper provides a theoretical overview on the issue which could serve as a basis for operational approaches in the field of wildfire resilience-building strategies at local/community level, to be further explored within the framework of FirEUrisk H2020 project.

1.1. Social Vulnerability

[1] ECOSTRESS (DG ECHO): ISIG developed a Relative Social Vulnerability Index and SWOT Analysis of Coastal Case Studies in the Upper Adriatic. RESILOC (H2020): ISIG coordinated the activities related to the analytical framework for the vulnerability analysis at Local Community level. FirEUrisk (H2020): ISIG is coordinating the definition of a methodological framework for wildfire vulnerability assessment, with a specific focus on societal vulnerability.

Vulnerability, both as a concept and as a phenomenon, does not have a univocal definition, nor a unique methodology for its assessment (Füssel, 2007; Fekete & Montz, 2018; Cutter, 2018). It may be broadly understood, however, as the potentiality for loss of a unit/system in the light of stressors. The UNDRR defines vulnerability as "the conditions determined by physical, social, economic and environmental factors or processes which increase the susceptibility of an individual, a community, assets or systems to the impacts of hazards"[2].

Vulnerability is a multifaceted concept: it lacks a definitional unity and clarity (Cutter, 2018) both within, and between, academic research and policy and practitioner driven work (Füssel, 2007; Fekete & Montz, 2018). It is also a dynamic concept, eventually shaped by the recent waves of increased awareness regarding the profound climate change impacts (Hinkel, 2011).

Especially after the 1994 *World Conference on Natural Disaster Reduction* in Yokohama, the concept of vulnerability has become very prominent in the field of risk reduction studies (Cutter, 2018). Vulnerability has been increasingly associated with the term "resilience", whose success was at least partially determined by its positive tone.

There are several elements that are generally acknowledged as being entailed by the concept of vulnerability:

- Exposure: the stress or stresses to which an individual, community, society, ecosystem, structure, etc. are exposed (i.e., they are at risk from a hazard).
- Sensitivity: the extent to which the exposed elements are affected or indeed modified by the stress.
- Adaptive capacity/coping mechanisms: existing or lacking skills, resources, opportunities that allow the exposed/affected elements to survive, absorb the impacts, and manage the adverse outcomes.

Vulnerability studies investigate on different thematic dimensions or types of vulnerability; every dimension has shaped different research perspectives, academic corpuses of knowledge, and consequently different assessment/measurement methods. The MOVE framework (Birkmann et al., 2013) and the 4-dimensional model proposed by Fuchs and Thaler (2018) stand as relevant attempts to systemize different perspectives on the issue of vulnerability under the same framework. The former identifies six dimensions of vulnerability: social, economic, physical, cultural, environmental, and institutional. The latter works on a combination of physical, economic, institutional, and social dimensions of vulnerability.

Within the abovementioned frameworks, social vulnerability describes a state of people, or populations, rather than physical structures, therefore a 'social space' whose boundaries are defined by the "political, economic, and institutional capabilities of people at a specific time and place" (Burton, Rufat, & Tate, 2018, p. 53). Social vulnerability refers to the inability of people, organisations, communities, and societies, to resist adverse impacts from stressors to which they are exposed.

1.2. Social Vulnerability to Wildfires

Social vulnerability to wildfires refers both to the magnitude of social impact deriving from wildfires, and the inability of local society to cope with stressors to which it is exposed. It entails both a structural and a processual dimension. According to the *FAO Strategy on Forest Fight Management*, 90% of wildfires are caused by human activities and behaviours, which are in turn interrelated with meteorological conditions, territorial topography, and fuel availability, following a non-linear and dynamic relationship.

Leone et al. (2003, 2009) proposed a systematisation of the main human-related variables explaining wildfire occurrence, stemming from several previous studies. Martínez et al. (2009) identified seven groups of anthropogenic risk factors associated with wildfires:

- Socio-economic transformations in rural areas.
- Human presence and socio-economic transformations in urban areas.
- Persistence or transformation of traditional activities linked to fire in rural areas.
- Accidental or negligent events related to infrastructures and facilities.
- Landscape structure and housing patterns.

[2] https://www.undrr.org/terminology/vulnerability

- Indirect factors (i.e., regulations and behaviours) of intentional fires.
- (Lack of) forest policy.

These or similar dimensions are used by the authors to identify relevant variables (i.e., indicators) describing exposure and sensitivity associated with fire risk in different geographical contexts (Martínez et al., 2009; Ager, Preisler, Arca, Spano, & Salis, 2014; Vallejo-Villalta et al., 2019; Costafreda-Aumedes et al., 2017).

In the broader framework of human activities, consolidated and/or emerging patterns of territorial development, as well as local policies, play a relevant role in adapting the whole system to wildfire risks, as well as in making available coping mechanisms. Also in this case, relationship between established policies/practices and efficiency and efficacy in fire risk reduction is hard to be traced, for instance in the case of fire management procedures (Fernandes, 2013; Moritz et al., 2014)

Jucker Riva et al. (2018) investigated the impact of land management practices (LMPs) in the enhancement of forests and rangelands resilience vis-à-vis environmental disturbances, including wildfires. They isolated 16 LMPs, clustered in five groups, highlighting that that removal of vegetation was the most beneficial single LMP: clearing of vegetation; managed grazing; planting of shrubs; planting of trees; other practices.

2. Assessing Social Vulnerability: towards a participatory approach

If defining vulnerability is fraught with difficulty, assessing and measuring it is even more difficult. While the notion of measurement refers to the elaboration of specific quantification instruments which can describe the phenomena of vulnerability, the notion of assessment includes a broader spectrum of approaches to identify, investigate, quantify, weight and rank of a set of vulnerabilities.

Various critiques have been voiced at the methodologies of measurement, mainly in relation to the challenges of using indexes, to problems associated with spatial and context differences and assessment of data at various scales of analysis (Barnett, Lambert, & Fry, 2008; Fekete & Montz, 2018). Comparisons have been warned against, on the argument that vulnerability is a context-specific rather than a generic condition (Barnett, Lambert, & Fry, 2008). Also, another critique is focused on the dynamic nature of the vulnerability phenomena (Adger, 2006), which determines shortcomings in the use of static indicators. When considering analysing vulnerability from a community perspective, the dynamic nature of both the phenomenon (i.e., vulnerability) and of the unit of analysis (i.e., the community) plays indeed a fundamental role. Quantitative methods and data can provide for a static picture of a community but limited in the understanding of the real implications and connections of intervening factors at community level, for instance adaptive capacity elements (i.e., skills and resources). Moreover, each community is very different than the other, so in order to be able to grasp fully the interactions and implications of the identified variables with the context itself, there is the need to incorporate in the analysis the local knowledge and awareness. This may be achieved by means of participatory approaches to assess vulnerability.

The understanding of vulnerability and resilience at community level depends on who, what, where, and for whom – all of which are socially constructed and temporally changing (Cutter, 2018). Resilience and vulnerability are embedded in interdependencies between systems, scales, and historical processes. It may be thus challenging to identify thresholds or benchmarks in vulnerability assessments (Fekete, 2019). In a word, vulnerability, as well as resilience, may be approached from a relative perspective rather than in absolute terms (Cutter, 2016; Fekete, 2019). Understanding vulnerability as a relative concept means to consider it in context, so to allow for its observation in comparison with other similar units of analysis, for example neighbouring communities exposed to similar hazards.

Most studies derived from the methodologies devised by Cutter[3] provide a spatial assessment and an empirical ranking. A vulnerability score (a numerical value which aggregates all the operations performed through collecting values for indicators, aggregating them, etc.), is not considered to be high or low *per se*, but by reference (distance) to a mean value, therefore, only by reference to other units of analysis, which compose this mean. Such approach, adopted for the purpose of this paper and of illustrated research projects, enables

[3] See for instance Cutter, Boruff, & Shirley, 2003; Cutter, Burton, & Emrich, 2010; Guillard-Gonçalves, Cutter, Emrich, & Zêzere, 2015.

participatory assessments of vulnerability and resilience of communities, which could allow for a more grounded integration of context knowledge. The later, appears to be key to ensure an accurate analysis/representation of the status quo at community level, that might escape to top-down approaches.

3. Applications of proposed methodology: results and benefits for building targeted resilience strategies at local level

The RESILOC Community Vulnerability Indexes are the result of a participatory process that engaged project end-users (i.e., pilot local communities) in both data collection process and assessment. Starting from a standard set of indicators and related proxies (i.e., quantitative, and qualitative variables), aggregated in five dimensions (social, economic, institutional, human capital, environmental) each pilot Community was requested to select the most relevant ones and to attribute different weights among those considered relevant (i.e., medium and high). The vulnerability relative indexes were then calculated, based on available statistical data, as well as on qualitative variables gathered from end-users. Vulnerability community scores have been calculated for involved pilots (i.e., municipalities) in a relative perspective, against their area of reference (i.e., neighbouring communities).

Ultimately, snapshots of community vulnerability were developed for each pilot, representing an initial 'needs assessment' at local level, enabling the identification of 'vulnerability areas' upon which building a resilience-strengthening strategy perspective. An example of such snapshot is provided in Figure 1, while Figure 2 provides an example of visual representation of a Relative Social Vulnerability Index, performed in more than 300 contiguous communities within the Turin Metropolitan City area (2019, RESBA, Interreg Alcotra Project).

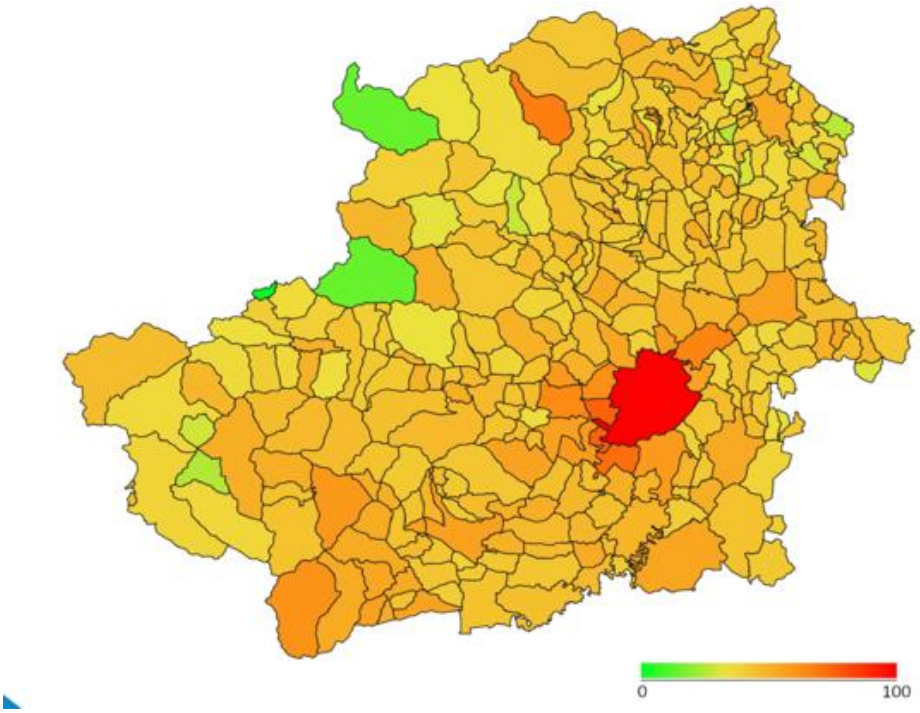

Figure 1 - Example of visual representation of a Relative Social Vulnerability index in contiguous communities, ReSBA Project, Interreg Alcotra, 2019

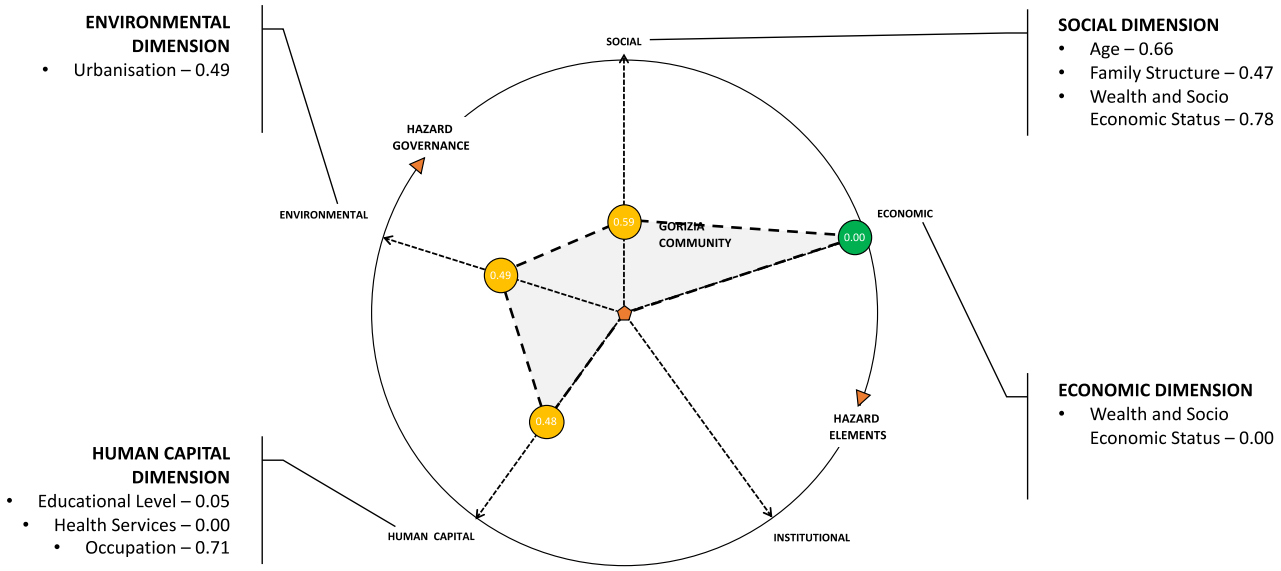

Figure 2 - Example of Vulnerability Snapshot at local level - indication of variables scores per each dimension.

3.1. FirEUrisk Project –relative perspective and participatory approach towards analysing in social vulnerability of communities to wildfire

Building on the previous experiences of constructing relative indexes of vulnerability, within the framework of FirEUrisk project, the direct and indirect effects of fire on people's lives, and more generally, communities, will be analysed based on a methodological framework that:

- Identifies 5 dimension shaping the community and in terms of which vulnerability is assessed.
- Entails a relative approach, in which the 'vulnerability' of a community is analysed in comparison with other similar units of analysis.
- Integrates the role of community experts in the selection of the vulnerability indicators and proxies, as well as in the assessment of their relevance for the specific context.
- Integrates 'local knowledge' and 'context-related' insights within the calculation of the indexes, as variables are weighted according to the assessed level of relevance for the context at stake.
- Indexes allow for depicting the Vulnerability Framework of a Community based on static elements (i.e., statistical data), while expert interviews will allow for the integration of the "dynamic" components of the analysed communities.

Beyond the analysis of susceptibility to fire impacts, the methodology aims to support local communities in analysing their vulnerability to wildfire as a starting point for designing and implementing strategies that aim to strengthen adaptive capacities and overall resilience at the local level.

4. Conclusions

The literature review presented in this paper provides a glance on the extensive, yet diverse, theoretical basis for the definition of wildfire social vulnerability assessment methodologies at a local level. The paper argues that, in order to encompass the complexity of a relative, multi-dimensional, multi-scalar, temporally and spatially dynamic concept such as (social) vulnerability, the assessment processes must be implemented with a great degree of context-awareness, and eventually with the direct involvement of analysed communities.

The issue of vulnerability multi-scalar dimension(s) needs to be further investigated in order to develop effective ways to embed in the same assessment framework qualitative and quantitative information, which very often are collected on different scales and with different granularities (as illustrated in Burton, Rufat, & Tate, 2018).

Moreover, the analysed literature suggests that correlations among different elements characterising "social spaces" in terms of impact on the system exposure, sensitivity and adaptive/coping capacity, play a relevant role in increasing or lowering wildfire social vulnerability. From this perspective, the application of the Forest

Fire Circle model (Tàbara, Saurí, & Cerdan, 2003) might be useful to take into account the relevance of these relationships in wildfire social vulnerability assessment methodologies.

FirEUrisk project provides for the fertile ground in which to further explore the integration of multi-scalar dimension in social vulnerability assessment, as well as for consolidating participatory approaches towards vulnerability assessement across the five projet pilot sites.

5. Disclaimer

This paper is funded by the H2020 Project FirEUrisk (Grant Agreement Number:101003890). Considerations provided are the results of discussions matured between the authors and do not necessarily reflect the point of view of the funder.

Flammability assessment, fuel moisture content, ignition, risk assessment

Abstract

An experimental investigation into the impact of moisture content on the flammability of Scottish heathland vegetation has been undertaken in this work. Two different vegetation types are studied; Molinia caerulea and moss. The approach followed in this work consisted of developing an appropriate sample preparation procedure to ensured homogeneous drying in a conditioning chamber and the development of an apparatus to support a consistent ignition procedure. The probability of ignition is evaluated as a function of fuel moisture. For Molinia caerulea, ignition is very likely to occur for a moisture content of less than 75%. For moss, this transition stage revolves around 20% of moisture content. Additionally, drying curves have been drawn for the specific drying conditions (30 ºC and 90% relative humidity), which can provide insight into the rate of drying of organic materials for these given environmental conditions. Finally, a discussion presents the main findings and limitations of this work, while providing insight into possibilities for future research.

1. Introduction

Previous studies (Legg et al., 2007; Nolan et al., 2016) have identified that the fuel moisture content (FMC) of "thin" or "fine" fuel elements responds more rapidly to changes in the environmental conditions than thicker fuel elements. Often fine vegetative matter is the fuel first ignited in wildfire events and therefore understanding the response of these fuels to drying is essential to accurate wildfire risk mitigation (Viegas et al., 1992; Chuvieco et al., 2011; Davies and Legg, 2011). Within the United Kingdom (UK), *Molinia caerulea* and mosses represent two typical fine fuels found on heathlands. This study seeks to develop an understanding on the drying response of these fuels and the conditions required for ignition using a small flame. The likelihood of ignition of a fuel when subjected to small ignition sources is determined. In this study, the probability of ignition is determined as a function of the fuel moisture content. This approach gives an indication of the relationship between fuel moisture content and ignition and can be used to evaluate when different fuels are susceptible to ignition by small sources. The FMC of live and wet dead fuel can be affected differently by environmental conditions, and this work uses only dead Molinia grass which might not be representative of the behaviour of live grass. A separation between live and dead moss was not possible.

Repeatability of results is important, both in the drying behaviour and the flammability response, given the high level of natural variability that exists in wildland fuels. This idea shaped the methodology employed, which was designed to ensure a homogeneous drying of the fuel and consistent flammability responses in a practicable way.

The steps followed throughout this process and the reasoning behind them is presented to ensure clarity, transparency, and highlight the approach's limitations. The methodology section outlines the tools and equipment used to carry out the experimental procedure. Then the results of that procedure are presented, followed by a discussion on the findings. This last section is supplemented by an explicit declaration on the limitations of this approach.

2. Methodology

2.1. Overview

Different preparation and testing methodologies are developed for the grass and moss samples to account for their differing structure. An illustration is presented in Figure 1 that visualises the processes followed for the grass and moss. Blue boxes indicate a process, and green boxes indicate an outcome of the linked process. These are discussed in more detail in the following sections.

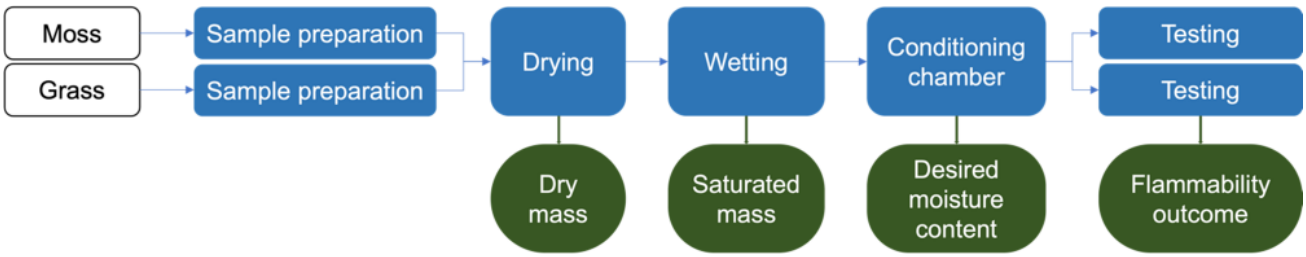

Figure 1. An outline of the process followed for examining relationships between fine fuel moisture (FMC) and flammability

2.2. Sample preparation

2.2.1. Molinia grass

Samples were received in a cured dry condition and required rewetting and drying to obtain the FMC of interest. Repeatable sample preparation was essential to ensure consistent results and homogenous conditioning of the samples. Samples were prepared by attaching a fixed mass of grass to electrical tape. Each sample was of approximately 0.45 g (dry mass). Care was taken to distribute the sample evenly along the tape (Figure 2).

Figure 2. Molinia grass sample prior to testing fixed with electrical tape

2.2.2. Moss

The nature of moss means that it must be supported on a frame prior to testing. A set size of 10 x 10 x 5 cm was chosen for the moss sample holders because this enabled consistency amongst the sample sizes and weights, (Figure 3). Moss samples were prepared by removing grass or other litter to prevent this from impacting on the results. The height of the moss samples was approximately 20 mm.

Figure 3. Moss sample preparation prior to testing

2.2.3. *Drying*

Both Molinia and moss samples were dried straight after preparation in an oven at 60°C to determine their dry mass. The samples remained in the drying oven until their mass remained stable over 4 consecutive hourly measurements. This typically took less than 24 hours. This temperature was chosen to avoid the loss of any volatile organic compounds which can occur in organic fuels when dried at higher temperatures (Samuelsson, Nilsson and Burvall, 2006).

2.2.4. Wetting

After the grass samples were prepared and totally dried, they were placed in groups of 4 in a 500 ml glass beaker of tap water and were left submerged overnight to saturate, covered with aluminium foil.

After the moss samples were prepared and totally dried, they were placed in large tank with tap water and were left submerged overnight to saturate.

2.2.5. Drying for moisture content control

An environmental chamber (TAS ECO MTCL400) was used for the controlled drying of the samples before every experiment. The conditions in the chamber were set at 30°C and 90% relative humidity (RH). These conditions were chosen as suitable for providing a rate of sample drying that allowed for measurements to be taken while maintaining a manageable timeframe of every experimental run. Mass readings were made using a precision balance (Mettler Toledo NewClassic MS), with readability of 0.01 g.

2.2.6. Calculations

The dry basis moisture was used for the calculation of the samples' moisture content, which is defined as the amount of water over the dry sample. This is calculated through the formula:

$$MC = 100\frac{m_w}{m_{ds}}$$

Where:

- MC is the sample's moisture content in percentage form,
- m_w is the mass of the water contained in the sample,
- m_{ds} is the mass of the dry sample.

The drying curves were based on the drying rate normalised per each sample's dry mass, calculated as follows:

$$DR = \frac{m_{i+1} - m_i}{t_{i+1} - t_i}\frac{1}{m_{di}}$$

Where:

- DR is the sample's drying rate normalised to its dry mass,
- m_i is the mass of the sample at a given time t_i,
- t_i is the time of the measurement.

2.2.7. Ignition source

A small flame ignition source was used. This was obtained using a commercially available wax candle. The flame was approximately 15 mm high. This was chosen to give a consistent ignition source both in terms of size and burning duration and seeks to represent a small ignition source. The results presented in this work are strongly dependent on this choice of ignition source.

2.3. Molinia apparatus

For the grass samples, the developed and used apparatus is shown in Figure 4. The sample and sample holder remained in a fixed position while the ignition source could be positioned manually. The vertical orientation of the apparatus was chosen to provide conservative results.

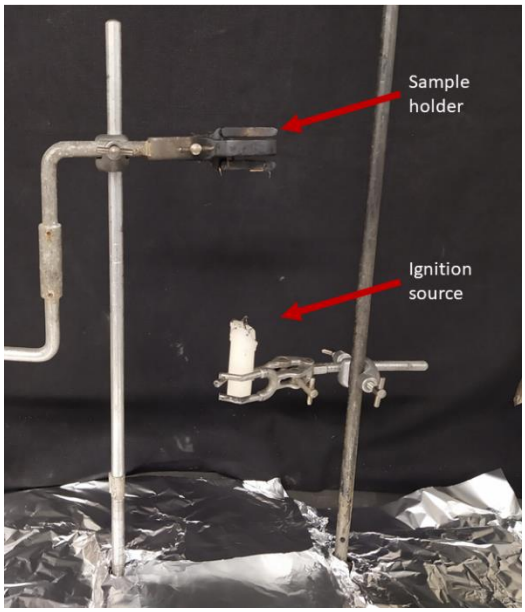

Figure 4. The Molinia grass ignition testing apparatus

2.3.1. Molinia procedure

Once a sample reached the desired moisture content, it was rolled into a clump with diameter of approximately 15 mm at the tied end and placed in the sample holder. This shape was chosen so that the full sample area would be simultaneously exposed to the ignition source, and grass strands would be in such proximity with each other that would be representative of their field condition. The ignition source was placed just below the sample for 5 seconds. Then the ignition source was removed and the resultant burning (or otherwise) of the sample observed.

2.3.2. Moss apparatus

The apparatus used for the moss samples, is shown in Figure 5. The wire mesh was assembled to place the sample holder and ignition source in position. The horizontal orientation of the apparatus was chosen to emulate conditions in which moss is likely to be found.

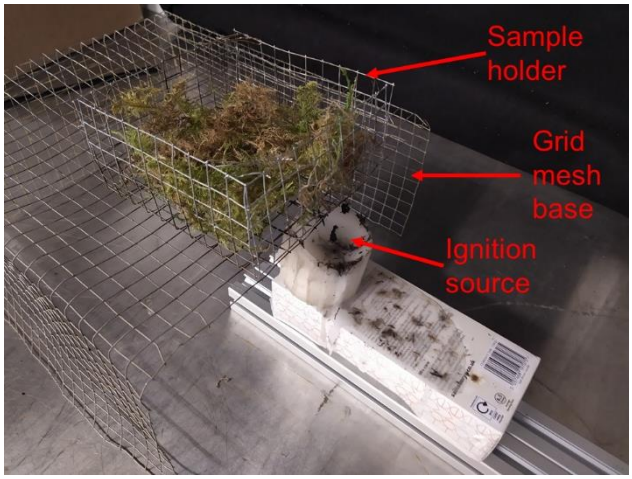

Figure 5. The moss testing apparatus: sample holder, base mesh grid, and ignition source are indicated.

2.3.3. Moss procedure

Once a sample reached the desired moisture content, it was placed on a metal grid above the ignition until the estimation flammability was definitive; either sustained burning or local ignition but no propagation.

2.3.4. Probability of burning

Subjective probabilities were used for the assessment of flammability. This is a type of probability that expresses the observer's belief on a system or outcome, derived from their personal judgment or experience. In this work, these were defined by the amount of fuel consumed by the ignition source alone, and the ability of the sample to sustain burning individually after the ignition source is removed (0 – no fuel consumed, 0.25 – some fuel consumed but no burning, 0.5 – some fuel consumed and some smouldering followed, 0.75 – fuel consumed and some flaming follows, 1 – sample fully consumed in flaming combustion).

3. Results

In this section the results from the measurements and experimental procedure are presented. Initially the indicative moisture loss graphs and the drying curves are presented for Molinia grass and moss, respectively. Following that, the moisture loss graphs up to ignition, and the flammability graphs linking the moisture content with the probability of ignition are provided.

3.1. Moisture loss graphs and drying curves: Molinia

The findings from the 20 indicative samples of grass that were dried from saturation to dryness are presented in the figures below. Figure 6(a) presents the loss of moisture over time. Figure 6(b) also shows the drying curve for these grass samples. The drying curve is characterised by a decreasing drying rate as a function of time. After 60 minutes, the drying rate approaches zero and the samples reach equilibrium with the environmental conditions in the chamber.

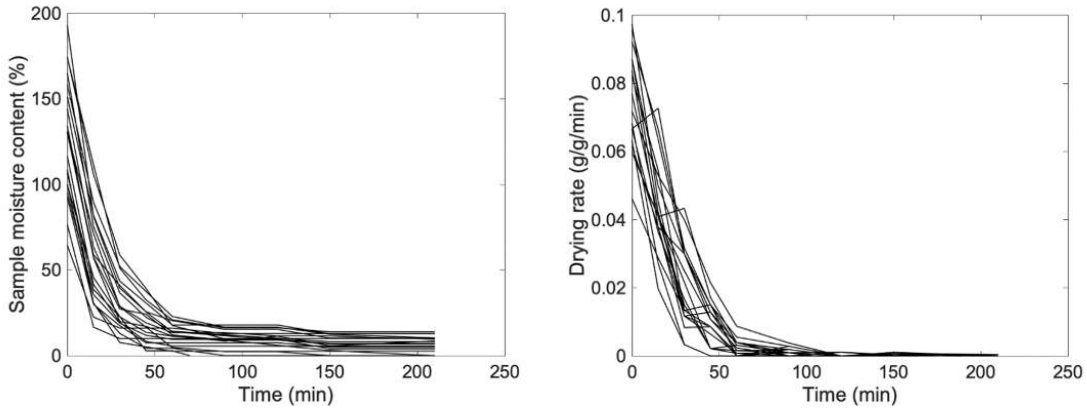

Figure 6. (a) moisture loss, (b) drying curve; for Molinia grass

Change in FMC as a function of time from the 13 indicative samples of moss that were dried from saturation over a period of seven hours are presented in Figure 7(a). Compared to the Molinia samples the characteristic time of the drying is much longer with none of the samples reaching a stable FMC over the time period available. There is a higher degree of variability in these results compared to the Molinia. This is attributed to the differing thickness and more complex structure of the samples compared to the grass. Figure 7(b) below shows the drying curve for these moss samples, which as was presented in the Calculations sub-section, is the drying rate normalised by dry sample mass. Again, given the nature of the fuel structure there is some scatter in the results but for a moss sample in this condition, the drying rate appears to be on the order of 0.01—0.03 g/g/min.

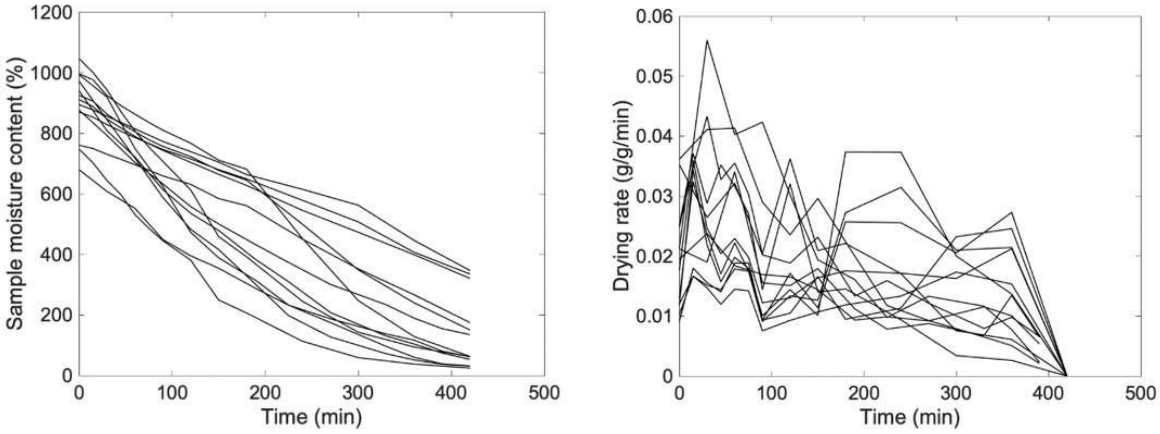

Figure 7. (a) moisture loss, (b) drying curve; for moss

3.2. Flammability graphs

Characterising the drying times allows for target moisture contents to be reached for testing. New samples were prepared, wetted, and dried for a duration required to achieve the desired FMC for testing. Figure 8 shows the resulting probability of ignition for Molinia grass as a function of FMC.

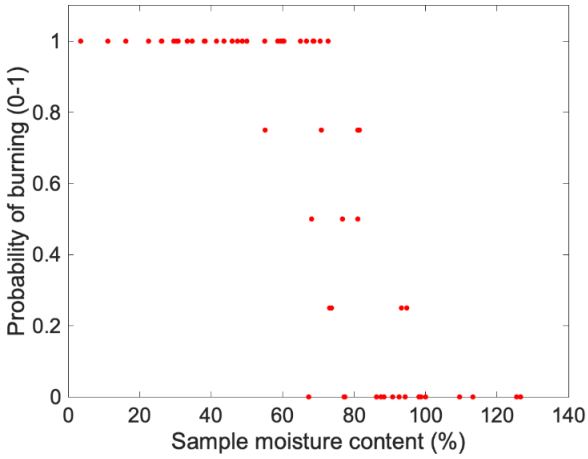

Figure 8. ignition probability as a function of fine fuel moisture content (FMC) for Molinia grass.

From Figure 8 above it can be inferred that there is not a critical FMC at which the behaviour of the fuel changes. Instead, the ignition probability increases from 0 to 1 in the range 85—65% FMC. FMC lower than 65% are almost certain to ignite and burn to completion.

Figure 9 shows the resulting probability of ignition for moss as a function of FMC. Similar to the behaviour of Molinia grass, for this graph too it can be inferred that there is not one point where the behaviour of the fuel immediately changes, but it is rather defined as a region in between 10 and 20% FMC.

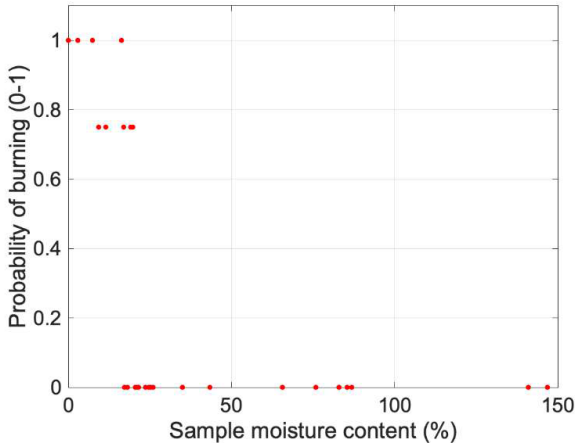

Figure 9. ignition probability as a function of fine fuel moisture content (FMC) for Molinia grass.

4. Conclusions

This study has highlighted the ignition probability for Molinia and moss subject to a small flame source. These fuels were chosen as they are found on the ground where small ignitions sources may arise accidentally e.g. dropped matches, discarded cigarettes. The approach employed in this work is not intended to replace standardised methods of assessing fuel flammability, where a well-defined exposure and combustion environment exists, but provide complementary, easy-to-acquire insights on the behaviour of wildland fuels when exposed to these small ignition sources. These results, however insightful, may not be appropriate as direct inputs in fire models, but the approach could be used as a practical means to provide threshold values in local wildfire risk indices, such as any adaptation to the Canadian Forest Fire Weather Index System, that are relatively easy and quick to produce experimentally.

The Fuel Moisture Content (FMC) for ignition of Molinia grass was found to be in the range below 85%. With a high probability for samples with less than 65% FMC. The ignition of moss was found to occur at FMC below 20% with a high probability at FMC less than 10%. These results serve to calibrate ignition thresholds and to evaluate the relative hazards posed by different fuels. Combining the drying rate data and the ignition probabilities allow an estimation of the timescales required for the different fuels to become ignitable. For Molinia this is on the order of 30 minutes. For the moss, this is on the order of 5 hours. These differing timescales are strong indicators that the hazard associated with different fuel elements requires careful consideration, while acknowledging that they can be affected differently by any wind present and the climatic conditions of the region

When interpreting these results, there are some limitations that should be considered. Firstly, the nature of the ignition source and the duration of the application will have an impact on the results. Particularly it may be possible to ignite samples with FMC outside the ranges quoted here with larger heat sources or longer durations. For example, these results would not be appropriate for determining the ignition arising from discarded barbeques. The variability in the natural structure of the fuel and its impact should be acknowledged. Additionally, qualitative observations suggest that the FMC of the samples after drying was not uniform in some cases, mainly for the moss samples, which would suggest that a thinner sample might be more appropriate. Finally, the extent of burning used to derive probabilities was subjective.

Fire activity; Fire Radiative Power; Two generalized Pareto tail lognormal body distribution; Iberian Peninsula; Fire Weather Index

Abstract

The Iberian Peninsula is recurrently affected by severe wildfires resulting from an interplay of human activities, landscape features, and atmospheric conditions. Here we assess the role played by atmospheric conditions on wildfire activity as measured by Fire Radiative Power (FRP) derived from observations by the MODIS instrument. The study spans the period 2001-2020 and is performed in four pyroregions covering the Iberian Peninsula that have been used in recent years, namely the northwest (NW), southwest (SW), north (N) and east (E). Atmospheric conditions are characterized by means of the Fire Weather Index (FWI), which rates fire intensity. For each pyrogegion, the distribution of $\log_{10} FRP$ is characterized by means of a statistical model that combines a truncated lognormal distribution central body with a lower and an upper tail, both consisting of Generalized Pareto (GP) distributions. The model is then improved by using FWI as a covariate of the parameters of the lognormal and the two GP distributions. Then, for each pyroregion, a set of 100 synthetic time series of total annual FRP is set up using the statistical models with and without FWI as a covariate. The role played by meteorological conditions is finally assessed by comparing the two sets between each other and against the time series of annual FRP derived from observations by the MODIS instrument. Results obtained for region SW show an increase from 90% to 96% of interannual explained variance of FRP when progressing from the model without to the model with FWI as covariate. Increases from 95% to 96%, 84% to 89% and from 79% to 86% were obtained for regions NW, N and E. It is worth stressing that these are conservative estimates of change, since the dependence of number of ignitions on FWI was not taken into account.

1. Introduction

The Iberian Peninsula is recurrently affected by severe wildfires that relate to an increase in fuel availability due to land abandonment and the expansion of forest and shrubland areas (Pausas and Vallejo, 1999; Lloret et al., 2002), as well as to an increase in the occurrence of prolonged droughts and in the number of days with extreme fire weather associated to climate change (Pereira et al., 2005; Trigo et al., 2006; Carvalho et al., 2011; Pereira et al., 2013; Sousa et al., 2015; Pérez-Sánchez et al., 2019; Turco et al., 2019).

The Iberian Peninsula has been affected by large wildfires in the recent decades, and the tragic years of 2003, 2005 and 2017 in Portugal are worth being pointed out. The Iberian Peninsula was struck by a severe heat wave in August 2003 and by two severe heatwaves in 2017 (the first in mid-June and the second in the second week of July), and 2005 and 2017 were affected by two severe droughts, that of 2005 being the most severe in recent times (Garcia-Herrera et al., 2007). Several studies have underlined the critical role played by different meteorological variables, including temperature, humidity and wind on the occurrence of extreme years of fire activity both at shorter (e.g. summer heat waves) and longer (e.g. prolonged droughts) time scales (Ruffault et al., 2020).

The fact that the entire Mediterranean basin, and the Iberian Peninsula in particular, is considered as a hotspot of climate change, increases the likelihood of occurrence of extreme fire weather and of more intense droughts (Turco et al., 2019; Ruffault et al., 2020). This strongly suggests that particular attention should be devoted to the role played by atmospheric conditions on wildfire activity. The aim of this work is to assess the impact of

meteorological conditions on the interannual variability of fire activity in four pyroregions of the Iberian Peninsula (Trigo et al., 2016).

2. Data and Methods

The study area comprises four pyroregions in the Iberia Peninsula (Northwestern, Northern, Southwestern and Eastern) as identified by Trigo, et al. (2016) based on a cluster analysis of monthly burned area (Fig.1).

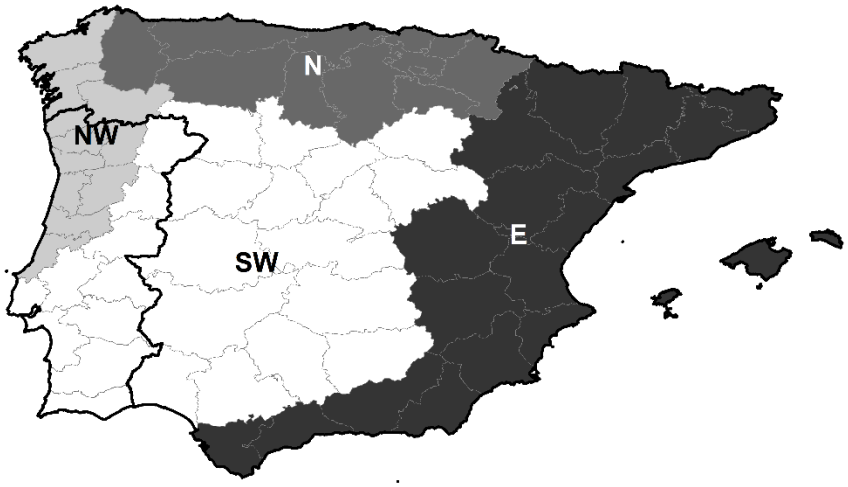

Figure 1- The four pyroregions of the Iberian Peninsula: Northwestern (NW), Northern (N), Southwestern (SW) and Eastern (E). Adapted from Trigo et al. (2016)

Fire activity is measured by the radiative power released by wildfires, as measured by the MODIS instrument on-board Terra and Aqua satellites (Giglio et al., 2020) and meteorological fire danger was rated using the Fire Weather Index (FWI), an index of fire danger that rates fire intensity (Stocks et al., 1989).

Information about Fire Radiative Power (FRP) was obtained from Collection 6 Terra and Aqua MODIS fire product covering the 20-year period from 2001 to 2020 (Giglio et al., 2020). Information about FWI covering the same period was obtained from ECMWF ERA5 reanalysis (CEMS, 2019).

For each pyroregion, a statistical model is adjusted to the distribution of the decimal logarithm of fire radiative power, $\log_{10} FRP$, and the model is then improved by incorporating FWI as a covariate of the model. The statistical models of $\log_{10} FRP$ combine three components, namely a truncated lognormal distribution central body with a lower and an upper tail, both consisting of Generalized Pareto (GP) distributions. For each pyroregion, the eight parameters of the model (namely the two points separating the central body from the tails, the location and dispersion parameters of the central truncated lognormal and the scale and shape parameters of the GP distributions of the tails) are obtained by maximizing the joint log-likelihood of an i.i.d. sample of $\log_{10} FRP$.

Finally, for each pyroregion a set of 100 synthetic time series of annual values of FRP is generated using the statistical model without FWI as covariate according to the following procedure: for each hotspot detected by the MODIS instrument, a random value of probability is generated and the corresponding value of FRP is obtained by inverting the statistical model. A time series of synthetic annual values of FRP is then obtained by adding up the generated values of FRP on a yearly basis. This process is then repeated 100 times. A second set of 100 synthetic time series of annual values of FRP is generated, this time using the model with FWI as covariate. The procedure is identical to the preceding one, with the difference lying in that FRP values are synthesized using a randomly generated probability value, together with the observed FWI value at each hotspot. The role played by meteorological conditions is finally assessed by comparing the two sets between each other and against the time series of annual FRP derived from observations by the MODIS instrument.

3. Results and discussion

Figure 2 provides an overview of results obtained when fitting, for each pyroregion, the statistical models to the samples of observed values of $\log_{10} FRP$ for the period 2001-2020. Cumulative distribution functions of the fitted model closely follow the corresponding empirical cumulative distribution function derived from the samples, and this reflects on Q-Q plots that closely follow the 1:1 straight lines. Pyroregion NW presents the higher probabilities of exceedance for values of $\log_{10} FRP$ between 0.5 and 2 whereas the lower values of exceedance are found in pyroregion E for values of $\log_{10} FRP$ between 0.5 and 1.5 and in pyroregion N for values of $\log_{10} FRP$ between 1.5 and 2.

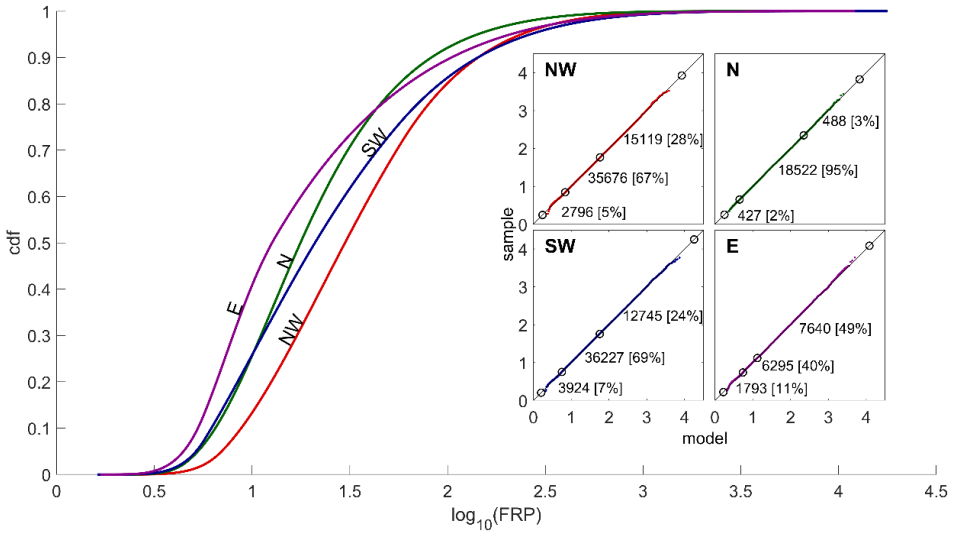

Figure 2 – Cdf curves and Q-Q plots (inside squares) of fitted statistical models of log_10 FRP (in MW) for regions NW (red), N (green) SW (blue), and E (magenta). The open circles in the 1:1 lines of the QQ plots delimit the central body and the upper and lower tails of the distributions, and the small colored dots represent the fire events of the sample. For each pyroregion, the number of events and respective fraction (in brackets) of the sample in the central body and in the lower and upper tails of the distribution are indicated next to the 1:1 line of the respective Q-Q plot

Figure 3 illustrates the results obtained when FWI is added as a covariate of the parameters of the distributions. As might be expected, there is a right displacement of the cumulative distribution functions with increasing FWI, which reflects substantial increases in probability of exceedance of a given threshold of $\log_{10} FRP$.

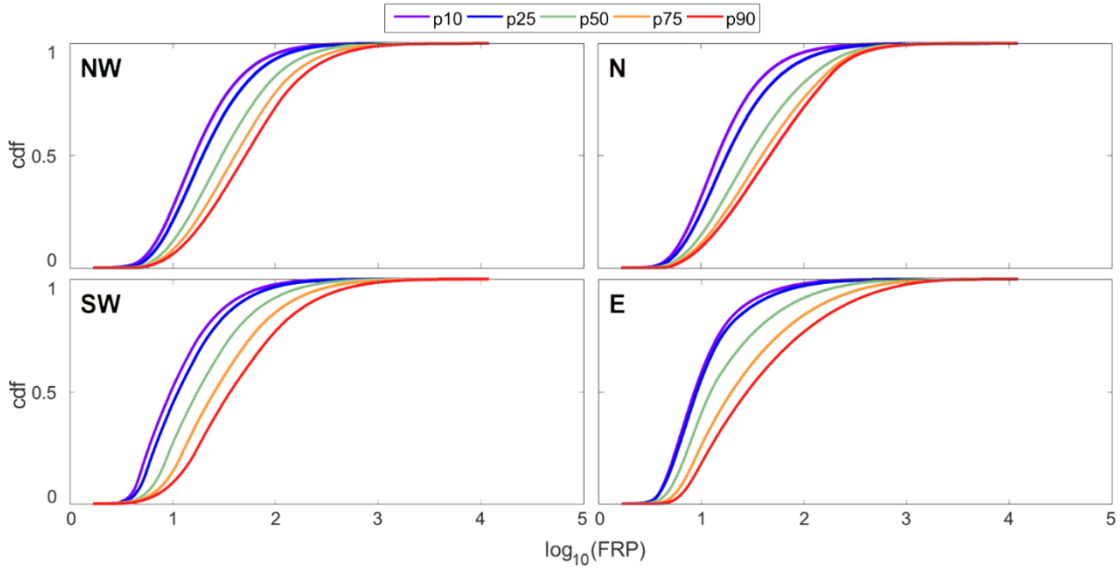

Figure 3 –Sensitivity to FWI of cumulative distribution functions of fitted statistical models of $\log_{10} FRP$ (in MW) for the four subregions. Colors of each curve identify the prescribed value of FWI, respectively percentiles 10 (purple), 25 (blue), 50 (green), 75 (orange) and 90 (red) of the respective samples.

Figure 4 presents, for each ecoregion, the time series of annual FRP as derived from observations by the MODIS instrument (black curves) and the two time series obtained by averaging the two sets of 100 annual values of FRP as derived from the statistical models without (green curve) and with (red curve) FWI as covariate. The interannual variability of the time series generated by the model without FWI as covariate is just due to the interannual variability of hotspots observed by the MODIS instrument, and it is worth noting that some years with large (small) values of total FRP tend to be underestimated (overestimated). The underestimation is conspicuous in 2017 for pyroregions NW and N, in 2003 for pyroregion SW, and in 2012 for pyregion E, whereas the overestimation, although less pronounced, occurs e.g. in 2014 for pyroregion N and in 2007 and 2008 for pyroregion SW. In the case of the time series generated by the model with FWI, an improved behavior is observed that is particularly noticeable for years with large values of total FRP, where synthetic values obtained from the model with FWI are much closer to observed values than synthetic values from the model where meteorological conditions are disregarded.

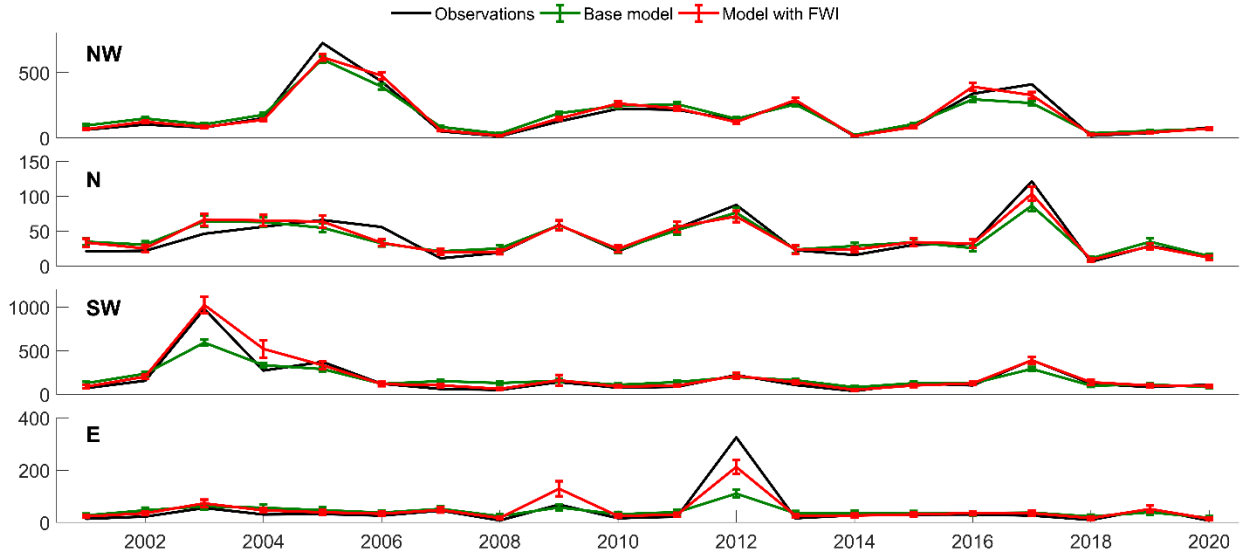

Figure 4 – Time series, for each pyroregion, of annual values of observed (black curves) and of the mean values of the set of synthetically generated annual values of FRP using the statistical models without (green curves) and with (red curves) FWI as covariate. The error bars in the synthetic time series delimit the mean plus/minus one standard deviation.

A quantitative assessment is provided in Table 1, which presents the mean and the standard deviation of the time series of annual FRP derived from MODIS observations and of the annual FRP synthetically generated by the statistical models without and with FWI as covariate. Results indicate that synthetic time series generated by both models are unbiased, the only exception being pyroregion E, where the time series generated by the model with FWI as covariate presents a mean value 12% larger than the mean of time series of observed FRP. Considerable differences do, however, occur with the values of standard deviation, for which time series of synthetically generated FRP present considerably lower values than the corresponding time series of observed FRP. However, time series generated using the model with FWI as covariate systematically display larger variability than the corresponding ones obtained with the model lacking FWI as covariate. For instance, there is an 11% increase (from 21 to 24 GW) for pyroregion N, a 17% increase (from 143 to 167 GW) for pyroregion NW, a 48% increase (from 121 to 179 GW) for pyroregion SW and a 230% increase (from 20 to 46 GW) for pyroregion E. These results indicate that atmospheric conditions are especially important to better reproduce interannual variability in the case of pyroregions E and SW.

Table 1 also presents, for each pyroregion, the explained variance accounted for the synthetic series when they are used to simulate interannual variability. Explained variance was estimated by squaring the linear correlation of the time series of annual observed FRP with the corresponding synthetic time series generated by the statistical models lacking and including FWI as covariate. For all pyroregions there is an increase in explained variance when shifting from synthetic values of annual FRP generated by the models without FWI as covariate to those by the models with FWI. Increases in explained variance are modest for pyroregion NW (95 to 96%),

and are even larger for the other three pyroregions N, SW and E (84 to 89%, 90 to 96% and 79 to 86%, respectively).

Table 1 – Mean value and standard deviation for the period 2001-2020 of time series of annual FRP derived from observations by the MODIS instrument and from the mean of the 100 synthetically generated annual FRP using the statistical models without and with FWI as covariate, and explained variance as obtained by squaring the linear correlation between the observed and each the two synthetic time series of annual FRP.

		NW	N	SW	E
Mean [GW]	Observed	179	40	185	43
	Model without FWI	180	40	184	42
	Model with FWI	179	40	186	47
Standard Deviation [GW]	Observed	181	29	211	68
	Model without FWI	143	21	121	20
	Model with FWI	167	24	179	46
Variance Explained [%]	Model without FWI	95	84	90	79
	Model with FWI	96	89	96	86

4. Conclusion

Results obtained clearly indicate the importance of atmospheric conditions as drivers of interannual variability in fire activity, measured by annual FRP values. This is especially true in pyroregions SW and E, where climate change is expected to have a pronounced impact in terms of increase in frequency both of drought events and of days with extreme fire weather (Sousa et al., 2015).

It is worth pointing out that the assessment performed in this work is likely to be conservative, given that time series of annual FRP were estimated by randomly generating values for all hotspots identified by the MODIS instrument for the study period. Since the number of hotspots strongly depends on the number of large fire events, which in turn depend on atmospheric conditions, the interannual variability of synthetically generated time series of FRP was very likely overestimated when using the model without FWI as covariate. Circumventing this problem would imply modelling the interannual variability of hotspots (with and without FWI as covariate), a task that is well beyond the purpose of the present work.

Models such as the ones proposed in this study provide valuable information about fire activity in the Iberian Peninsula, namely when comparing different scenarios of climate change. On the other hand, following a methodology previously developed by some of the authors (DaCamara et al., 2014; Pinto et al., 2018), the proposed models with FWI can be used to calibrate FWI in four pyroregions of the Iberian Peninsula and then define classes of fire danger that represent an important added value in fire prevention and firefighting of rural and forest fires.

5. Acknowledgments

This work was supported by national funds through FCT (Fundação para a Ciência e a Tecnologia, Portugal) under project FIRECAST (PCIF/GRF/0204/2017), IDL (UIDB/50019/2020) and CEF (UIDB/00239/2020) and by EUMETSAT Satellite Application Facility on Land Surface Analysis (LSA SAF).

Forest Fires, Risk Perception, Fireshed

Abstract

Forest fires are increasingly affecting forest ecosystems, with severe ecological and socio-economic impacts on neighboring communities. In this context, evaluating the risk of fires at the fireshed level is considered a crucial step towards improving knowledge about fire risk management, therefore, minimizing potential damages of wildfires on people, properties, and natural resources. The aim of this study was to assess forest fire risk perception of communities at two firesheds in Lebanon. In-person surveys were conducted in areas of high fire risk within each fireshed. The analyzed data showed variability in opinions and challenges about fire risk management. Most of the provided recommendations included advocating for the increase of awareness about fire risk and safety, inducing training about fire-fighting and creating networks to facilitate communication within communities at risk.

1. Introduction

Forest fires represent an increasing risk not only to forests but also to the livelihood of neighboring communities (Verkerk et al., 2018). Accordingly, forest fire risk assessment is essentially needed to improve management of risk, therefore minimizing potential impacts of fires on vulnerable people, properties, and natural resources (Abedi Gheshlaghis et al., 2019; Çolak and Sunar, 2020). Various studies around the world have been conducted to assess forest fire risk and consequently identify fire susceptible regions (Abedi Gheshlaghi, 2019). This study aimed at assessing forest fire risk perception of communities at two firesheds in Lebanon. In this context, a fireshed takes into account all communities located within a specific watershed. More specifically, a fireshed is "an area where social and ecological concerns regarding wildfire overlap and are intertwined" (GSFFC, 2022).

2. Study area

The study area comprised both the Qadisha-Abu Ali watershed and the Hasbani watershed (Figure 1). All the villages included in the study were selected using a national fire risk assessment report (Mitri et al., 2019) that identified high risk areas and "priority sites" in the respective fireshed.

The Qadisha-Abu Ali fireshed is located in North Lebanon and it is characterized by a Mediterranean landscape with dense mixed forest which is mainly composed of broadleaf and coniferous trees (Figure 1). Its lowest altitude is at sea level and its highest mountain peak reaches 3080 asl. It is composed of 5 vegetation successions within a typical Mediterranean floristic ensemble (Figure 2).

The Hasbani fireshed is located in Southeast Lebanon and it is characterized by a pre-steppic landscape with sparse oak forests dispatched between agricultural lands, rangelands, and urban settlements. Its lowest altitude is 200 m asl and its highest elevation is 2810 m asl. It is composed of four vegetation successions distributed in a typical Mediterranean floristic ensemble (Figure 2). Forests at high risk are scattered in a steppingstone pattern between the urban settlements and the agricultural areas.

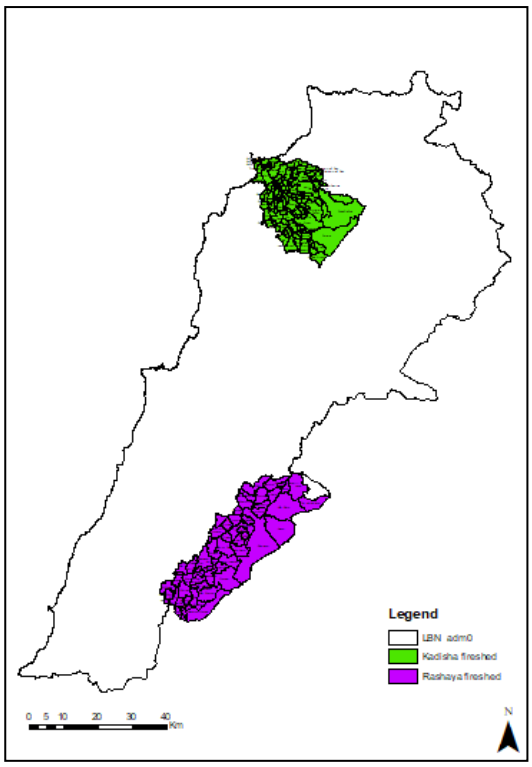

Figure 1: Geographic location of the fireshed

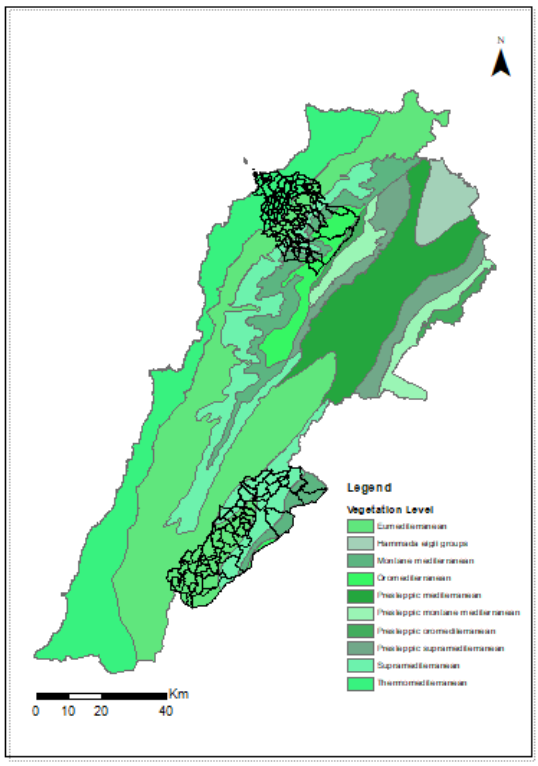

Figure 2: Vegetation levels succession in Lebanon

3. Methodology

Fire risk maps of the two targeted firesheds were generated using the Geographic Object-Based Image Analysis (GEOBIA) approach (Mitri et al., 2015). Fire risk represented the product of hazard and vulnerability. Priority zones of high fire risk villages were identified based on the risk map classes. Accordingly, field surveys were conducted in these priority zones of the two firesheds. A total of 100 participants were selected using a purposive-snowball sampling method while including representatives from local authorities and local community groups. The data was collected through direct interviews using the KOBO application (KOBO, 2020). The questions in the survey aimed to identify the respondent viewpoint on different aspects of fire risk such as causes/origin, damages, responsibilities and cost. The first set of questions aimed at evaluating exposure to fire events. The second set of questions revolved around forestry activity types and associated threats. The third set of questions were designed to recognize stakeholder's engagement towards managing risk. As for responsibilities, the fourth set of questions intended to assess people's judgment on who bears responsibility as well as costs.

4. Results and discussion

4.1. Exposure to fire events

Questions in this category tackled the perceived damage extent of forest fires and respondents' familiarity with the inherent threats and likelihood of fire occurrence.

The majority of respondents (88%) have witnessed at least one fire during the past ten years, and most of them witnessed a number of fire events varying between 1 and 10 fire events (Figure 3).

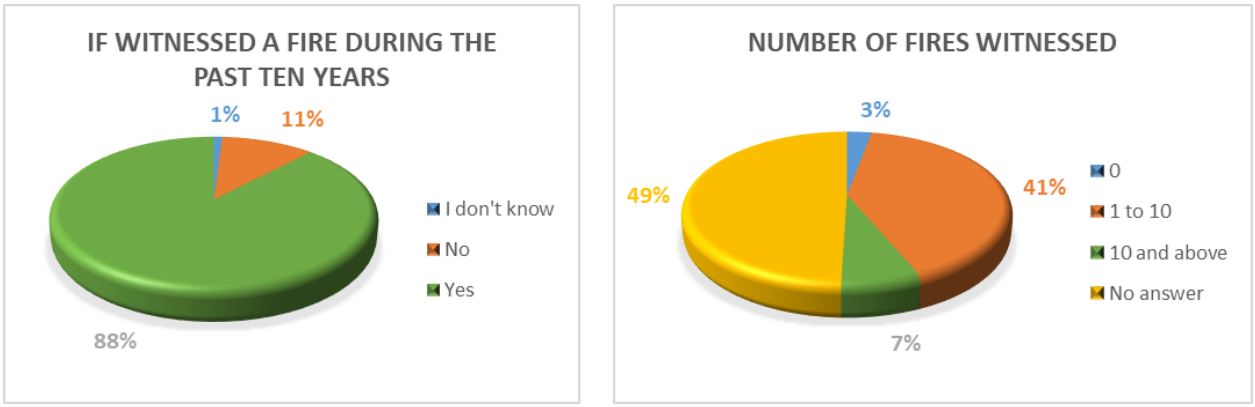

Figure 3. Numbers of fires witnessed by respondents

As for the likelihood of fire occurrence, the respondents' risk perception was very low. Only 10% of respondents indicated a high probability (Figure 4) even though the study was carried out in high-risk zones. This implied a relatively low awareness about fire risk.

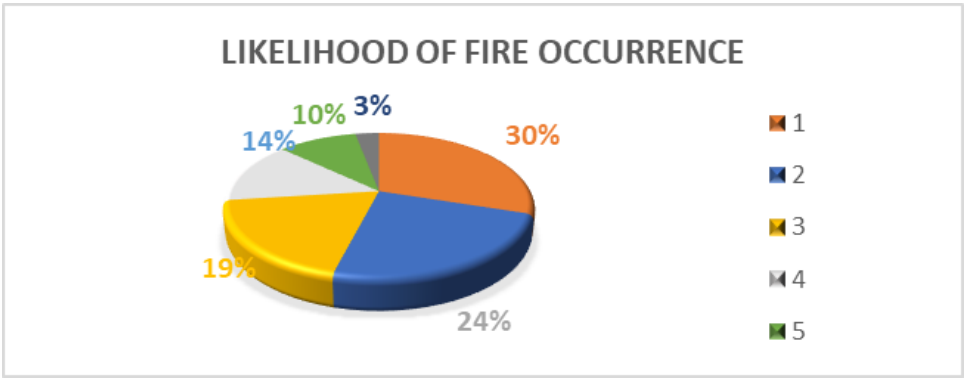

Figure 4. Likelihood of fire occurrence (1 - Not likely - 2 Unlikely - 3 - Neutral - 4 - Likely - 5 - Very likely)

4.2. Types of forest activities

The set of questions in this category revolved around the knowledge of respondents about forest activities usually undertaken to reduce fire risk and familiarity with related threats. To assess the awareness of the respondents about the main forest activities undertaken in their villages, the below matrix was produced crossing mostly identified activities with the type of land ownership. Most of the respondents linked forest activities to private lands (33%).

Table 1. The main forest activities and the type of land ownerships

Activities/Ownership	Mashaa	Government	Private	Waqf
Collection of wood or charcoal making	32	33	37	12
Charcoal making	33	34	38	12
Collection of non-wood forest products	41	42	52	14
Grazing	38	40	39	9
Tourism	38	31	39	9
Hunting	39	40	48	11
Religious ceremonies	16	15	18	9
Conservation/Preservation	34	33	32	10
Beekeeping	41	41	42	9

4.3. Engagement towards managing risk

Respondents were asked to identify measures taken in their villages to reduce fire risk. These mostly included equipping civil defense stations, increasing water sources, increasing firefighters' number, and organizing awareness activities as well as introducing forest management and other fire prevention measures such as roadsides cleaning, firebreaks, and trail opening, among others. Around 29% of the respondents were informed

about activities which were undertaken within their villages to reduce fire risk, while 71% did not refer to any activity of fire prevention (Figure 5). Nevertheless, when asked about their opinion to prioritize specific prevention activities, "awareness raising" came first with 33 answers, "equipping civil defense" followed with 28 answers (Figure 6). Whereas "forest management" came third, therefore entailing the need of creating more awareness about the importance of implementing forest management plans for reducing fire risk.

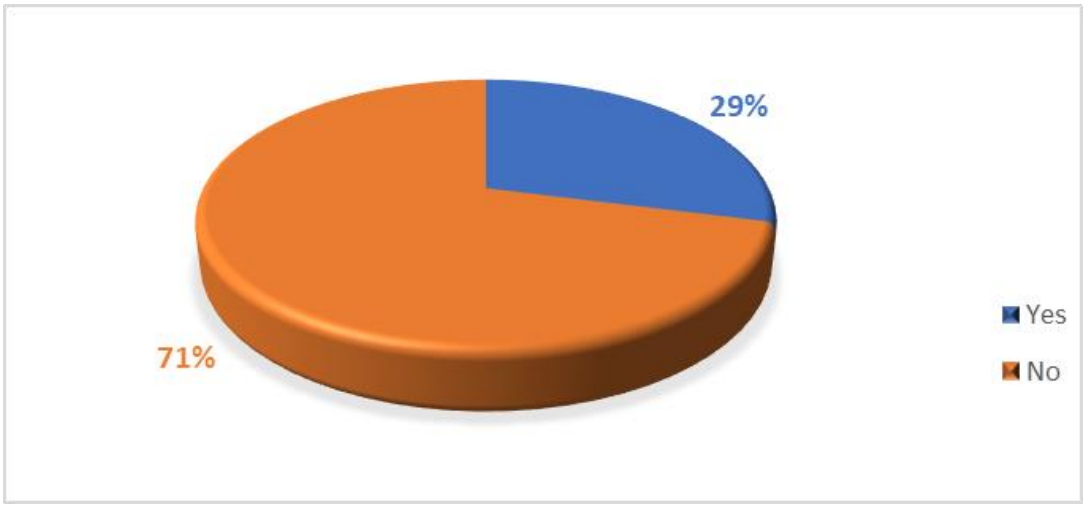

Figure 5. Feedback about fire prevention measures conducted in the respondents' villages

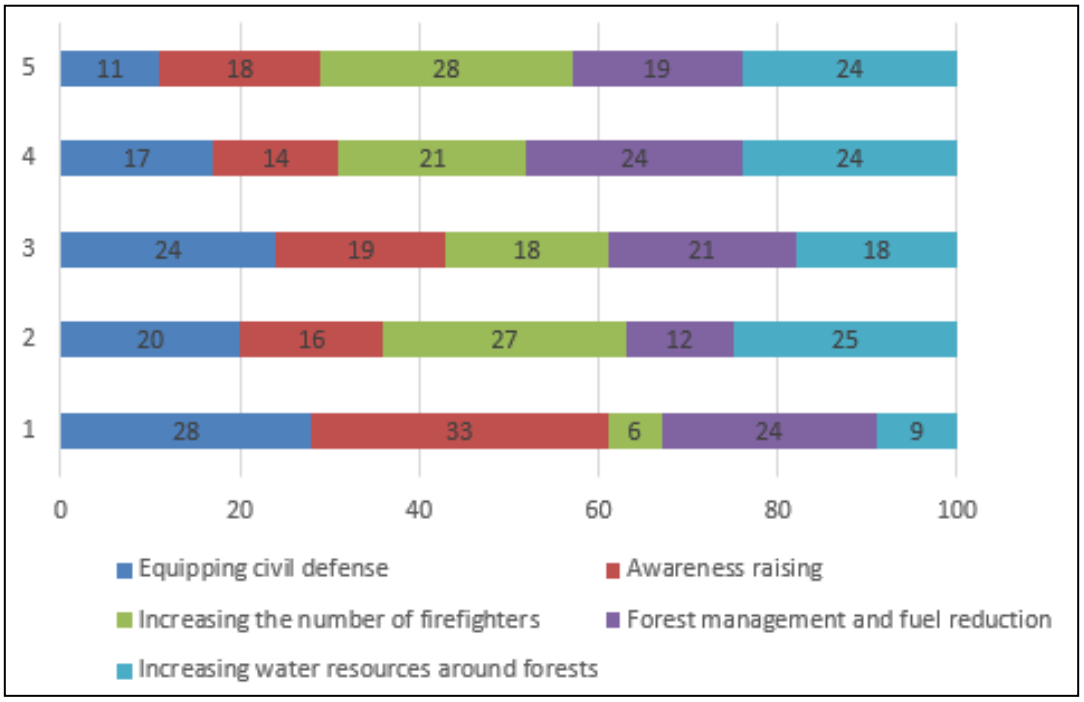

Figure 6. Rank of priorities of fire prevention activities

4.4. Responsibilities and cost

The last set of questions addressed public understanding of responsible bodies for 1) the main damages caused by fire and 2) the main fire-fighting operations. Also, it included inquiries for cost estimation of fire-fighting operations. When asked to estimate a cost of 1-day of fire-fighting in a potential fire incident occurring in their village, 33 % of the respondents were unaware of incurred costs (Table 2). The majority of respondents expressed that local municipalities and civil defense centers were in charge incurred costs.

Table 2. Cost estimation of 1-day of fire-fighting

Cost range	Percentage of answers
Between $2,500 and $5,000	12%
Between $5,000 and $10,000	9%
Between $500 and $2,500	22%
I don't know	33%
Less than $500	9%
More than $10,000	15%
	100%

As for post-fire direct and indirect impacts, responsibilities were mostly misperceived. The respondents did not grasp that such fire incidents were mostly attributed to human impact on nature in addition to environmental changes. Stakeholders and future fire managers could benefit from knowledge about how current actions and choices may influence future events and beliefs instead of focusing on a single solution at a time (Mccafrey, 2013).

5. Conclusions

Understanding key characteristics of the complex social dynamics behind forest fire incidents could greatly facilitate fire management, decrease future risks and dangers, and benefit the ecology of forests. In this study, there seems to be a lack of awareness around the rising issues of climate change and increasing fire risks; nonetheless, the respondents clearly exhibited the willingness to learn more about risks associated with their current activities and choices and how to reduce economic and environmental costs. Most of the recommendations included advocating for increase of awareness about fire risks and safety, induction of training about firefighting, and creation of networks to facilitate communication among the stakeholders. Future studies will target more respondents from different socio-economic backgrounds and different sectors.

Fire regime, Biophysical drivers, Classification and regression trees, Central Portugal

Abstract

The spatial and temporal properties of burned areas are a major component of fire regimes. We analyse three parameters related to burned area within central Portugal, and then investigate the degree to which their variation is influenced by a set of biophysical drivers. Using civil parishes as units of analysis, we study three complementary parameters over a reference period of 44 years (1975-2018): cumulative percentage of parish area burned, Gini concentration index of burned area over time, and area-weighted total number of wildfires. Cluster analysis is used to aggregate parishes into groups based on similarities regarding burned area parameters. A classification tree model is then employed to assess the relative capacity of each driver to differentiate between groups of parishes. Drivers included slope, summer temperature and spring rainfall, land use/land cover (LULC) type and patch fragmentation, and net primary productivity. Results allowed to distinguish four parish types in terms of burned area features and show that these can be significantly differentiated by the biophysical drivers, of which LULC, slope and spring rainfall are the most important. Among LULC classes, shrubland and herbaceous vegetation play the foremost role, followed by agriculture. Our results highlight the importance of vegetation type, availability, and rate of regeneration, as well as that of topography, in influencing burned area patterns in the study area, while suggesting that other drivers, likely of a social nature, should also be taken into account.

1. Introduction

Understanding the drivers of fire regimes is highly important due to the damage regularly caused by wildfires. Among the southern European countries, Portugal is one of the most affected despite its relatively small size (San-Miguel-Ayanz et al., 2020). The largest burned areas tend to occur in the forest/shrubland dominated central sector of the country, which has been the subject of several studies (Catry et al., 2010; Maia et al., 2012), and was the most affected by the extreme wildfires occurred in 2017 (Benali et al., 2021).

In a recent work, we employed three complementary variables to express fire regime over a 44-year study period in Central Portugal, and we quantified the influence of a set of 12 biophysical drivers over each fire regime variable using ordinal logistic regression (Bergonse et al., 2022). Drawing upon those results, we intend to differentiate fire regimes in Central Portugal by integrating the three fire regime descriptors, and to characterize their interactions with biophysical conditions.

The study area corresponds to NUTS 2 Centro, comprising 28 199 km^2 within central mainland Portugal (Figure 1). This region is marked by a high variability regarding wildfire hazard and its control factors (Oliveira et al., 2020), with 49.7% of the region classified in the High and Very High hazard classes. The 972 civil parishes

(*freguesias*) of the study area are the spatial units of analysis, which vary in extent between 1.98 km^2 and 373.50 km^2.

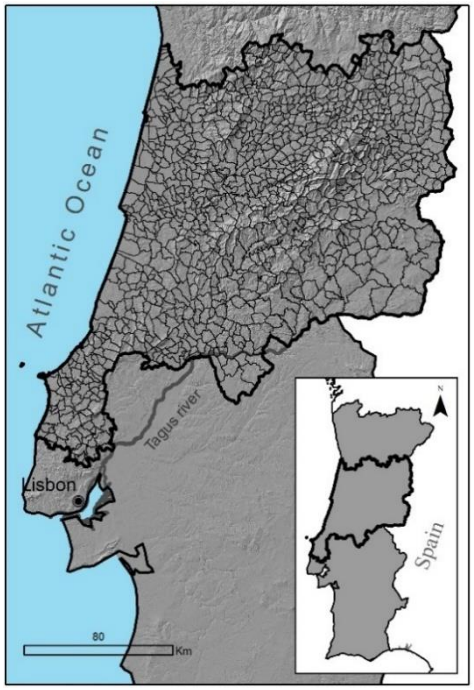

Figure 1 – Location and limits of the study area within mainland Portugal (NUTS 2 Centro), including parish limits. Parish boundaries were extracted from the official administrative map of Portugal (CAOP), produced by the Portuguese Directorate-General of the Territory (DGT).

2. Data and Methods

2.1. Data collection and pre-processing

2.1.1. Fire regime parameters

Fire regime characteristics were described with three parameters for the period 1975-2018 (44 years), following Bergonse et al. (2022). All were obtained from annual burned area maps produced in vector format by the National Forests Service (ICNF). The cumulative percentage of parish area burned (CPAB) was used to measure the propensity of each parish to burn extensively over time. Area-weighted wildfire frequency (AWWF) was calculated as the total number of wildfires recorded within the parish over the study period, divided by its area (km^2). The Gini Concentration Index (GCI) of burned area over time was adopted as an indicator of the temporal concentration of wildfire damage. It was applied to the annual burned areas of each parish over the 44 years and expressed as percentage. Ranging between 0 and 100, the GCI allows to differentiate parishes where most burned area is concentrated in a small number of years (high values), from those where the burned area is more regularly distributed over time (low values), regardless of the extent of that burned area.

Out of the total of 972 parishes, 35 (3.6%) never burned during the study period, having therefore no values in any of the fire regime parameters. These were removed from all analyses.

2.1.2. Biophysical drivers

A set of 12 biophysical drivers was considered (Table 1), which we previously demonstrated to be significantly associated, separately, with the three fire regime parameters under analysis (Bergonse et al., 2022).

Table 1- Description and characteristics of the potential fire regime drivers. Data sources and methods of calculation are described in Bergonse et al. (2022).

Type	Variable code	Variable	Temporal extent	Original spatial Resolution	Units
Topography	**SLO80**	Slope percentile 80	n.a.	25 m	º
Climate	**RFAJ**	Mean cumulative rainfall April-June	1970-2000	Approx. 1000m	mm
	TPJS	Mean monthly temperature July-September			^{0}C
Biomass	**NPP**	Net Primary Productivity	2000-2014	500 m	KgC/m^2
Land use/Land cover (LULC)	**AGR**	% parish area occupied by agriculture	1990-2018	Vector data. Minimum mapped area 1 ha	%
	OAK	% parish area occupied by cork-oak and holm-oak forests			
	EUC	% parish area occupied by eucalyptus forests			
	INV	% parish area occupied by forests of invasive species	1995-2018		
	CON	% parish area occupied by forests of coniferous species other than maritime or stone pine	1990-2018		
	BRD	% parish area occupied by forests of broadleaved species other than eucalyptus, cork-oak and holm-oak			
	SHR	% parish area occupied by brushland and spontaneous herbaceous species			
LULC patch fragmentation	**FRAGF**	Fragmentation of forest patches	1995-2018		centroids/ha of forest

2.2. Statistical techniques

Hierarchical cluster analysis was employed to identify groups of parishes with similar behaviour regarding the fire regime parameters. Clustering was performed using Ward's method, an agglomerative process which begins with as many clusters as cases, successively agglomerating clusters using the solution that minimizes within-cluster variance (Everitt et al., 2011). Prior to inclusion, the three fire regime parameters were converted into z-scores, to ensure an equal contribution regardless of contrasting value ranges (Maroco, 2007).

SPSS's CRT tool was then employed to build a classification tree model with the purpose of assessing the capacity of the biophysical drivers to differentiate between clusters. A 10-fold cross-validation procedure was adopted, with the Gini index being used as criterion of impurity for node splitting.

3. Results and discussion

3.1. Cluster analysis

A four-cluster solution was chosen taking into consideration a preliminary analysis of distances between clusters and the fire characteristics of the clusters identified.

FR1 (includes 450 parishes) is characterized by the lowest CPAB, the highest GCI, and the lowest AWWF values (Fig. 2-A). This fire regime is marked by the lowest extension of burned areas and the lowest wildfire frequency within the study area, with the resulting damage being relatively concentrated over time (corresponding to the highest GCI obtained). Spatially, it occurs mostly along the coastal swath and in the SE extreme of the study area (Figure 2-B).

FR3 (86 parishes) expresses opposite characteristics in relation to FR1. It has the highest CPAB values, as well as the highest AWWF and the lowest GCI. This indicates relatively frequent wildfires, which produce very extensive burned areas over time and result in a temporal dispersion of the damage. It occurs exclusively in the NE and the northern limit of the study area. FR2 (401 parishes) occupies an intermediate position between FR1

and FR3 regarding all three fire regime parameters. Spatially, it concentrates on the central and eastern portions of the study area.

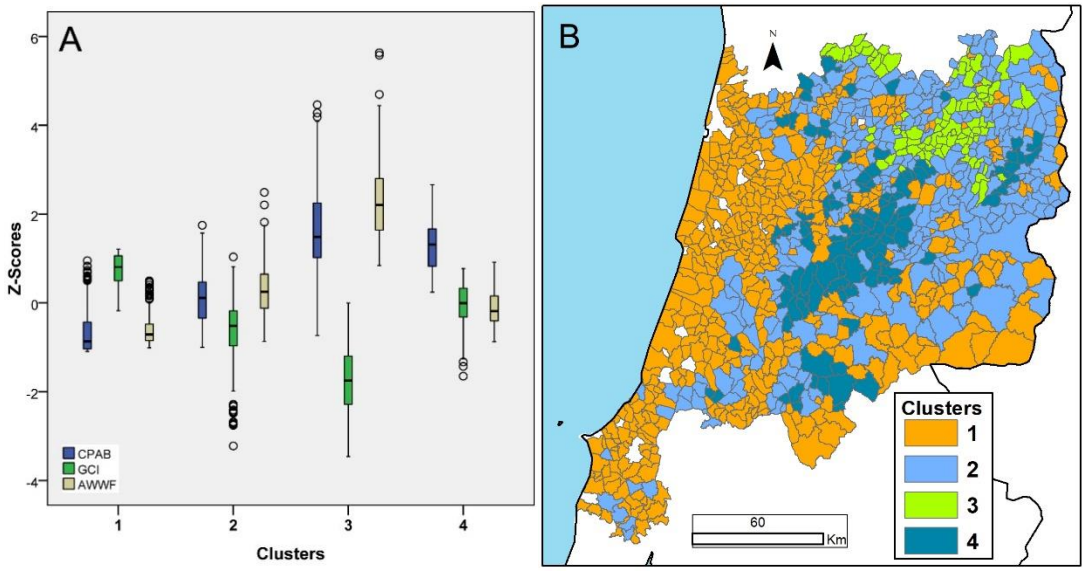

Figure 2 - (A) Box-plots for the values of the three fire regime parameters associated to each cluster/fire regime. Values expressed as z-scores. For each variable, the box includes the 1st and 3rd quartiles as well as the median. The whiskers identify the maximum and minimum values excluding outliers. Outliers (shown as circles) are defined as values between 1.5 times and 3 times the interquartile range, respectively above the 3rd quartile and below the 1st quartile; (B) Spatial distribution of the four clusters/fire regimes.

Finally, FR4 (102 parishes) has the second highest CPAB and the second lowest AWWF, resulting in the second highest temporal concentration of damage (GCI), and indicating relatively extensive but infrequent wildfires. It is mostly concentrated in the central sector of the study area.

3.2. Classification tree model

The CT model correctly classified 72.4% of all parishes, with the accuracy being slightly lower (68.7%) when independently validated using a 10-fold cross-validation process (Table 2). The overall accuracy demonstrates that the biophysical drivers are strongly related to the FRs within the study area. Regarding FR-specific accuracy, results show a notable contrast between the first three FRs (minimum accuracy 69.9%, maximum 82%) and FR4, with only 38.2% of all parishes correctly classified. This indicates that FR4 cannot be adequately discriminated using only the set of biophysical drivers employed in this study. Social variables, such as road or population density, can influence fire regimes, as previously shown in other studies (Pausas & Fernández-Muñoz, 2012; Rogers et al., 2020), and could eventually improve the accuracy of the classification.

Table 2 – Classification accuracy for the final tree model and for the tree models produced in association to the 10-fold cross-validation procedure. FR-specific accuracy values are for the final tree model.

Observed	Predicted				%
	1	2	3	4	Correct
1	369	70	1	10	**82.0**
2	58	209	17	15	**69.9**
3	0	22	61	3	**70.9**
4	17	42	4	39	**38.2**
			Final tree accuracy		**72.4**
			Cross-validated accuracy		**68.7**

All 12 biophysical drivers were integrated into the CT model (Figure 3). The percentage of shrubland and spontaneous herbaceous vegetation (SHR) was the most important driver, closely followed by spring rainfall (RFAJ). Slope (SLO80) and agriculture (AGR) have about half the importance of SHR and RFAJ, whereas eucalyptus forests (EUC), broadleaved species other than eucalyptus, cork oak and holm oak (BRD), and net

primary productivity (NPP) have a relative importance between 40% and 50% of SHR. The remaining drivers vary in relative importance from about 30% down to less than 10%.

To facilitate interpretation of the influences of biophysical drivers, Figure 4 shows the values of each driver in each of the four FRs.

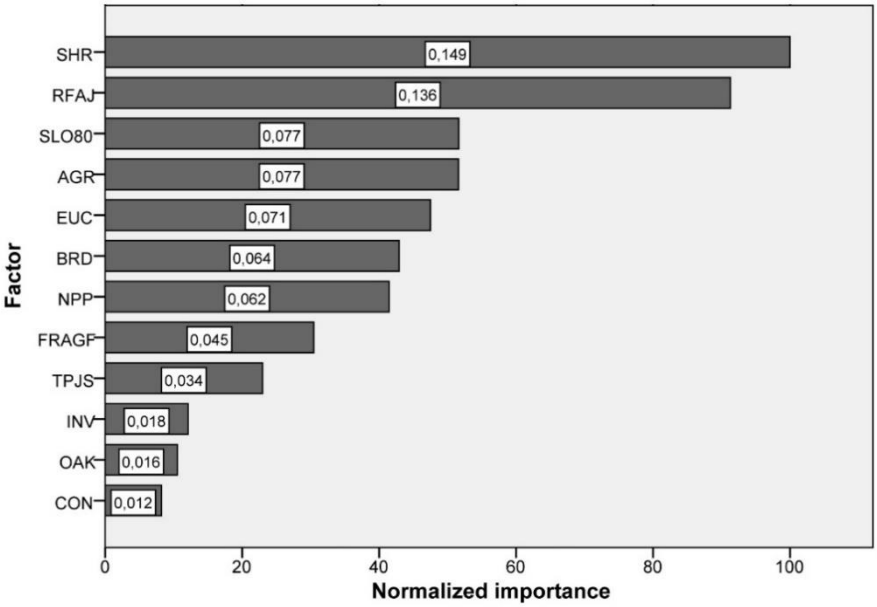

Figure 3 – Importance of each biophysical driver for the classification tree model, shown normalized by the most important driver (SHR).

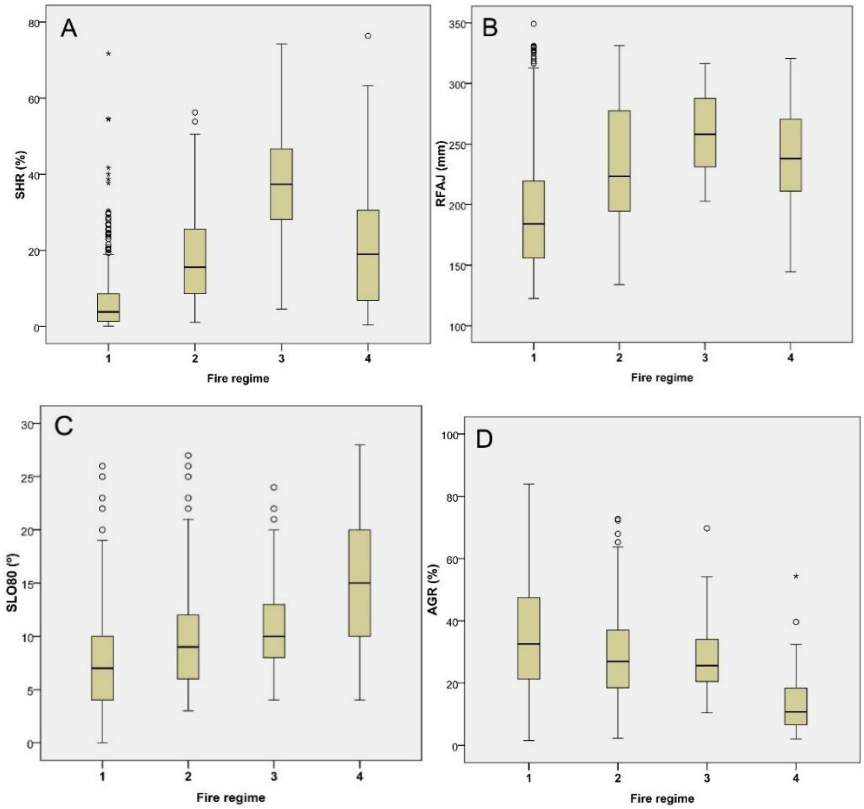

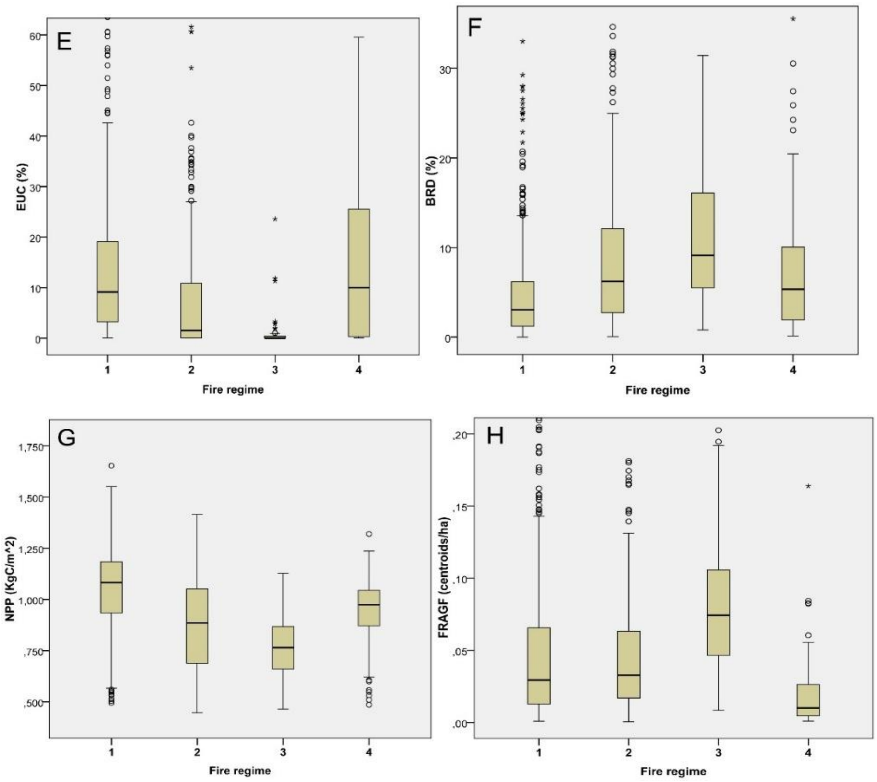

Figure 4 – Boxplots for the values of each biophysical driver in each of the four fire regimes, by decreasing order of importance in the classification tree model. A – SHR; B – RFAJ; C – SLO80; D – AGR; E – EUC; F – BRD; G – NPP; H – FRAGF. The four lowest importance drivers are not shown because their very small values and high level of dispersion in all FRs do not indicate clear patterns. Circles identify potential outliers, defined as situated between 1.5 times and 3 times the interquartile range below the 1st quartile and above the 3rd quartile. Asterisks identify potential extreme outliers, exceeding 3 times the interquartile range below or above the 1st and the 3rd quartile.

FR1 has the lowest percentage of parish area occupied by shrubland, the lowest spring rainfall, the lowest slope and the highest percentage of area occupied by agriculture. These are the four most important variables in the CT model, and their values in FR1 are in accordance with its low CPAB and AWWF. FR1's low shrubland proportion likely contributes to its low cumulative burned area (CPAB) and fire frequency (AWWF), since this landcover type's fire-proneness and quick regeneration promotes extensive and frequent fires (Bergonse et al., 2022; Moreira et al., 2009; Oliveira et al., 2014, 2020), as seen in FR3. Spring rainfall is linked to vegetation growth and thus fuel availability during the warmer summer months, therefore having a positive influence both over AWWF and CPAB (Bergonse et al. 2022), as highlighted by different authors (Oliveira et al., 2012; Xystrakis et al., 2014). Low spring rainfall values will, conversely, be associated with both low wildfire extensiveness and frequency, as seen in FR1. Slope promotes wildfire spread (Marques et al., 2011; Parente & Pereira, 2016), with the lowest slope values in the study area being in accordance with the minimum CPAB values shown by FR1 in relation to all other FRs. Finally, the higher proportion of agricultural land is also expected to contribute to the low CPAB and AWWF of this fire regime, due to its low fire-proneness (Moreira et al., 2009; Oliveira et al., 2014).

FR3 presents opposite characteristics to FR1, showing the maximum percentage of shrubland and the maximum values of spring rainfall, as well as second highest slope values. This fire regime has also the lowest percentage of eucalyptus among all four FRs, which would seem contradictory given the relative fire-proneness of this LULC (Meneses et al., 2018; Xanthopoulos et al., 2012). However, this suggests that the fuel availability behind FR3's high CPAB is mostly dependent on shrubland and its faster response to spring rainfall. This is confirmed by FR3's low Net Productivity Ratio, the lowest among all FRs, which is indicative of a relatively reduced forest cover. Nevertheless, FR3 is marked by the highest incidence of forests of broadleaves other than eucalyptus, cork oak and holm oak of all FRs. As this LULC class has a positive effect over CPAB and AWWF (Bergonse et al., 2022), this suggests that forest-type fuels also have some importance in FR3.This fire regime also shows the greatest burned area extension (CPAB), despite having the highest forest patch fragmentation of all FRs. Although a high level of fragmentation can be expected to constrain extensive wildfires (Gralewicz et

al., 2012; Ryu et al., 2007), the dominant fuel type in FR3 is shrubland; therefore, even if each individual wildfire is constrained in its spread, the quick regeneration of fuels will nonetheless allow for frequent burning, leading to an important accumulation of burned area over time.

FR4 shows a relatively high cumulative burned area (CPAB), which is in accordance with its biophysical characteristics: a relatively high percentage of shrubland, high spring rainfall, the highest slope inclination, and the lowest percentage of agriculture. This fire regime also shows a relatively high percentage of eucalyptus forests. The importance of forest cover in FR4 is indicated by the relatively high Net Productivity Ratio, suggesting that, unlike FR3, this fire regime is more dependent on slowly regenerating forests for fuel instead of shrubland. The high damage concentration over time (GCI) found can be linked to the degree of forest patch fragmentation, the lowest amongst all FRs, indicating the potential influence of fuel and forest continuity to the occurrence of higher damages even when wildfire frequency (AWWF) is low. This suggests the importance of creating fuel discontinuities at the landscape level to prevent large and severe wildfires (Benali et al., 2021).

4. Conclusions

Four distinct fire regimes (FR) can be differentiated within central Portugal. FR1 occurs along the coastal area and in the southeasternmost limit and is marked by the least extensive burned area and the lowest wildfire frequency, as well as the maximum temporal concentration of damage. FR2 occurs in most of the centre and eastern sectors. It is marked by more extensive burned areas and more frequent wildfires than FR1, as well as lower temporal concentration of damage. FRs 3 and 4 are characterized by the most extensive burned areas, and contrast in terms of wildfire frequency and temporal concentration of damage. FR3 occurs mostly in the NE of the study area. It has the most extensive burned area of all, as well as the most frequent wildfires, with burn damage dispersed through time. FR4, occurring mostly in the central sector, has slightly less extensive burned areas, but a much lower wildfire frequency, with the damage being more concentrated in time. LULC, slope and spring rainfall are the most important drivers of these distinct fire regimes. The most relevant LULC classes are shrubland/spontaneous herbaceous vegetation and agriculture, the first due to its fire-proneness and quick regeneration, and the second due to its constraints over wildfire spread. Slope facilitates wildfire spread, whereas spring rainfall promotes fuel availability for burning later in the year. Despite the good discriminating capacity of the classification tree model, other drivers, likely of a social nature, might also influence the fire regimes in the study area.

5. Aknowledgments

Abstract

Fire is a major disturbance affecting Mediterranean ecosystems. Due to a lack of exhaustive fire registration, fire drivers in the Middle East have been hardly investigated. We propose here the analysis of a newly produced fire patch reconstruction from remote sensing over the 1984 – 2020 period in Lebanon and Syria, experiencing peculiar Mediterranean climate and socio-political conflicts. We identified a particular bimodal and late-season fire regimes in the two neighboring countries. Then, taking into account their different socio-political differences since the Syrian civil war in 2011 by using the ICEWS conflict database, we could highlight the dominant role of these conflicts in extreme fire years in the region.

1. Introduction

Wildfire is among the main shaping factors of Mediterranean ecosystems (Paula *et al.*, 2009), affecting yearly about 1 million hectares of Mediterranean forests worldwide (Dimitrakopoulos and Mitsopoulos, 2006). Due to the particularly fire-prone conditions of the Mediterranean climate (Le Houérou, 1973), fires are intrinsic to the functioning of Mediterranean forests. Climate forcings, changes in traditional land use, as well as population movements and lifestyle, lead forest fires to increase after the 1970' in the Mediterranean basin (MB) (Gill *et al.*, 2013; Pausas, 2004; Xanthopoulos and Nikolov, 2019), causing adverse impacts on economic, social and ecological assets (Gill *et al.*, 2013; Xanthopoulos and Nikolov, 2019).

This natural disturbance is mostly being addressed by studies focusing on the European part of the MB where fire events have been registered since the 1970s (San-Miguel-Ayanz *et al.*, 2012). Studies conducted in the Eastern and Southern parts of the basin are more limited and systematic uniform documentation of fires is still lacking (cf. Aini *et al.*, 2019; Belhadj-Khedher *et al.*, 2018; Chergui *et al.*, 2018).

On the Eastern rim of the MB and intermediate between the North ridge where fire activity is driven by summer drought promoting large fires (Turco *et al.*, 2017), and the Southern ridge where fire activity is driven by heat waves during Saharan dry winds (Belhadj-Khedher *et al.*, 2020), Lebanon and Syria lack exhaustive fire registration, an obligate prerequisite for studying fire regimes. In addition, as of 2011, Syria experienced a series

of protests that quickly escalated in 2012 to a full-fledged war (ongoing). Scholars have recently described the effects of war on the fire risk by relying mostly on MODIS global remote sensing data (Schon *et al.*, 2021; Zubkova *et al.*, 2021), over a short period (Mahfoud, 2020; Mohamed *et al.*, 2020) or focusing on agricultural lands (Schon *et al.*, 2021).

In such scarcely documented areas, remote sensing offers the most effective alternative to national statistics, providing global coverage, and multispectral and multitemporal information. Since the late 20th century, satellite imagery has been used to map fires (Xiao-rui *et al.*, 2005), from coarse (Eastwood *et al.*, 1998; Justice *et al.*, 2002; Malingreau, 1990; Pereira, 1999) and medium spatial resolution sensors (Filipponi, 2018; Liew *et al.*, 1998; Wightman, 1973).

The public release of the global historical Landsat archive (1984 – present) by the United States Geological Survey (USGS) in 2008 (Loveland and Dwyer, 2012; Woodcock *et al.*, 2008) initiated the development of automated and semi-automated tools that multi-process long and complete time series of Landsat imagery, resulting in the fast reproduction of fire perimeters over long periods and large surfaces (local to global coverage).

Nevertheless, relying solely on Landsat data can't provide a complete record of past fires and prevents an accurate dating between Landsat's overpasses. Recently, semi- and fully-automated burned area (BA) mapping tools combining Landsat data and daily Moderate Resolution Imaging Spectroradiometer (MODIS) active fire-detection data (hotspots) helped to overcome these limitations (Boschetti *et al.*, 2015; Roteta *et al.*, 2021). Fires detected throughout spectral changes in Landsat data (30 m) are dated using the high temporal resolution MODIS hotspots (1 day) when the two data sets spatially and temporarily coincide, also allowing the visual validation of the burning signal to effectively eliminate commission errors (Chuvieco and Congalton, 1988) and the manual refining of the fire polygons to narrow omission errors (Koutsias and Pleniou, 2021).

Accordingly, the aims of this study were (a) to create a GIS database of wildfire events and spatial extent in Lebanon's and the coast of Syria's wildland vegetation, two neighboring countries with similar climate conditions but contrasted socio-political events, for the last 37 years based on historical satellite archives (1984 – 2020) and MODIS hot-spots data (2001 – 2020), and (b) to provide a description of the fire regime taking into consideration the impacts of the socio-political conflicts on the natural wildfire regime in Syria.

2. Material and Methods

2.1. Study area

The study area includes the wildland areas (forests, shrublands, and grasslands) over Lebanon (between latitudes 33° and 35° N and longitudes 35° and 37° E) and the Syrian coast (between latitudes 32° and 38° N, and longitudes 35° and 43° E) (Figure 1), characterized by a typical Mediterranean climate with hot and dry summers and mild, wet winters (Köppen, 1884).

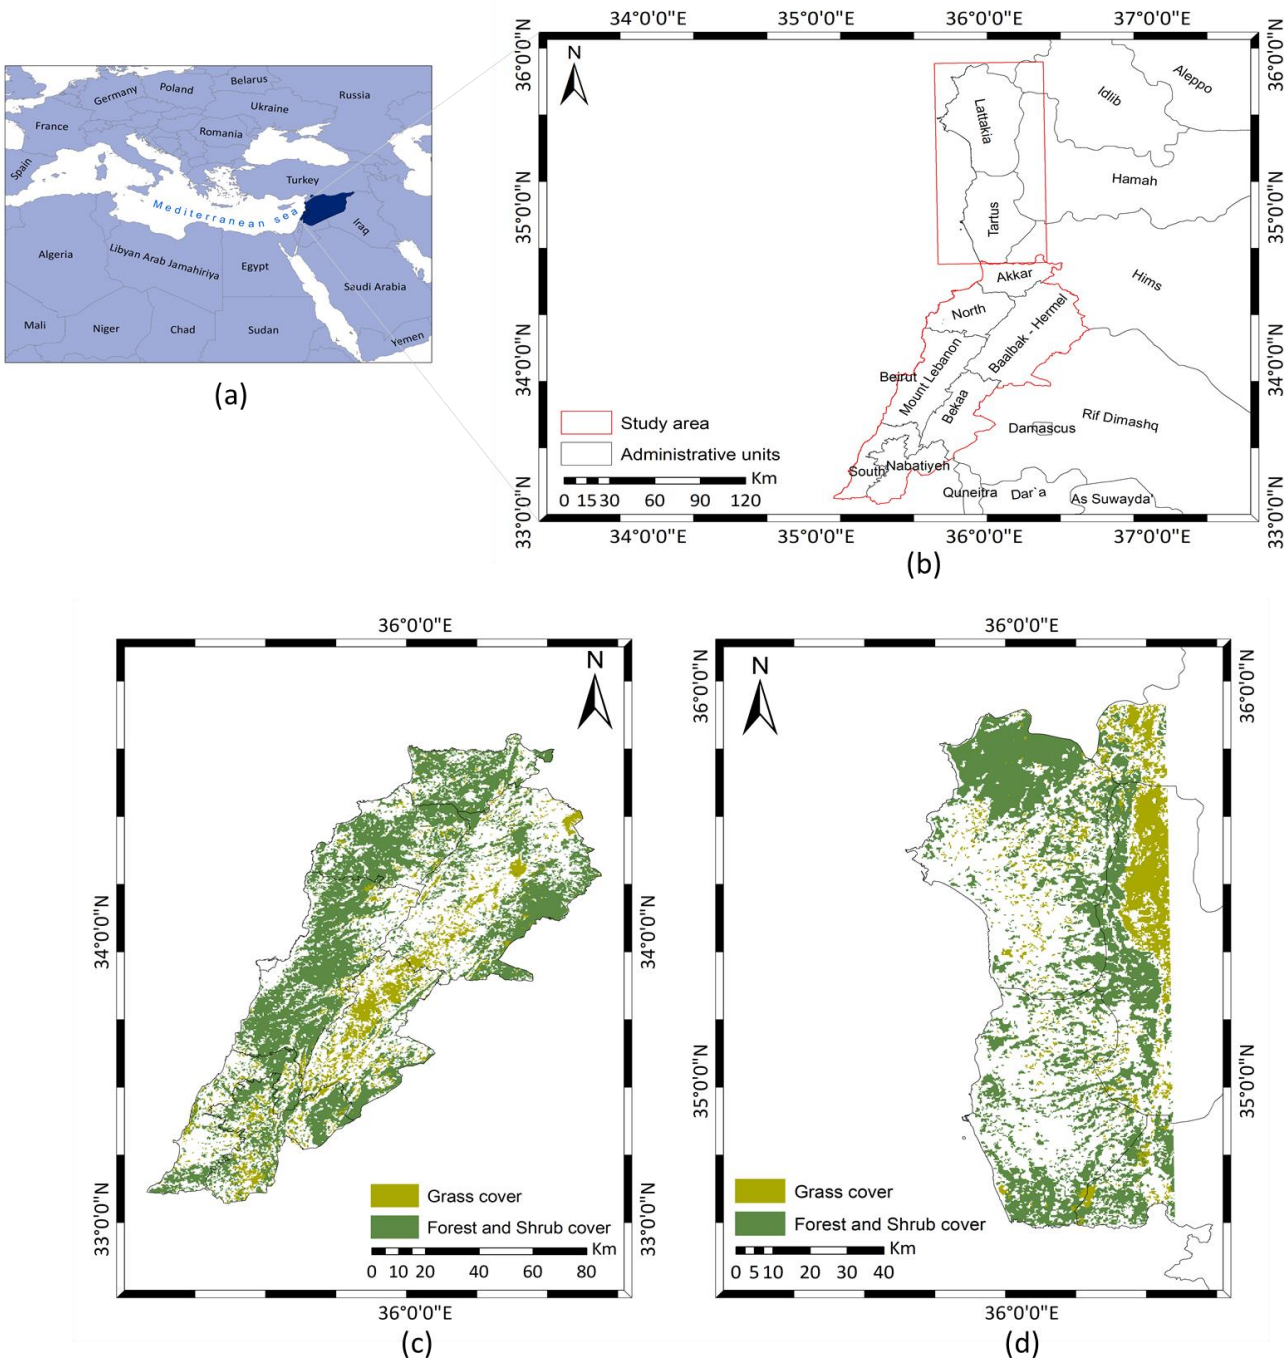

Figure 1- Location of Lebanon and Syria within the Mediterranean basin (a) and administrative units (b) overlayed with the forests/shrub cover (Deep green) and grass cover (light green) in Lebanon (c) and Coastal Syria (d).

The study area is delimited in red.

2.2. Data

2.2.1. Fire data

For the period 2001 – 2020, fire contours were generated over wildlands using the Burned Area Mapping Tools (BAMTs). BAMTs is a semi-automated tool, available on the Google Earth Engine platform (https://github.com/ekhiroteta/BAMT) whereas common spectral indices, used to characterize burnt pixels, are calculated for a pair of Landsat or Sentinel scenes and a random forest classifier algorithm is trained to identify burnt vegetation patches (Roteta *et al.*, 2021).

Fire events were first located and dated based on MODIS MCD14ML hotspots (2001 – 2011) and VIIRS hotspots (2012 – 2020) (available at https://firms.modaps.eosdis.nasa.gov/download/).

Based on the timing and location of each fire hotspot, their contours could be amped by pre and post-fire Landsat time series using BAMTS and visually checked for accuracy.
Due to the lack of hotspots for the period 1984 – 2000 to tackle the location and timing of fire events in BAMTs, a second semi-automated tool relying solely on Landsat data was used to produce the fire contours of 1984 – 2020. The tool, described in Koutsias and Pleniou (2021), is based on a set of valid rules applied to Landsat scene pairs (pre-and post-fire) to identify burnt areas. Fires produced were only yearly dated due to the coarse temporal resolution of Landsat scenes (~ 16 days). Over the period 2001 – 2020, small fires undetected by BAMTs could be identified and added to the database while fires identified from both methods were compared and merged.

Due to the lack of reliable local fire records to filter out commission errors (Faour, 2004; Faour et al., 2006), the accuracy assessment was a visual checking filtering out all detected fires occurring in croplands or with no visual changes in reflectances. Within the red–green–blue (RGB) display, BAs have a very strong spectral signal appearing as a deep red coloring in post-fire scenes (Figure 2), allowing a high accuracy visual assessment (Koutsias and Karteris 2000; Roteta *et al.*, 2019).

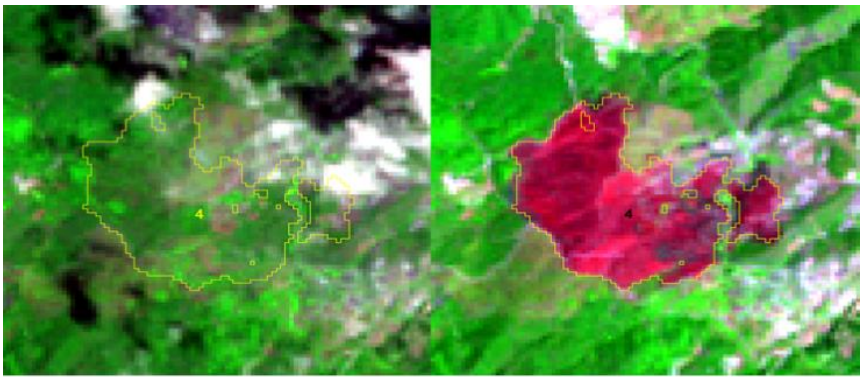

Figure 2 - Pre- (left) and post-fire (right) images showing the burnt signal (red).

2.3. Climatic data

To investigate the climatic control on the seasonal and interannual fire activity, we tested the Fire Weather Index (FWI) (Van Wagner, 1974), previously used in Mediterranean ecosystems (Chelli *et al.*, 2015; Dimitrakopoulos *et al.*, 2011; Moriondo *et al.*, 2006). We computed FWI with the R-cran "*cffdrs*" package and "*fwi*" function based on midday values of temperature (C), wind speed ($km.hr^{-1}$), precipitation (mm), and relative humidity (%) from the ERA5 Land climate database (https://confluence.ecmwf.int/display/CKB/ERA5-Land?src=contextnavpagetreemode) over the cities of Beirut (Lebanon) (33.68°E, 35.5°N) and Lattakia (Syria) (36.0°E, 36.05°N) for the period 1984 – 2020.

2.3.1. Conflict Data

To investigate our hypothesis of the potential impact of conflicts on the wildfire activity in Syria, we used the Integrated Crisis Early Warning System database (ICEWS) (Boschee *et al.*, 2020), previously used in studies about protests, fire, and conflicts driving forces in Syria (Ash and Obradovich, 2020; Linke and Ruether, 2021; Zubkova *et al.*, 2021). ICEWS consists of socio-political conflict and mediation global events identified and extracted automatically from news articles, available from January 1995 until April 2020. For our study, 1,607 violent events taking place in Syria between 1995 and April 2020 (29 out of 290 event types) were retained.

3. Results and Discussion

3.1. General information and Burnt Area database for the period 1984 – 2020

An exhaustive GIS fire database was produced for Lebanon and Mediterranean Syria for the period 1984 – 2020 with a spatial resolution ranging between 20 m (2016 – 2020) and 30 m (1984 – 2015). Each of the fire polygons is associated with a unique identification number, a surface area (ha), and minimum and maximum fire dates based on MCD64ML and VIIRS hotspots.

In Lebanon, a total of 3,232 fires were mapped, affecting a total area of 83,437 ha for the period 1984 – 2020. 0.42% of the wildland was burnt each year (2,255 ha.year^{-1}) with the highest fire years being 2007, 1998, and 1985. The majority of the fires (66.3%) occurred in forests and shrublands. 33.7% of the fires occurred in grasslands (Figure 3).

In Syria, a total of 1,544 fires were mapped, affecting a total area of 106,766 ha for the period 1984 – 2020, 1% of the wildland was burnt each year (2,885 ha.year^{-1}), with the highest fire years being 2020, 2012, and 2015. The majority of the fires (80.6%) occurred in forests and shrublands. 19.4% of the fires occurred in grasslands. (Figure 4).

3.2 Bimodal fire seasonality

In both countries, we observed a particular bimodal distribution of BA over the fire season with a reduced fire activity in August and peaks in the early and late fire seasons (Figure 5). Both the late end of the fire season (October/November) and the reduced fire activity in August are rarely seen in the MB where the fire season usually ends in September (Belhajd Khedher *et al.*, 2018; Ruffault *et al.*, 2020) and the largest BA is observed in August (Aini *et al.*, 2019; Belhadj-Khedher *et al.*, 2018; Chergui *et al.*, 2018; Im *et al.*, 2006). The dry season actually extends from June to early November, quite a long period for the region. During this dry period, we found that air relative humidity (RH) in August doesn't reach the low values observed in the late fire season (October-November in Lebanon; September-October in Syria). In addition, wind speed tends to decline in summer, while the highest temperatures (95% percentile) are stable from May to October leading to higher FWI events in June and September to November (Figure 6).

3.3 Non-climatic abrupt fire regime change in Syria since 2011

While no significant temporal trend of BA is observed for the two countries (Lebanon: p= 0.21, Syria: p= 0.06), contrasting with the general decreasing trends in the European Mediterranean region (Turco *et al.*, 2016), one breakpoint occurs for the year 2011 in Syria with significantly higher BA observed during the period 2012 – 2020 (81,492.5 ha) compared to the whole time series (25,273.5 ha during 1984 - 2011). This abrupt change in the fire regime, usually due to non-climatic factors (Pausas and Keeley, 2017; Syphard *et al.*, 2017), was not observed in neighboring Lebanon (Figure 7).

A higher, yet not significant, correlation was found between the BA and maximum FWI values for Lebanon (r= 0.29) and Syria (r=0.44) than with mean FWI values (Lebanon: r=0.1, Syria: r=0.24). During the pre-conflict period, maximum FWI could detect high fire years in 2010, 2007, 2002, 1994, and 1998 in Lebanon, as well as in 2007, 1986, and 1985 in Syria. We observed that during the conflict period since 2011, the years with high fire activity in Syria (2020, 2012, 2015, and 2013) still experience the highest FWI with the breaking record of 2020, as well as Lebanon for the years 2010, 2013, and 2019 (Figure 8). However, no significant temporal trend of FWI (Lebanon: p = 0.42, Syria: p = 0.09) nor breakpoints were significant in both countries, confirming the poor impact of climate on the BA trend.

When finally considering the ICEWS database, we could find a significant increasing temporal trend in the number of conflict events (p=0.049, slope=4.53) and two breakpoints (2010 and 2016) matching the breakpoint and increase of BA observed during the conflict period in Syria (Figure 9). A highly significant positive correlation between the number of conflict events and BA within each Syrian governorate was also found (p=0.04) (Figure 10).

The poor trend correlation between FWI and BA in Syria, the decorrelation in BA between Lebanon and Syria after 2011 with similar climate while the number of conflicts appeared as a significantly correlated variable suggest that the wildfire trend in Syria has socio-political drivers stronger than climate. Still, extreme fire years, as 2020, remain related to climate with 2020 being the most extreme fire weather since 1984 observed in Syria. The combined effect of climate and social troubles lead to the most extreme fire year observed in the region. In neighboring Lebanon, the social troubles (mostly urban) during the civil war ending in 1990 did not lead to major fire events. However, the political troubles in 2006 might have significantly contributed to the high BA during this year with no extreme fire weather.

Peat fire, Peat properties, Fire break canal, Forest reserves

Abstract

Peat in the tropical country was developed from accumulated dead plant materials. Due to frequent fire occurrences, a fire break canal technique is implemented as part of prevention measures to protect the forest reserve from fire spread. Although fire cases in peat swamp forest reserves in Malaysia are minimum, the occurrences can cause changes in the peat properties if they happen frequently. Therefore, this study focuses on determining the peat properties near the fire break canal in low and high fire frequency areas. Peat samples were collected from 0 cm (surface) to 150 cm at 50 cm intervals at 75 m to 300 m from the canal. The findings show that the peat properties were not affected by the presence of fire break canal for porosity (%), moisture content (%), bulk density (g cm3), ash content (%), organic carbon content (%), and organic matter content (%) for both study areas ($p<0.05$). However, peat's lignin and cellulose content from both study areas increased as the distance from the canal increased ($p>0.05$). Other than contributing to vegetation changes in both areas, the peat properties are also different. The High Fire Frequency also shows statistically different properties compared to the Low Fire Frequency area. In summary, fire break canal can reduce the fire spread to forest reserve area and improve the peat properties to protect the land from further degradation.

1. Introduction

Tropical country peat swamps are prone to have poor drainage and water-logging conditions where plant residues usually decay faster (Taufik *et al.* 2019). With the anthropogenic influence nearby the peat swamp area, there is a possibility of fire to spread into the forest reserve and thus may degrade the area. According to the statistics provided by the Annual Report of the Sabah Forestry Department (SFD 2020), it was reported that open burning and arson contributed to the cases of previous fire incidents spread to the forest reserve (FR). In the reports, forest reserves burnt annually for 706 ha (2015), 20,000 ha (2016), 60 ha (2017), 279 ha (2018), 1313 ha (2019), and 556 ha (2020). Additionally, the issue of owners clearing their land by setting it on fire has been the primary threat to the forest (SFD 2019; SFD 2020).

Forest fire in the peat swamp forest is associated with a smouldering fire. Smouldering fire damaged the ecosystem, which caused a slow recovery of the forest (Davies *et al.* 2013). This type of fire is very persistent and may last for a long time (Rein 2013; Rein and Huang 2021). For example, fire incidents that happened in 2016 lasted for six months during the El-Nino phenomenon and lasted for two months without El-Nino influence (SFD 2017; SFD 2020). The government enhanced their fire prevention measures, including constructing a fire break canal in the repeatedly burnt area in Sabah, Malaysia. The fire break canal is meant to reduce the fire spread to the FR and was efficient in Klias FR and then implemented in Binsuluk FR. At this point, it is crucial to observe the properties of peat near the fire break canal at both Klias and Binsuluk FR. Thus, this work studied the fire influence on the peat conditions at Klias and Binsuluk FR near the fire break canal and conveyed the

analysis of the peat properties further from the fire break canal at a different depth to explore if peat fire will influence up to 1.5 m below ground.

2. Methodology

2.1. Sampling method

This research involved two study areas represented the low fire frequency area (LFF), where vegetation is still intact (Klias FR), and the high fire frequency area (HFF), where less vegetation cover presents (Binsuluk FR). The study plots were established at 75 m, 150 m, 225 m, and 300 m from the canal. A total of 192 samples were collected at different levels, i.e. 0 cm, 50 cm, 100 cm, and 150 cm (Figure 1), using a bulk density ring for physical analysis purposes and a peat auger for chemical analysis purposes.

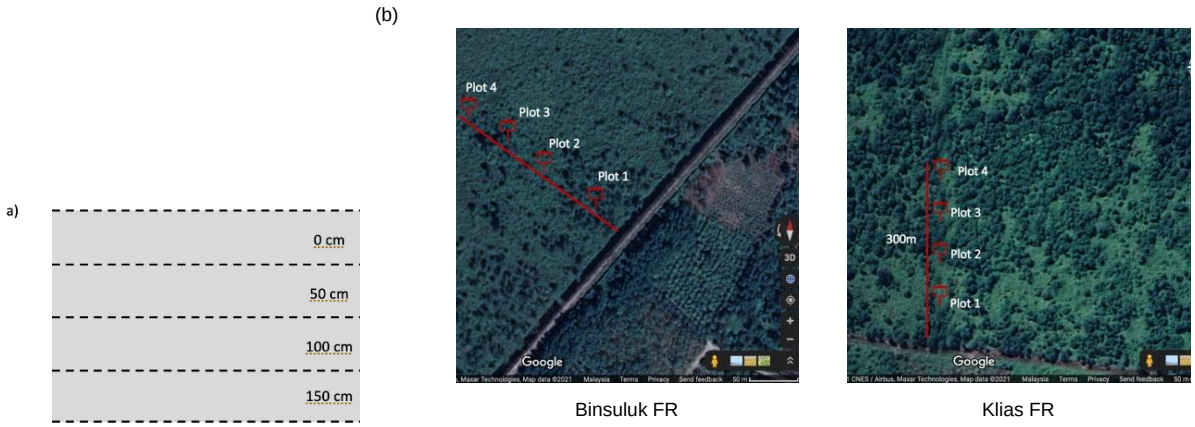

Figure 1- (a) Samples of peat collected at a different level, (b) Plot constructed at both study sites LFF and HFF) for peat samples collections.

2.2. Statistical analysis

The physical and chemical analyses involved are bulk density, moisture, porosity, organic matter, organic carbon, ash, lignin, and cellulose contents. Statistical comparisons between the plots and depths were made by using a two-way analysis of variance (ANOVA) at a 95% confidence level ($p<0.05$). A Pearson-correlation analysis is also done to determine the relationship between the variables.

3. Results and discussion

3.1. Physical properties of HFF and LFF areas

The physical properties studied in this work are bulk density, moisture content, and porosity. In this section, we want to understand how these physical properties were influenced by fire frequency. Also, the relationship between the properties will be presented in Figure 2. Based on analysis of variance analysis (Tukey's test) in the HFF area, peat at 150 m and 300 m further from the canal shows a significant difference in each variable ($p<0.05$) between the depth. In the HFF area, the porosity *has a reasonably strong relationship with bulk density (r=0.988) and a moderate relationship with moisture content (r=0.584). The peat surface has a moisture content of up to 1200% and* low vegetation cover with only tall grass and a few big trees spotted in the study sites. The rain will directly be pouring to the surface of the water. This situation will influence the significantly high moisture content on the surface (0 cm). *However, a fire frequently spreads to the area. A new fire break canal construction does not dry the area to the furthest 300 m from the canal. Because of the frequent fire, the porosity level and moisture content have a moderate relationship (0.584) but still indicate that the three fundamental properties of peat are dependent on each other. However, the higher moisture content on the surface indicates that weak peat can retain the water (Perdana et al. 2018) known as a hydrophobic condition because of a previous fire event.*

The LFF area experienced peat fire, but it was not frequent as the fire break canal was implemented in this area to prevent the fire from spreading. The peat properties in this area were not similar to the HFF area, as the fire

did not change the peat properties too much. The moisture content and porosity have a strong correlation-coefficient of 0.838, or 70% of the moisture content is dependent on the porosity of the peat. Similarly, the peat's bulk density and compaction are 78% dependent on the peat porosity for Klias Forest Reserve. However, the surface moisture content of the peat ranged from 180-400%, which was statistically lower than HFF surface moisture. The highest mean moisture content was 900% at 100-150 cm below the surface. 150 m further from the canal shows a significant difference in variables between the LFF area depth and 225 m further from the canal (p=0.002).

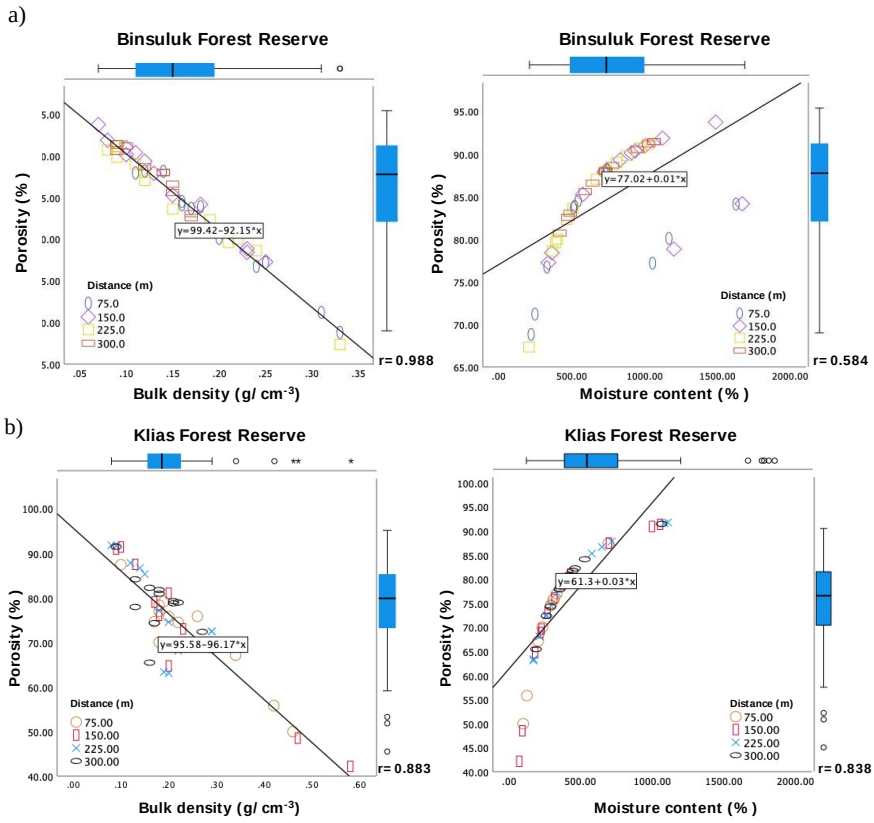

Figure 2- Influence of distance on peat physical properties of porosity (%), bulk density (g/cm3), and moisture content (%) of the a) Binsuluk Forest Reserve (HFF) and b) Klias Forest Reserve (LFF).

3.2. Chemical properties of LFF and HFF areas

The chemical properties studied were organic matter content (OMC), organic carbon content (C_{org}), Ash content, lignin, and cellulose. The analysis of correlation regression (Figure 3) between the chemical content indicates that all variables have a strong correlation for both forest reserves (r=0.998, r=1.000). The findings suggest that all chemical variables are dependent on each other. Ash content studies to identify the area burnt before the show that it was present from 0 cm to 150 cm and up to 300 m further from the canal. Based on the analysis of variance, the significant difference between the depth for the HFF area was shown at 150 m, 225 m, and 300 m further from the fire break canal.

The correlation regression analyses were used to relate each chemical properties studied. The peat's total organic matter content in the HFF area varied from 71.43% to 98.04% at a 75 m distance from the canal, which indicates no significant difference (p>0.05) between the depths. In the Pearson-correlation analysis, the HFF area shows a strong correlation (r=0.998, 0.998, 1.000) for OMC, C_{org}, and Ash content relationship. The findings were similar to LFF, where the variables have a strong (r=1.000) relationship and were expected to have no difference within the depth despite the distance from the canal (p>0.05). The LFF area findings do not influence much of the chemical peat properties on these content, organic carbon content and organic matter content.

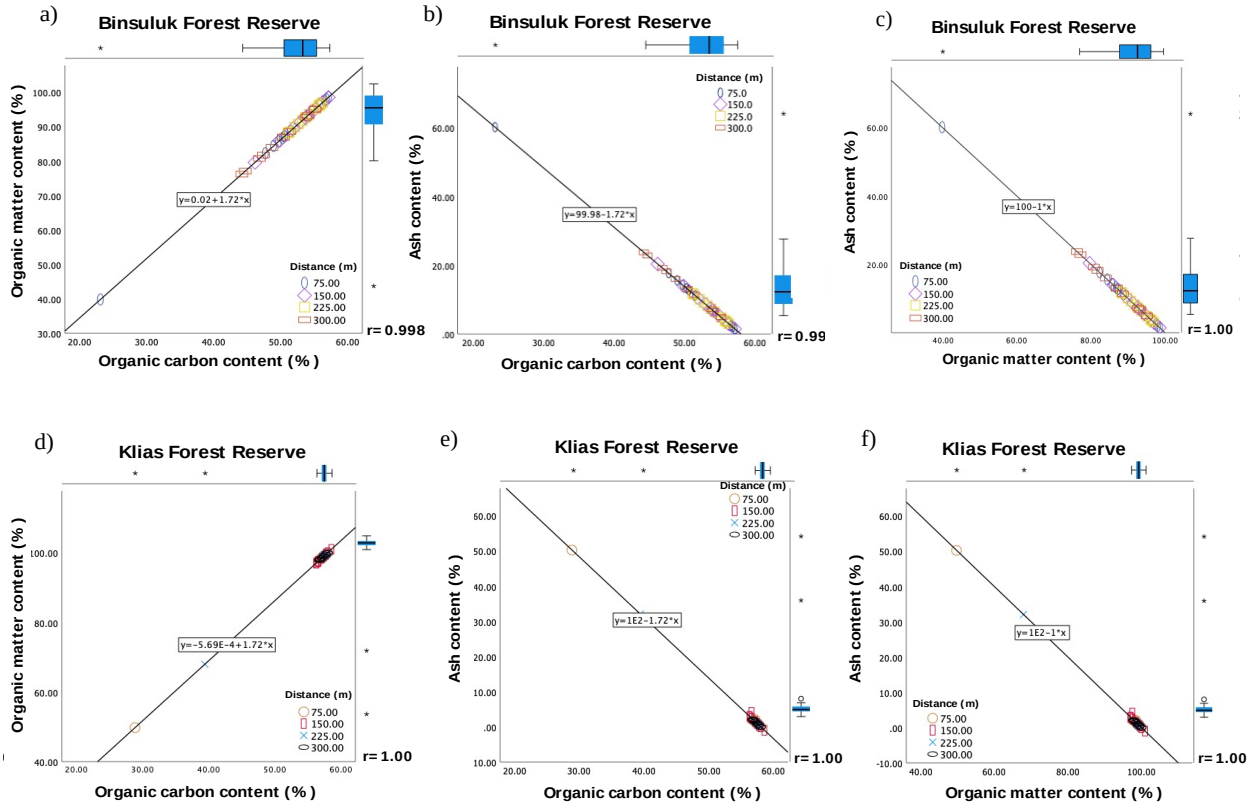

Figure 3- The correlation-regression of the chemical properties of peat-based on the distance from the canal in both Binsuluk Forest Reserve (HFF) - a) OMC (%)-Corg (%); b) Ash content (%)-C_{org} (%); c) Ash content (%)-OMC (%) and Klias Forest Reserve (LFF) - d) OMC (%)-C_{org} (%); e) Ash content (%)-C_{org} content (%); f)Ash content (%)-OMC (%).

The lignin and cellulose content were studied to determine the influence on the moisture content of the LFF and HFF area (Table 1). Based on the findings, the lignin and cellulose content have a significant difference between the plots, where the further the plot from the canal, the higher the cellulose and lignin content ($p<0.05$). The correlation regression analyses were used to relate the lignin and cellulose to moisture content. The findings show that cellulose has a fair relationship with moisture content in the HFF area. Burning the dead material might contribute to these changes as the LFF shows no relationship between the moisture content with lignin and cellulose content.

Table 1 - Pearson-correlation for lignin and cellulose with moisture content

Variable	Moisture content (%)	Lignin (g/kg)	Cellulose (g/kg)
Moisture content (%)	1.000	**-0.280** *0.451*	**-0.062** **0.692*
Lignin (g/kg)		1.000	***0.783** **0.828*
Cellulose (g/kg)			1.000

Note:
*: is used where the relationship between the variable was detected (<0.001, 2-tailed)
Font: Italic is HFF area, Bold is LFF

4. Conclusion

In conclusion, this research focuses on the peat properties nearby the firebreak canal of two other forest reserves and the influence of the canal on the properties. The samples taken were peat from Binsuluk FR, representing the HFF peat, and peat samples from Klias FR, representing the LFF frequency areas. The smouldering fire releases a substantial amount of carbon into the environment to aid the carbon emission in the area (Davies *et al.* 2013). The moisture content was found to be higher in the HFF area and there were ash in each plot indicates

the carbon has been lost during the burning. The repeatedly burnt peat consisted of high lignin and cellulose content, almost similar for 75 m from the canal to 300 m further from the canal. The LFF otherwise have significantly different results between the plots. The further the peat samples from the canal, the higher the cellulose and lignin content. Fire cases is found to influence the fibre content. The changes in peat properties will make it more vulnerable to fire occurrences when the fire from outside spreads to this area.

The importance of this research represents the protected peat swamp forest in Malaysia. This work provides information on soil properties near fire break canals in different hydromorphic settings to identify type-specific threats and derive implications for conservation, cultivation and restoration (e.g. rewetting) (Gabriel *et al.* 2018). When peat is repeatedly burnt, the peat properties will change along with its structure. Therefore, this work could help understand the changes made by a fire outbreak and how the peat will influence the re-occurrences of fire in the future. As a result, this will increase the vulnerability of the land to future fire incidents. The restoration effort and minimum fire incidents might improve the peat properties. Knowing the physical and chemical properties near the fire break canal will provide soil scientists and land managers with important information on these properties of the peat soil.

Fire behaviour, junction fires, thunderstorms, fire and atmosphere interaction

Abstract

Two fires that started near Pedrógão Grande in June 2017 were affected by the presence of a thunderstorm in the region and spread out of control as two initially separate fires. Sometime later these fires merged creating a very intense and fast spreading fire that threatened the lives of hundreds of persons. In a period of around two hours 66 persons were killed by the fire most of them trying to run away in their cars. The physical processes of fires start, interaction with the thunderstorm and merging were studied in detail as well as the circumstances in which the accidents occurred.

1. Introduction

The fires that started in the early afternoon of the 17th June of 2017 near Pedrógão Grande (PG) will be remembered as the worse in record in Portugal as they destroyed around 45000hectares but above all because they caused the death on 66 persons. Several authors analyzed this fire and produced reports studying various aspects of this very complex event, namely Viegas *et al.* (2017), Guerreiro *et al.* (2017), San-Miguel-Ayanz, *et al.* (2020).

The interaction between the thunderstorm, organized as a mesoscale convective system (MCS), and the fire was extensively analyzed in Pinto *et al.* (2022) using weather stations, satellite and radar observation data. The present work complements the previous reference, as the very unusual conditions that resulted from that interaction and produced the catastrophic fire during the late evening of that day are described in detail.

2. Fire ignitions and Spread

The fire of PG occurred in the district of Leiria, in Central Portugal (Figure 1), in a period of drought with air temperatures above 40°C and very low relative humidity. The wind flow in the region was from NW and not very strong. A large MCS developed over central-western Iberian Peninsula and moved towards W-NW causing several fires due to lightning, but at 14.30h (all indicated times are local time which is UTC plus one hour), when the fire of PG started, the more active part of this system was still nearly 100 km far from it and electrical strikes were not registered in the area of the fire until 18.00h (IPMA, 2017).

The fire of PG was actually caused by two ignitions that occurred near Escalos Fundeiros (EF) at 14.30h and near Regadas (RE) at 15.40h (Figure 2). Both ignitions were caused by an electrical line that was touched by tree foliage agitated by the wind that passes by both places which are 3.2km apart.

As there were other fire ignitions in the operational area the firefighting resources were dispersed and were not capable of coping with the very difficult spread of the EF fire which started to spot and threaten houses in the village of EF. When the fire of RE was detected there were not forces to deploy there and the fire was left spreading practically on its own. Between 18.00h and 18.15h a down flow from the MSC, which was not yet over the region of the fire, forced the fire column to tilt towards SW, spreading flames in a wide area and making the control of the fire virtually impossible from that time on (Figure 3). The RE fire which was smaller at that

time started to spread also completely out of control, towards NW forming the right side of a large pincer that was now advancing like a curved fire front more than 20km long, threatening a roughly circular area of 10km diameter (cf. Figure 1).

Figure 3 – Views of the column of the fire of Escalos Fundeiros at 18.00h and at 18.15h, showing the interaction with the down flow produced by the mesoscale convective flow.

3. Merging of the two fires

There is evidence that after 19.30h both fires had their inner flanks very close to each other making a small angle between them, therefore with the ideal conditions to merge as a junction fire that was studied by Raposo, 2012 and Viegas and Raposo 2018. Between 19.30 and 20.30h the process of merging induced very strong winds in the area ahead of the fire. The ROS of the head fire was of the order of 10 km/h. The quick combustion of a very large amount of vegetation produced a convection column that reached 12000 m at 20.10h and remained at that height for several hours. Flames of the order of 50m long and 50 to 100m long separated from the vegetation were registered, creating an environment near the ground like inside a furnace. There are reports of tree stands starting to burn from their tops to the ground (Figure 4). Persons in the area of the fire were under pitch dark and reported that the air was full of fire balls. Besides this there were pieces of wood, branches and bark flying all around, sometimes igniting new fires. In at least two much localized areas wind tornadoes twisted and broke a large number of 20cm diameter trees breaking them as toothpicks. The wind velocity required to cause this effect is estimated to be of the order of 200km/h.

Similar phenomena were observed in the process of merging of the McIntyre and Bendora fires near Canberra on the 18th January 2003, with a very fast spreading fire (27km/h) and a tornado that broke trees trunks larger than 30cm diameter (cf. Doogan (2006)).

The perception of the violence of the fire caused by the noise produced by its very tall and roaring flames, that threatened to destroy everything on their path, caused many citizens to decide to flee from their houses. Some of them took this decision in spite of knowing that their houses would normally sustain the passage of a fire, which most of them did. While running away in their cars many persons, sometimes entire families, were caught

by the smoke, loss of visibility and the flames and lost their lives. Particularly dramatic was the situation of a stretch of 200m of the Road N326-1, between Figueiró dos Vinhos and Castanheira de Pera (Figure 4), in which 30 persons were killed inside or near their cars.

Figure 4 – Some images of fire phenomena during its spread in the late afternoon of the 17th June.

The lack of maintenance of the vegetation - including trees – in the vicinity of the main roads contributed to the lack of survival conditions for the citizens. We identified one particular pine tree that was very close to the road edge and fell with the very strong fire induced wind over the road crossing it from one side to another. This tree and a group of cars that shocked with each other created a trap from which the cars could not drive out. Based on the testimony of survivors and of persons who passed by that road before or during the accident we were able to identify at least 16 persons whose death can be directly attributed to this tree.

The authors performed laboratory experiments at the Combustion Tunnel of the Forest Fire Research Laboratory of the University of Coimbra to simulate the development of the two ignition fires. Starting with the estimated perimeter of the fires at 19.30h with a flow of 2 m/s the merging of the two fires could be observed to follow very approximately the reconstruction that was made on the basis of testimonies and documented events during its spread. The isochrones of the fire spread are shown in Figure 5. It was also shown that the spread of a single fire (either EF or RE) would have been completely different if the other fire was not present, therefore confirming the relevance of the process of merging of the two fires.

The main fire was controlled on the 22nd June by 23.50h after consuming a total area of 45328ha, with the effort of more than 1400 fire fighters and other agents.

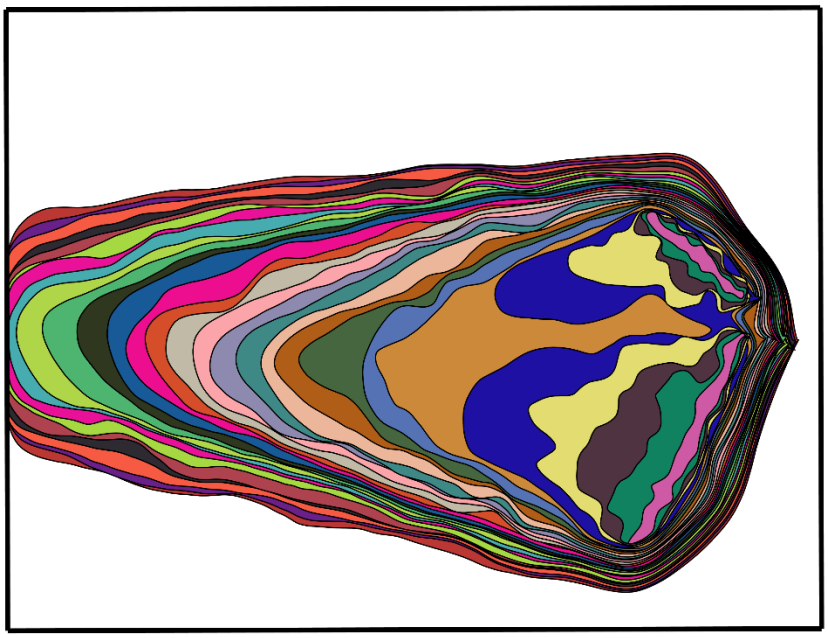

Figure 5 – Map with the isochrones of fire spread of the physical simulation of the two fires in the Combustion Tunnel of the University of Coimbra. The initial position of the fires (pink areas) corresponds at the situation at 19.30h. The time lapse between the lines is 20 seconds.

4. Conclusion

The fire that occurred on the 17th of June of 2017 near Pedrógão Grande covered and area of 45000 hectares resulted in the destruction of more than 1000 houses and structures and caused the death of 66 persons. It's very violent spread was caused by the fact that there were two separate ignitions that started 3km apart, caused by an electric line, and by the interaction of a down flow produced by a thunderstorm that was passing over the fire. The merging of the two fires produced very intense and unusual behaviour of the fire inducing many persons to escape from the fire in their cars.

Abstract

Fire is a natural phenomenon that has played a critical role in transforming the environment and maintaining biodiversity at a global scale. However, the plants in some habitats have not developed strategies for recovery from fire or have not adapted to the changes taking place in their fire regimes. Maps showing ecological vulnerability to fires could contribute to environmental management policies in the face of global change scenarios. The main objective of this work is to characterize the ecological vulnerability to fires based on how fires occur on a global scale. For this purpose, we are going to create zonal statistics by biome and by vulnerability category, finding out the average data of the different fire variables. For this, we have taken two spatial databases previously developed by us, Ecological Vulnerability to Wildfires and Wildfires Characteristics. Ecological Vulnerability to Wildfires is a global database that categorizes spatial vulnerability by ecoregion. Wildfire Characteristics collects global spatial mean data on recurrence, seasonality, patch size, and interannual variability. The results show that in areas with High/Very High vulnerability of tropical and subtropical biomes, fires are not very intense, with a small patch size and low interannual variability, but are highly recurrent and with extensive seasonality. The most vulnerable areas of the Mediterranean biome have more intense fires, with a considerable patch size and, in addition, they present considerable interannual variability, little recurrence and limited seasonality. Temperate forest biomes present their most vulnerable areas with moderate intensity, patch size and recurrence fires, but with high interannual variability. The most vulnerable areas of the montane grasslands biome show highly recurrent fires, with extensive seasonality, with moderate patch size, intensity, and interannual variability

1. Introduction

Fire is a natural phenomenon that has played an important role in the transformation of the environment and the maintenance of biodiversity on a global scale. It can have numerous positive and negative impacts. Most of the world's terrestrial habitats where fires occur depend on them for ecological sustainability. (Kirkman et al., 2001; Midgley & Bond, 2015). Fire can affect the distribution of habitats, carbon and nutrient fluxes, and the water holding properties of soils (Bowman et al., 2009). In habitats that are adapted to and even dependent on fire exclusion policies, this can result in a decrease in biodiversity (Guyette et al., 2002). In addition, the absence of fire results in increases in fuel loads (Bond et al., 2005), which frequently augment the risk of catastrophic fires over time. Fire has also been and continues to be used by humans as a crucial tool for managing terrestrial ecosystems, producing cultural landscapes that also benefit ecological health (Caprio & Graber, 2000; Guyette et al., 2002).

On the other hand, there are some habitats, such as moist tropical forests, that have never adapted to fires. The introduction of fire by humans can lead to an irreparable loss of their structure and composition (Cochrane & Laurance, 2002). Even in fire-adapted areas such as the Mediterranean ecosystems, recent human and climate related changes in fire regimes are having negative impacts on the functioning of ecosystems (Bajocco et al., 2011; Midgley & Bond, 2015). The increasing frequency and intensity of fires can have negative impacts on forest masses and landscapes, human life, infrastructures and ecosystem services and wildlife; and can cause changes in regeneration dynamics, hydrological regimes and air quality, among other environmental consequences on a global scale (Alcasena et al., 2016; Barrio et al., 2011; Buhk et al., 2007; Díaz-Delgado et al., 2002; Flannigan et al., 2009; Hobson & Schieck, 1999; Moreira et al., 2011; Scott & Van Wyk, 1990). As

a result of this process of change, forest fires have become one of the main environmental problems today at both global and local levels.

This means that fires must be included in global and regional assessments of vulnerability to global change (Houghton et al., 2001; Lindner et al., 2010). Furthermore, fire risk assessment should be carried out spatially in order to design and implement prevention strategies that enable the conservation of the ecological value of ecosystems and landscapes. When fires happen, assessments of this kind can also be useful for implementing post fire strategies to bring about the recovery of pre-fire ecological values and cultural and socioeconomic assets (Aretano et al., 2015; Chuvieco et al., 2010). In terms of natural hazards terminology, spatially measured fire risk is a combination of 'danger' and 'vulnerability'. 'Danger' is defined as the probability of fire occurring in a given place and time, while vulnerability refers to the potential damage that fire could cause to this place (Chuvieco et al., 2007). Vulnerability must include two parts: social and ecological.

There are few attempts to estimate the ecological vulnerability to fire locally or regionally, almost none globally, and none that show how fire occurs in ecosystems that are more or less vulnerable to fires in the world (Turner et al., 2003, Duguy et al., 2012, Aretano et al., 2015, Chuvieco et al., 2010, González, Kolehmainen, & Pukkala, 2007, Duguy & Vallejo, 2008, Giovannini & Lucchesi, 1997, Chuvieco et al. 2014).

In this paper, the main objective of this work is to characterize the ecological vulnerability to fires based on how fires occur on a global scale. This study will be carried out on a global scale so as to enable us to tackle the planetary ecosystem as a whole, unrestricted by governmental or geographic borders. In this way, this research could become an essential tool for decision-making about resource management and nature conservation across the globe.

2. Material and methods

2.1. Study Area

2.1.1. Section 1.1.1

The spatial units used in this study were the terrestrial ecoregions proposed by the World Wildlife Fund (WWF), as corrected in 2017 (Olson et al., 2001). The terrestrial ecoregion concept refers to a land unit large enough to house a set of natural communities composed of different species, dynamics and similar environmental conditions. Thus, ecoregions are a good way to structure ecological and fire information on a global scale, since they are relatively homogeneous in terms of climate and vegetation (Pausas & Ribeiro, 2017). The number of ecorregions and terrestrial biomes were reduced to 554 and 9 (figure 1)in order to exclude lack of data and zones in which forest fire were impossible to occur.

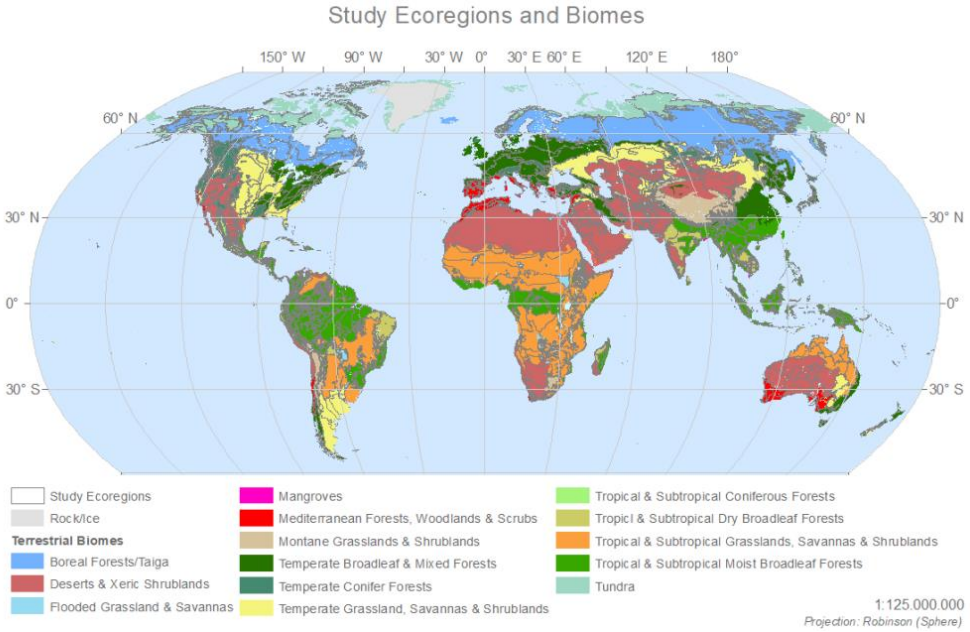

Figure 1. Terrestrial ecorregions within their biome for this study. (Source: The authors).

2.2. Ecological Vulnerability to Wildfires data

Ecological Vulnerability to Wildfire (figure 2) is a categorical spatial database at global scale in which each ecoregion contains a vulnerability category (Arrogante-Funes, F., Aguado, I., & Chuvieco, E. 2021). The categories of ecological vulnerability to fires are: Very High, High, Moderate and Low.

This database keeps in mind two ecological value indices: biological distinction and conservation status. Moreover, for the post-fire regeneration delay index, various factors were taken into account, including the type of fire regime, the increase in the frequency and intensity of forest fires and the potential soil erosion they can cause. These indices were combined by means of a qualitative cross-tabulation to create a new index evaluating Ecological Vulnerability to Wildfire.

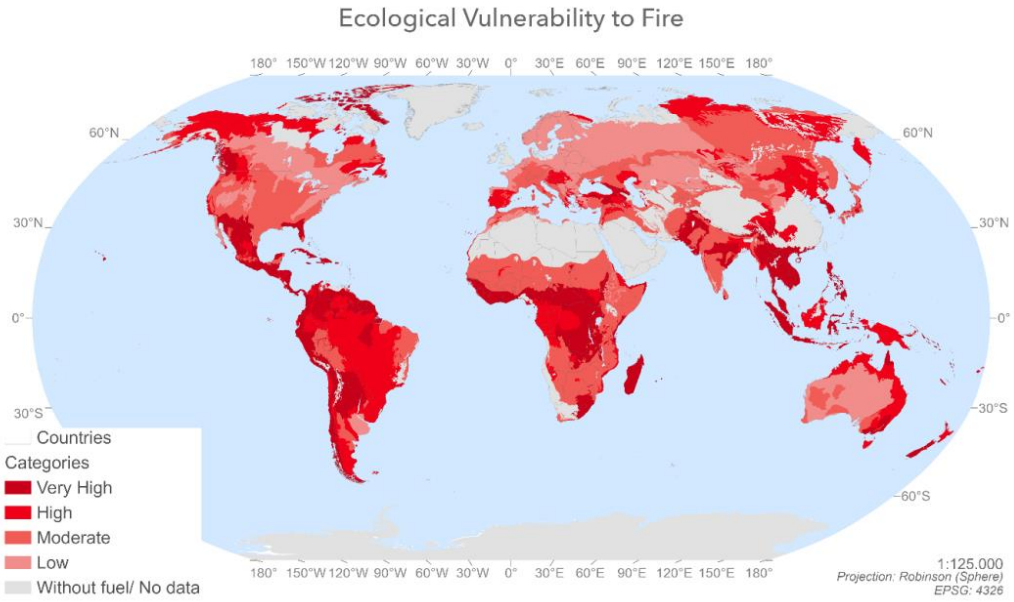

Figure 2- Spatial distribution of the Ecological Vulnerability to Fire.

2.3. Wildfire Characteristics data

Wildfire Characteristic data contain raster information at 0.25 grid for seasonality, recurrence, intensity, interannual variability and patch size, among others (García et al., 2022). This database was developed through the estimation of the mean data for each pixel from the information of remote sensing time series data of the last 20 years.

Seasonality is related to the numbers of months in which there are fire activity. Recurrence variable is the times burn each pixel in wherever part of it. Intensity is relative to the FRP which was estimated in MW through a patch method. Interannual variability measured the variance between patch size for the same zone during the years. Finally, patch size is related to the burned area estimated in km^2. All these variables contain a numeric data base on the mean data for all the time serie.

2.4. Zonal Statistics

Zonal Statistics is an analytical tool specifically for raster datasets used in a several works from different part of the knowledge (Jacox & Samet, 2007). Summarizes the values of a raster within the zones of another dataset and reports the results in a table. It can calculate the mean, median, sum, minimum, maximum, or range in each zone (Theobald, 2005).

Since we wanted to find the fire pattern for each vulnerability category by biome, we were able to use a zonal operation like this one. By using a Wildfire Characteristics raster as its value field, we were able to zone the Ecological Vulnerability to Wildfires categories by biome with the mean function. This process was computed by each fire variables previously cited.

3. Results

The Table 1 shows the results of the tool Zonal Statistics as a table with the mean data of each fire variable by ecological vulnerability to wildfires by biome. Red to green shows from lowest to highest values per column.

The results show that in areas with High/Very High vulnerability of tropical and subtropical biomes, fires have a high recurrence in addition to having an extensive seasonality. On the contrary, in this area the fires present low intensity, patch size and interannual variability.

The most vulnerable areas of the Mediterranean biome have more intense fires, with a considerable patch size and, in addition, they present considerable interannual variability, little recurrence and limited seasonality.

Temperate forest biomes present their most vulnerable areas with moderate intensity, patch size and recurrence fires, but with high interannual variability.

The most vulnerable areas of the montane grasslands biome show highly recurrent fires, with extensive seasonality, with moderate patch size, intensity, and interannual variability.

Table 1. Zonal Statistics as a Table with the mean function by each variables of fire inside the vulnerability categories belong per biome.

4. Discussion

Tropical & Subtropical Dry Broadleaf Forests and Moist Broadleaf Forest are biomes in which the origin of the fire may be due to the human being due to the low values of intensity, patch size and interannual variability, and due to the high values of recurrence and seasonality as in the case of Tropical & Subtropical Grasslands, Savannas & Shrublands (Crochane & Laurance, 2002). In addition, all the categories of ecological vulnerability to fires present similar values.

With Xeric Shrublands, the opposite of the previous case occurs since its origin could be natural and therefore said vegetation coexisted with fire, developing a vegetation with greater adaptation to fire (Moreira et al., 2011).

In the case of the Mediterranean forests, the fires are motivated by the periods of summer drought due to the highest values of intensity and interannual variability of the fire, while it presents lower values in the variables of recurrence and seasonality (Alcasena et al., 2016; Barrio et al., 2011; Bhuk et al., 2007)). In addition, it is more notable in the high and very high categories of the ecological vulnerability index, for which this biome could see its most outstanding ecological values affected (Diaz-Delgado et al., 2002).

In the case of biomes belonging to temperate zones, broadleaf and mixed forests are related to lower values of intensity, patch size, recurrence and seasonality, unlike what occurs in their grasslands, savannas and shrublands zones. This is generalized for all categories of ecological vulnerability to forest fires.

5. Conclusions

This is a first exploratory analysis of fire variables and ecological fire vulnerability categories.

Zonal statistics is a good tool for the spatial data of this work.

There are slight differences between the vulnerability categories within the biome for the various fire variables. The values are homogeneous within the biome.

Fire forecasting, IS4FIRES, Fire radiative power

Abstract

A challenging task of fire forecasting has been approached in climatological mode, i.e. for completely hypothetical meteorological scenarios (or for long meteorological archives) and without any relevant observational information on fires. This challenge has been approached by extending the methodology developed by FMI in collaboration with University of Latvia on the basis of statistical forecasting technique suggested by Main Geophysical Observatory (St. Petersburg). The technique was successfully applied to a wide variety of problems. The essence of the methodology is to establish a "static mapping", i.e. a set of non-linear statistical dependencies between a set of predictors (in the current case, meteorological parameters including cloud-to-ground lightning flash density, and fire danger indices) and the predicted variable - the fire radiative power FRP or its time-integral, fire radiative energy, FRE.

The methodology relies on a thorough investigation of the statistical properties of the data at hand and possible physics-based relations between the parameters. Therefore, the solution to the fire prediction problem started from investigating the statistical properties of the underlying datasets, first of all, MODIS FRP retrievals, which is presently the longest time series of FRP – over 20 years (2000 - present).

1. Introduction

Availability of satellite observations of active fires (Temperature Anomaly, TA, and Fire Radiative Power, FRP) allows for global fire detection in near-real-time. These data however tell very little about the fire pattern in (near) future: extrapolation of the observed patterns even over one day leads to large errors and moreover regional prediction of fire patterns for a few days turned out to be a challenging task (Di Giuseppe et al., 2017, 2016; Partanen and Sofiev, 2022). At the same time, quality and features of fire predictions largely determine the capabilities of downstream applications, such as atmospheric composition and air quality forecasts.

The current paper introduces a new fire prediction model, outlines its key features, and shows the first results.

2. Problem statement

The goal of the study is to construct a statistical model based on machine learning techniques for prediction of daily fire Radiative Power (FRP) released by vegetation fires at regional-to-global scales. The prediction time horizon is unlimited: the model should be able to operate at climate-relevant scales, both in past and future, using only meteorological predictions produced by weather forecasting and climate models.

The system is based on the Integrated System for Wildland Fires IS4FIRES (http://is4fires.fmi.fi, visited 20.08.2022), (Soares et al., 2015; Sofiev et al., 2012, 2009), which uses the FRP retrievals of MODIS instruments onboard of Aqua and Terra satellites and produces time- and space- resolving 4-D emission flux for 21 atmospheric pollutants.

3. Materials and methods

3.1. Input datasets

The detection procedure of Collection 6 of MODIS FRP fire products is based on an algorithm of (Wooster, 2003) that exploits the strong emission of mid-infrared radiation from fires. Details on the way the MODIS FRP is used by IS4FIRES are described in (Soares et al., 2015; Sofiev et al., 2009).

The ERA5 reanalysis (European Reanalysis v.5, https://www.ecmwf.int/en/forecasts/datasets/reanalysis-datasets/era5, visited on 21.08.2022) is a global meteorological dataset, which provides hourly estimates of atmospheric, terrestrial, and oceanic meteorological variables. The data cover the globe with a ~25km grid and resolve the atmosphere with 137 levels from the surface up to a height of ~80km. The current study uses the period 1980-2021.

Another source of meteorological information is ECMWF's Integrated Forecasting System (IFS) global forecast archive, with its advantage of the most recent modelling developments. Since 2018, ECMWF implemented a new lightning parameterization in IFS (Lopez, 2016) predicting total lightning flash density (in flashes km^{-2} day^{-1}). Together with height of convective cloud top and height of zero-degree wet-bulb temperature, it was used to calculate the cloud-to-ground lightning flash density following the approach of Price and Rind (1994). This parameter was used to simulate lightning as a major natural cause of wildland fires (Veraverbeke et al., 2017; Pérez-Invernón et al., 2021). The lightning data are currently available for the period since the lightning parameterization was implemented in IFS (mid-2018 – 2021).

3.2. Statistical procedures

The statistical methodology adapted to fire forecasting has its roots in the ground-setting works of Voeikov Main Geophysical Observatory for urban air pollution (Berlyand, 1991; Genikhovich et al., 2004). This approach has been adapted by the FMI team, in collaboration with University of Latvia, to a variety of tasks (Ritenberga et al., 2017, 2016; Sofiev et al., 2017). However, the statistical features of the fire problem represent an extreme case, which required more complicated arrangements.

Since the prediction of individual fire ignition is meaningless, the problem uses spatial and temporal averaging with adjustable kernels to catch the mean and/or upper percentiles of the fire events.

Apart from non-linear transformations described by Ritenberga et al., (2017, 2016) and Sofiev et al. (2017), the following additional transformation steps were implemented in order to cope with peculiarities of the fire prediction problem:

- MODIS detection limit was parameterized generally following the procedure of (Maier et al., 2013), who estimated it for FRP Collection 5 data in Australia. Modification of that analysis leads to a simple analytical parameterization of MODIS detection limit applicable over the globe.

- SEVIRI-based parameterization of diurnal FRP variation of IS4FIRES v.1.0 has been reviewed by adjusting the day-night spread but keeping the profile shape intact.

- Five popular fire danger indices (FDIs) have been reviewed and their coefficients re-optimized using MODIS fire detections as a fitting target: Fire Weather Index (Van Wagner and Pickett, 1985), Keetch-Byram drought index KBDI (Keeth and Byram, 1968), soil drought index SDI as quoted by (Kumar and Dharssi, 2015), McArthur grass fire danger index as presented by (Schreck et al., 2010).

- Due to episodic character of fires, the normalization step had to be skipped in the pre-processing and replaced with the post-processing alignment of distribution functions. This was realized as a point-by-point rescaling of quantile chart towards the 1:1 relation.

3.3. Input parameters for fire forecasting

The FDIs, both initial and after optimization, were accompanied by a set of basic meteorological variables, which had a theoretical possibility to influence the fire regime:

- temperature at 2m above the ground
- relative humidity at 2m above the ground
- soil skin temperature
- leaf area index for low vegetation

- leaf area index for high vegetation
- soil moisture content
- total cloud cover
- water-equivalent snow depth
- convective rain
- large-scale rain
- windspeed at 10 m above the ground
- day length in hours
- convective available potential energy CAPE
- cloud-to-ground lightning flash density.

All these variables were taken as daily-min, daily-mean and daily-max, while precipitation and lightning data were also used as daily-sum.

4. Results

4.1. Predicted fires and comparison with MODIS

The most-important predicted time series refer to the MODIS observation period, which allows for direct evaluation. For the comparison, the whole period 2000-2020 has been split to training and test subsets of days in proportion 70-30, so that the first 70% of days (approx..14 years) were taken as training and the last 30% of days (approx.. 6 years) were used for testing. This approach was used because: (1) for a global model the "year" term is ambiguous, (2) random split at daily level may facilitate "gap-filling" solutions between neighbouring days instead of time-agnostic predictions,

An example of predicted crop residue fires in Central Europe is shown in Figure 1. Red dots denote the actually observed FRP, blue small dots show the MODIS detection limit for the days when it did not see any fires. The FFM prediction is the brown line. An intriguing feature of these time series is that for the seasons of 2001 and 2002 FFM predicted very low fire intensity. For trees, these were indeed very weak years but for grasses and crop residues the season was among the strongest. The most-plausible explanation was the ignition irregularities: moderate conditions still allow for fires to go if they get ignited. Such sensitivity is characteristic for grass and shrubs fires, whereas forests are more resilient for fires unless conditions are strongly favourable for burning.

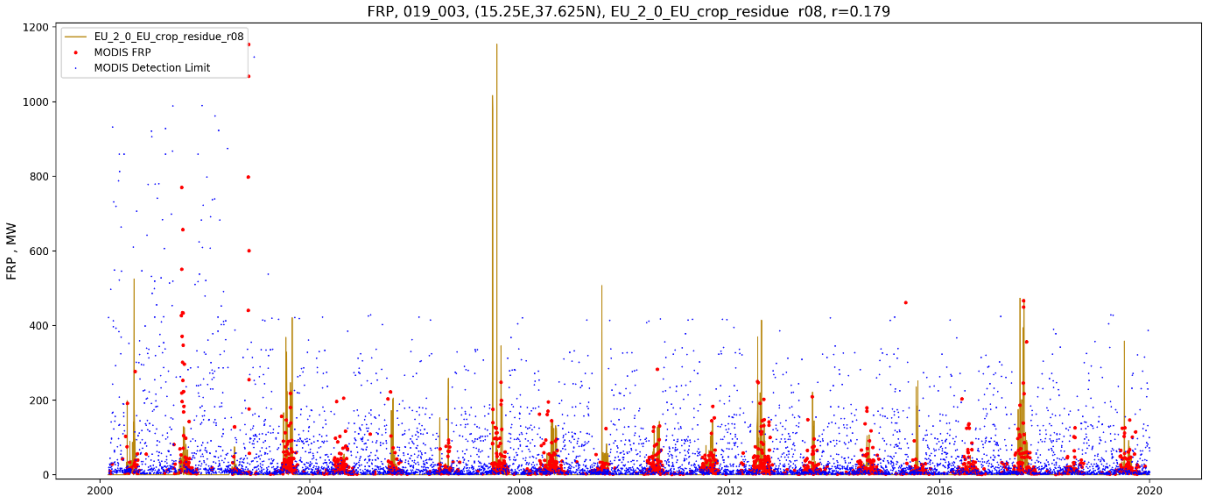

Figure 1. Example of time series for crop residue fires in Central Europe

4.2. Comparison with GFED v.4

Comparison with other fire emission databases is quite difficult because the new dataset has no direct analogies. However, one can compare, e.g., the distribution of total emission of IS4FIRES FFM and GFED v.4 (Figure 2). Since these datasets are based on different input (GFED is based on burnt area observations rather than on the

actual-fire counts), direct comparison of the maps is not very informative due to random fluctuations of the fields. However, the qualitative comparison of the fire patterns reveals both good agreement and striking regional differences.

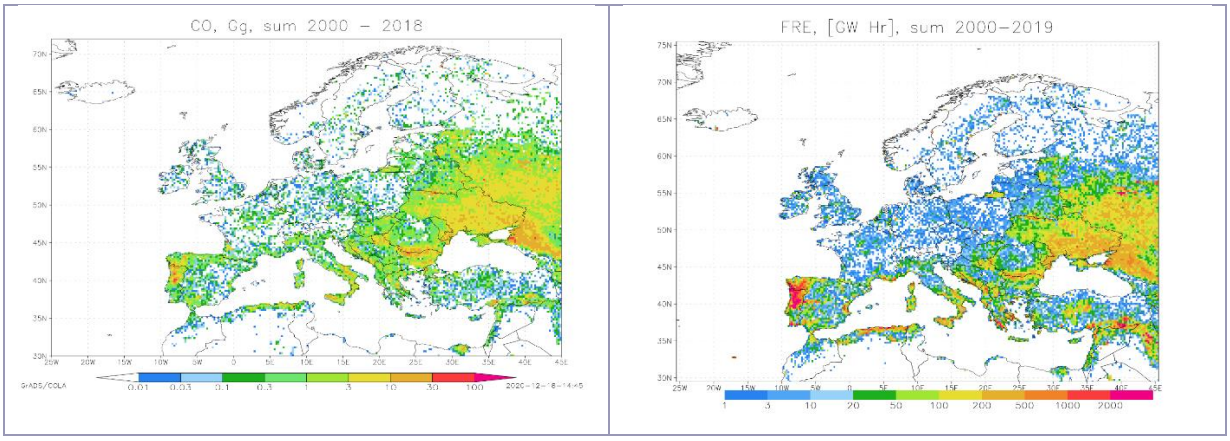

Figure 2. Left: Total CO emission from fires, GFED v.4, sum 2000-2018, Gg CO. Right: A predicted map of total FRE release 2000-2019 in Europe. Grid cell size is 0.25° × 0.25°.

4.3. Model improvements by the inclusion of lightning data

Incorporation of lightning into the list of predictors, on average, increased correlation with MODIS time series for the same region by 2-10% even with the very limited training dataset (2 years of FRP observations). The improvement is spatially distributed (Figure 3) depending on thunderstorm activity, fire frequency, and anthropogenic ignitions. Figure 4 shows an example of the impact of lightning predictor inclusion on the FFM predictions: a few fires in late July 2021 were missed by the original model while the model with the lightning input was able to predict them.

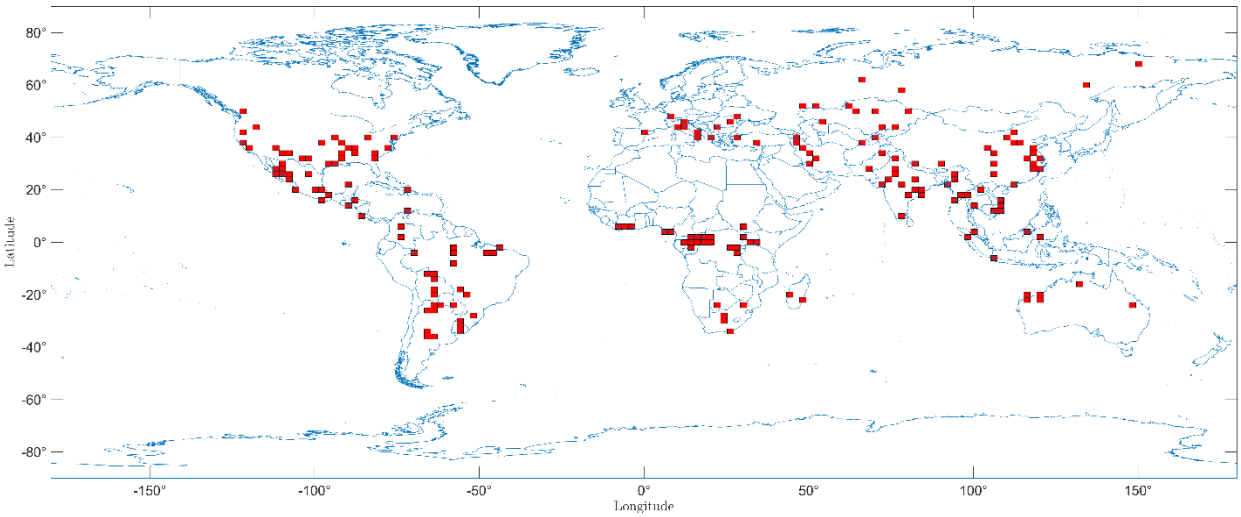

Figure 3. Map of model grid cells with statistically significant contribution of the cloud-to-ground lightning flash density to a predictor. Grid cell size is 2° × 2°.

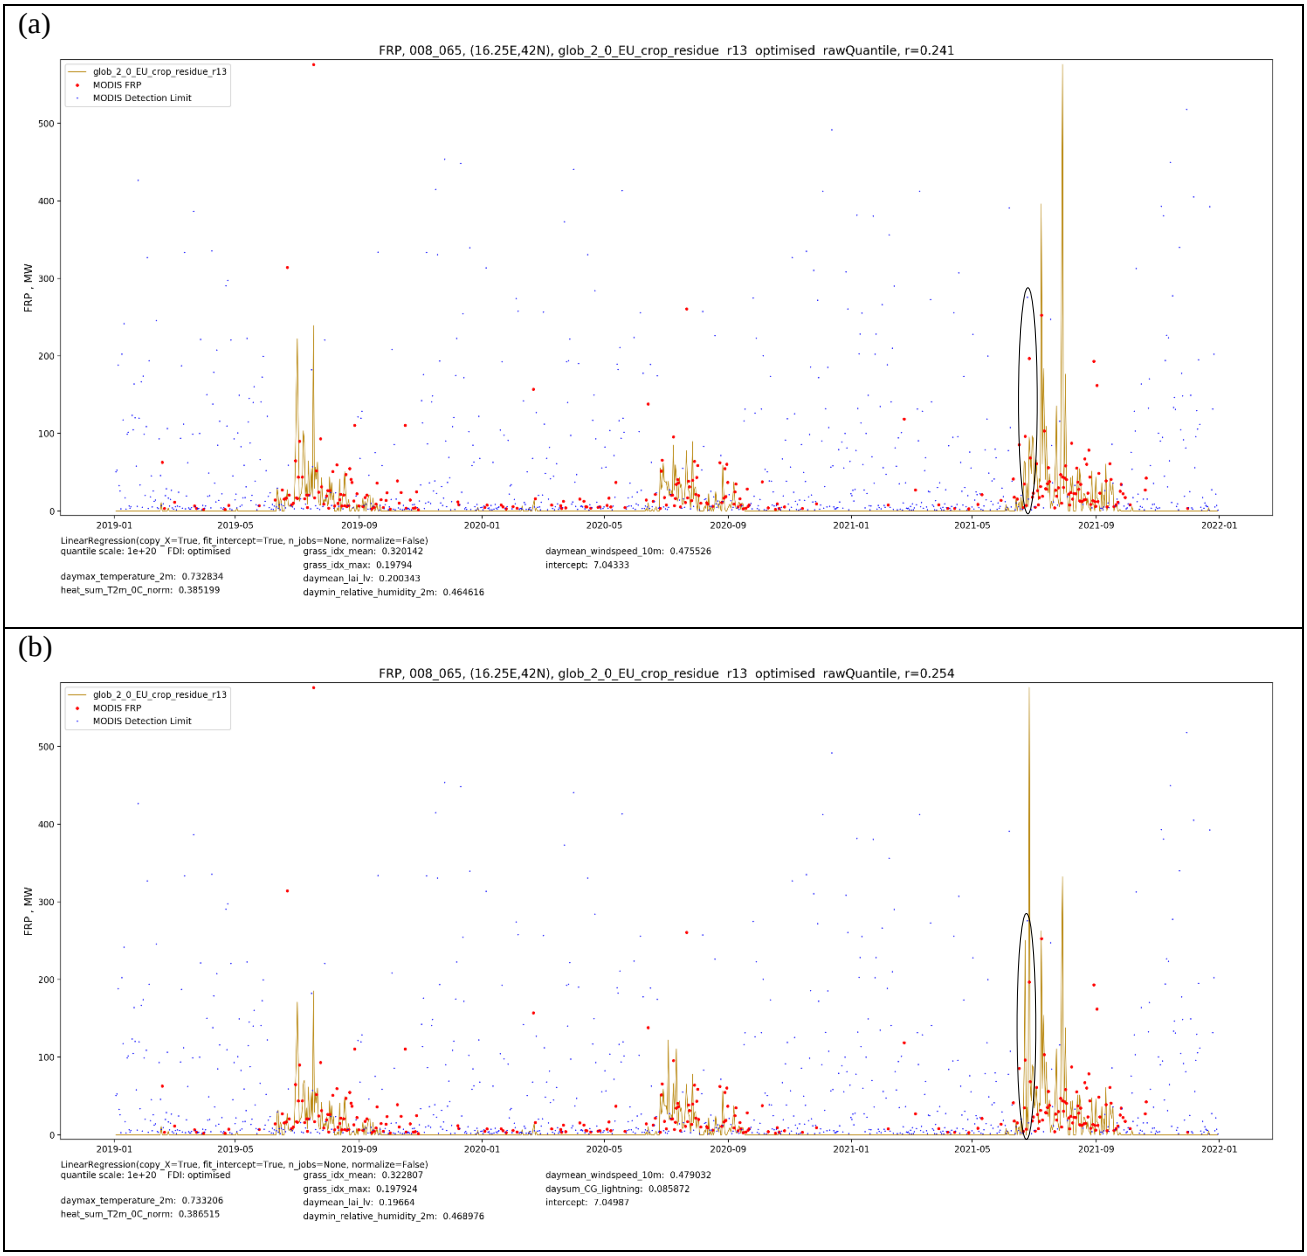

Figure 4. Example of the impact of lightning predictor inclusion on time series for crop residue fires in Central Italy. Panel (a) shows FRP by FFM trained with no lightning data compared to MODIS observations. Panel (b) shows FRP by FFM trained on the same meteorological predictors adding lightning predictions. The black ellipse denotes the area of improvement.

5. Conclusions

The current Fire Forecasting Model version 1.0 is the first practically applicable model capable of reproducing the main features of the fire seasons in Europe and, with some reservations, over the globe. Its time series seem to satisfy the requirements of the climatological-scale applications.

The main unresolved issue refers to handling the strongly non-Gaussian distribution function of FRP. The current approach ensured formal identity of the distribution functions and allowed usage of the data in downstream applications but left the core of the problem unresolved. This topic is closely related to the MODIS detection limit, which is partly behind the unusual features.

Drought, Forest Fires, Clusters Analysis, NUT III

Abstract

In order to better understand Extreme Fire Event conditions at the regional level in Portugal, a preliminary analysis on drought conditions and forest fires considering NUT III administrative organization was performed and is presented in this work. This analysis will support a more comprehensive study on the relation between weather-climate conditions (drought, heat, wind) and forest fires (occurrences and burned areas). To classify the drought, two drought indices were considered – PDSI (Palmer Drought Severity Index) and SPI (Standardized Precipitation Index), the last one for 3- and 6 months time scales. The computation was based on weather station observations for the period 1981 - 2019 in mainland Portugal, with aggregation in 23 NUT III on a monthly basis. To analyse the forest fires distribution per NUT III a monthly dataset of fire occurrences and burned areas during the period was used. The exploratory analysis was carried out in the STATISTICA software, using two clustering methods (K-Means and tree clustering). Since the results of those methods are subjective, before applying them, in the case of drought, the ideal number of clusters was calculated, making a sensibility analysis using the R tool NbClust. The results from clustering are presented through maps in which the groups of NUT III regions with the same behaviour are identified.

1. Introduction

Droughts are a natural occurring phenomenon, essentially associated with deficient precipitation values, over an extended period of time, resulting in low soil moisture and influencing water resources availability (Riley et al. 2013). Portugal is a country recurrently affected by drought, which has implications in fire occurrences and burned areas, with dry years usually being related with the greatest severity wildfires (Viegas et al. 1999). For a better understanding of the spatial distribution, an exploratory analysis of drought and forest fires was made separately. The final goal of the study is to analyse the regional distribution of the drought and its relation to the fires. The characterization of the droughts for mainland Portugal (in 23 regions of NUT III shown in Figure 1) is done using the Palmer Drought Severity Index (PDSI) and 3- and 6-months Standardized Precipitation Index (IPMA 2021), both presented in Table 1. This data is available on a monthly basis from January 1981 to December 2019. Likewise, for the characterization of the distribution of forest fires for mainland Portugal (in 23 NUT III regions), fires occurrences and burned areas on a monthly basis, from January 1980 to December 2018, were used. The first step was to develop a preliminary analysis of drought conditions calculating frequency and temporal evolution per NUT III. The second step aimed to understand how each NUT III is related to its neighbours considering the drought, through the use of correlation and applying two cluster analysis methods (K-Means clustering and Tree clustering) to identify the spatial drought and spatial distribution of forest fires in NUT III regions. Since this analysis has a subjective nature, to estimate the best number of NUT III clusters according to drought, a sensibility analysis based on the R tool NbClust was performed. The next chapters are organized as follows: i) preliminary analysis of the drought in Portugal, ii) detailed analysis of both drought and forest fires on a NUT III basis, and iii) conclusions drawn from presented data.

Figure 1 – Name of each regional division (NUTS 2013) applied in May 2015 (on the left) (the image is adapted from (INE 2015)) and the respective regional codes (on the right) (the image is adapted from (EUROSTAT 2016)).

Table 1 - PDSI and SPI index category with their respective value ranges and colour code. (the Table is adapted from (Portal do Estado de Ambiente 2021)).

PDSI	Drought classes	SPI
> = 4.00	extremely wet	> = 2.00
3.00 a 3.99	very wet	1.50 a 1.99
2.00 a 2.99	moderately wet	1.00 a 1.49
0.50 a 1.99	slight wet	0.99 a 0.50
0.49 a -0.49	near normal	0.49 a -0.49
-0.50 a -1.99	mild drought	-0.50 a -0.99
-2.00 a -2.99	moderate drought	- 1.00 a -1.49
-3.00 a -3.99	severe drought	- 1.50 a -1.99
< = - 4.00	extreme drought	< = - 2.00

2. Preliminary drought analysis

The first step was a frequency analysis of drought conditions per NUT III (see an example for PDSI in Figure 2). The analysis was followed by an evaluation of the temporal evolution of drought in the period 1981 to 2019, taking into consideration the spatial prevalence of drought on NUT III basis (see an example for PDSI in Figure 3).

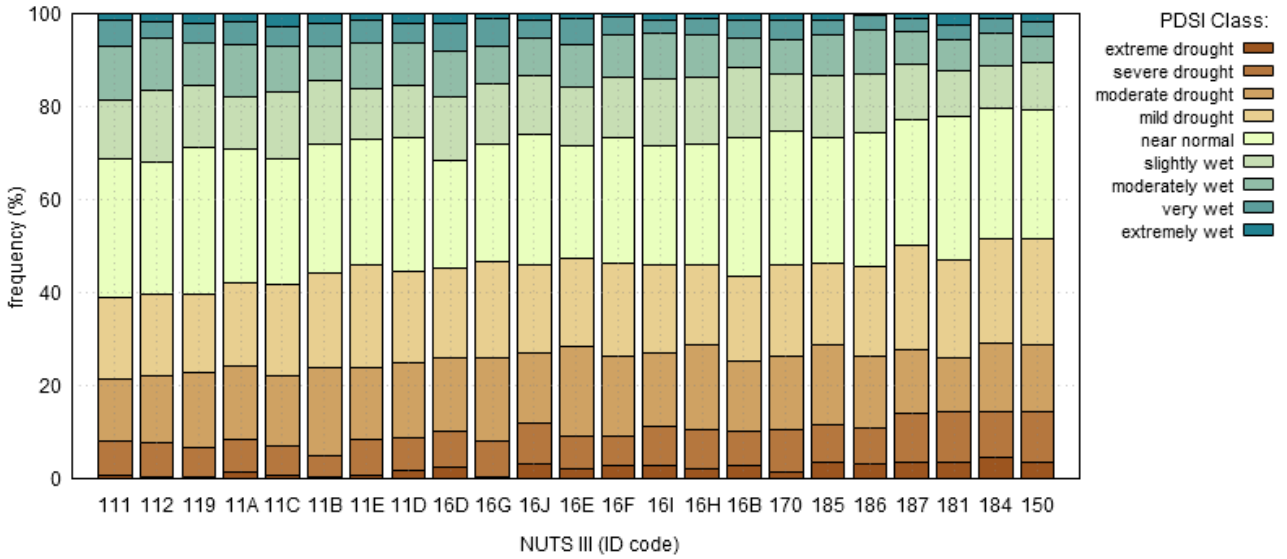

Figure 2 - Frequency of monthly PDSI classes (%) per NUT III in the period 1981-2019 for Portugal.

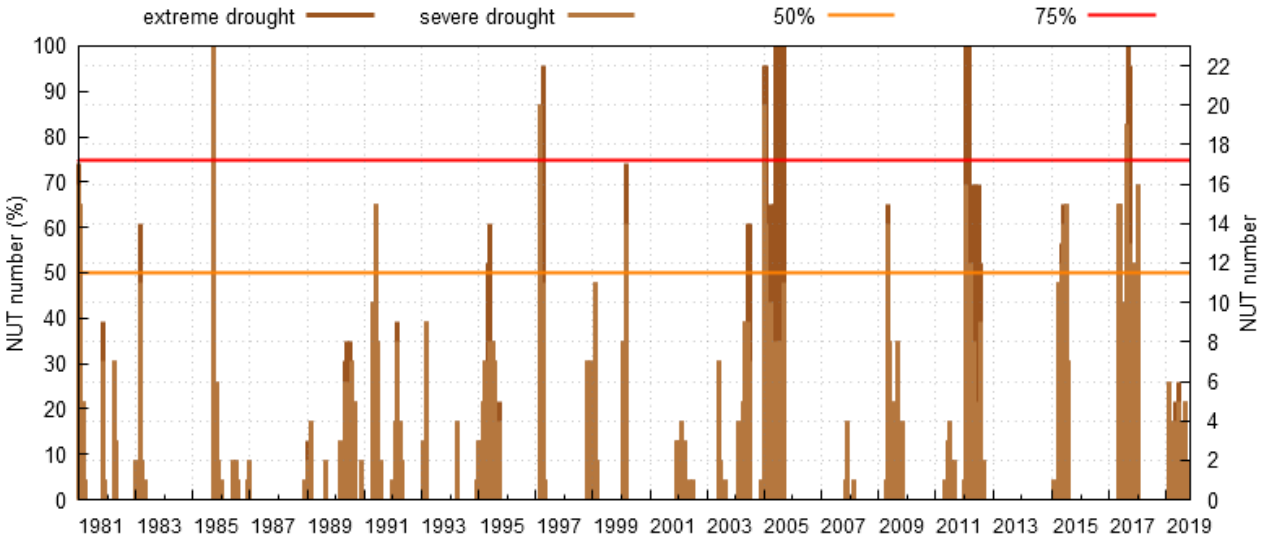

Figure 3 - Number of NUT III (%) in the 2 higher classes of PDSI index (severe and extreme) in the period 1981-2019 for Portugal.

3. Drought on NUT III basis

A second step aimed to understand how each NUT III is linked to its neighbours in relation to drought, through the use of correlation and clustering methods. Regarding correlation, simple correlation matrixes were used for a preliminary inspection of the data (see the example for PDSI considering all months of the year in Table 2).

Table 2 - Correlation matrix for PDSI in NUT III, considering all months within the year, from 1981 to 2019.

150	0,460	0,438	0,402	0,423	0,392	0,472	0,576	0,529	0,462	0,568	0,643	0,543	0,618	0,691	0,712	0,738	0,766	0,761	0,773	0,852	0,895	0,925	1,000

In what concerns clustering, two complementary approaches were taken. On one side, a sensibility analysis based on the R tool NbClust (Ghazzali 2014) was performed to find the best number of NUT III clusters according to drought. Most of the aggregation methods indicated 2 or 3 NUT III clusters to be the ideal number of clusters for Portugal, also with a high number of methods to indicate 8 NUT III clusters as ideal (see the example for PDSI considering all months of the year in Table 3).

Table 3 - Number of indexes (per aggregation method and for all methods – last column) that indicate the best number of NUT III clusters, using the R Tool NBClust, for PDSI considering all months.

Number of Clusters	Aggregation Method									All methods
	Ward.D	Ward.D2	Single	Complete	Average	McQuitty	Median	Centroid	Kmeans	
2	6	**11**	**12**	**10**	7	6	8	11	**13**	84
3	**11**	6	8	4	**8**	**11**	2	3	8	61
4	1	1	2	3	2	4	2	**12**	0	27
5	1	1	0	0	1	3	2	0	1	9
6	1	1	0	0	3	0	**12**	0	2	19
7	0	2	2	2	0	0	0	0	0	6
8	4	3	4	6	2	4	1	1	4	29

On the other side, final clustering results were obtained for K-Means (with 3 different initial cluster centers settings, named A (choose observations to maximize initial between-cluster distances), B (sort distances and take observations at constant intervals) and C (choose the first N (number of clusters) observations) and tree clustering methods (Ward's method for 2 metric distances, Euclidean and Pearson r) in STATISTICA software (TIBCO 2022). The example for PDSI considering all months of the year is shown in Figure 4. Four solutions were considered for addressing season sensibility: i) all months of the year; ii) summer months; iii) spring months; iv) non-winter months.

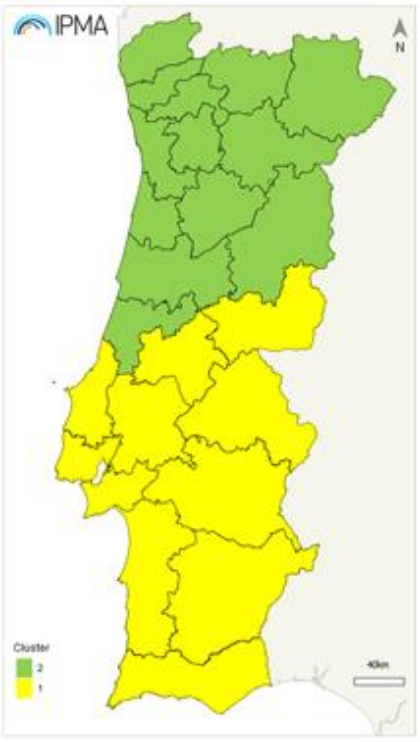

Figure 4 – NUT III aggregation in 2 clusters considering monthly values for 3 considered drought indexes PDSI, SPI3 and SPI6 for all months of the year between January 1981 and December 2019, using 3 different settings for K-Means and 2 metric distances, Euclidean and Pearson r for Ward's method.

4. Preliminary Results for Drought

The results suggest that the longer the period considered throughout the year (inherent to the drought index itself or the number of months considered for drought analysis), the greater the tendency for the drought behaviour to be dominated by the Montejunto-Estrela mountain system. For shorter periods within the year, a finer clustering should be the most appropriate.

Thus, for all months of the year or for the non-winter period (March to November) the drought presents a differentiated behaviour for two main sets of NUTS III (see Figure 4):

- Oeste, Lezíria do Tejo, Médio Tejo, Beira Baixa and other NUT III to the south;
- Região de Coimbra, Região de Leiria, Beiras e Serra da Estrela and remaining NUT III to the north.

In a finer aggregation as a function of drought, the sets of NUT III that show the same behaviour for the meteorological drought are identified below for each of the 4 periods of the year (see Figure 5):

Every month of the year:
- Terras de Trás-os-Montes + Douro;
- Região de Coimbra + Região de Leiria.

Summer:
- Terras de Trás-os-Montes + Douro;
- Região de Coimbra + Região de Leiria;
- Oeste + Lezíria do Tejo.

Spring:
- Terras de Trás-os-Montes + Douro;
- Alto Minho + Cávado;
- Oeste + Lezíria do Tejo.

Non-winter:
- Viseu Dão Lafões + Beiras e Serra da Estrela;
- Região de Coimbra + Região de Leiria;
- Beira Baixa + Alto Alentejo;
- Oeste + Lezíria do Tejo.

In summary, it can be considered that there are 3 sets of NUT III presenting the same behaviour in terms of drought, almost regardless of the period of the year considered:

- **Terras de Trás-os-Montes and Douro**, which just do not belong to the same set in the non-winter period;
- **Região de Coimbra and Região de Leiria**, which do not belong to the same set in the spring period;
- **Oeste and Lezíria do Tejo**, which just do not belong to the same set considering all the months of the year.

There are also other NUT III with drought similarities, but to which this analysis does not allow to attribute the same level of confidence, since there was one combination of drought index (PDSI, SPI3 or SPI6) and a clustering solution (in these cases the solutions "K-Means B", "K-Means C" or "Ward - Pearson") in which aggregation was not verified. In this situation, for 3 of the 4 periods of the year considered, the following sets of NUT III are identified:

Every month of the year:

- Alto Minho and Cávado;
- Viseu Dão Lafões and Beiras e Serra da Estrela;
- Beira Baixa and Alto Alentejo;
- Oeste and Lezíria do Tejo.

Spring:

- Alto Minho, Cávado and Ave;
- Alentejo Litoral and Baixo Alentejo.

Summer:

- Oeste, Área Metropolitana de Lisboa and Lezíria do Tejo.

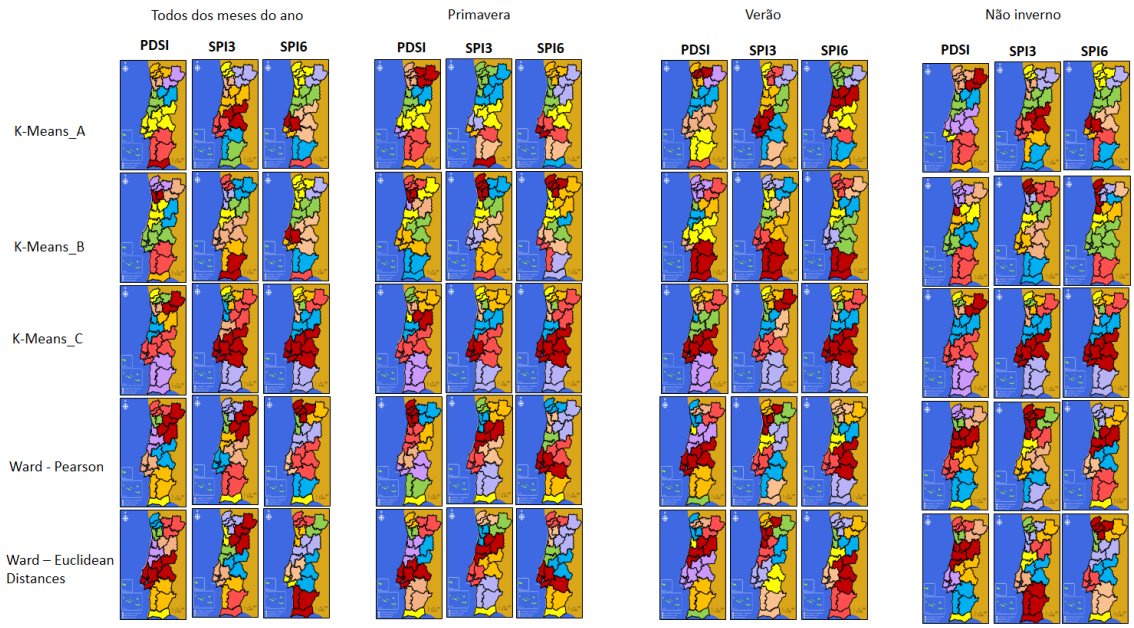

Figure 5 - Spatial aggregation of NUT III into 8 clusters for drought behavior between January 1981 and December 2019 as a function of; i) drought index (PDSI, SPI3 and SPI6); (ii) the time of year (All months of the year, spring, summer and non-winter) and iii) clustering solutions ("K-Means A", "K-Means B", "K-Means C", "Ward – Pearson", "Ward – Euclidean").

5. Forest fires distribution in NUT III

The third step was towards understanding NUT III spatial distribution of fire occurrences number and burned areas, considering both all months of the year (January to December) and forest fire seasons (June to October) for 39 years (1980 to 2018). The results obtained for 8 clusters by applying a tree clustering analysis - Ward's method with Pearson's metric distance r - are shown in the maps in Figure 6. It should be noted that the same results are obtained whether original or normalized data (division by the area of each NUT III) are used.

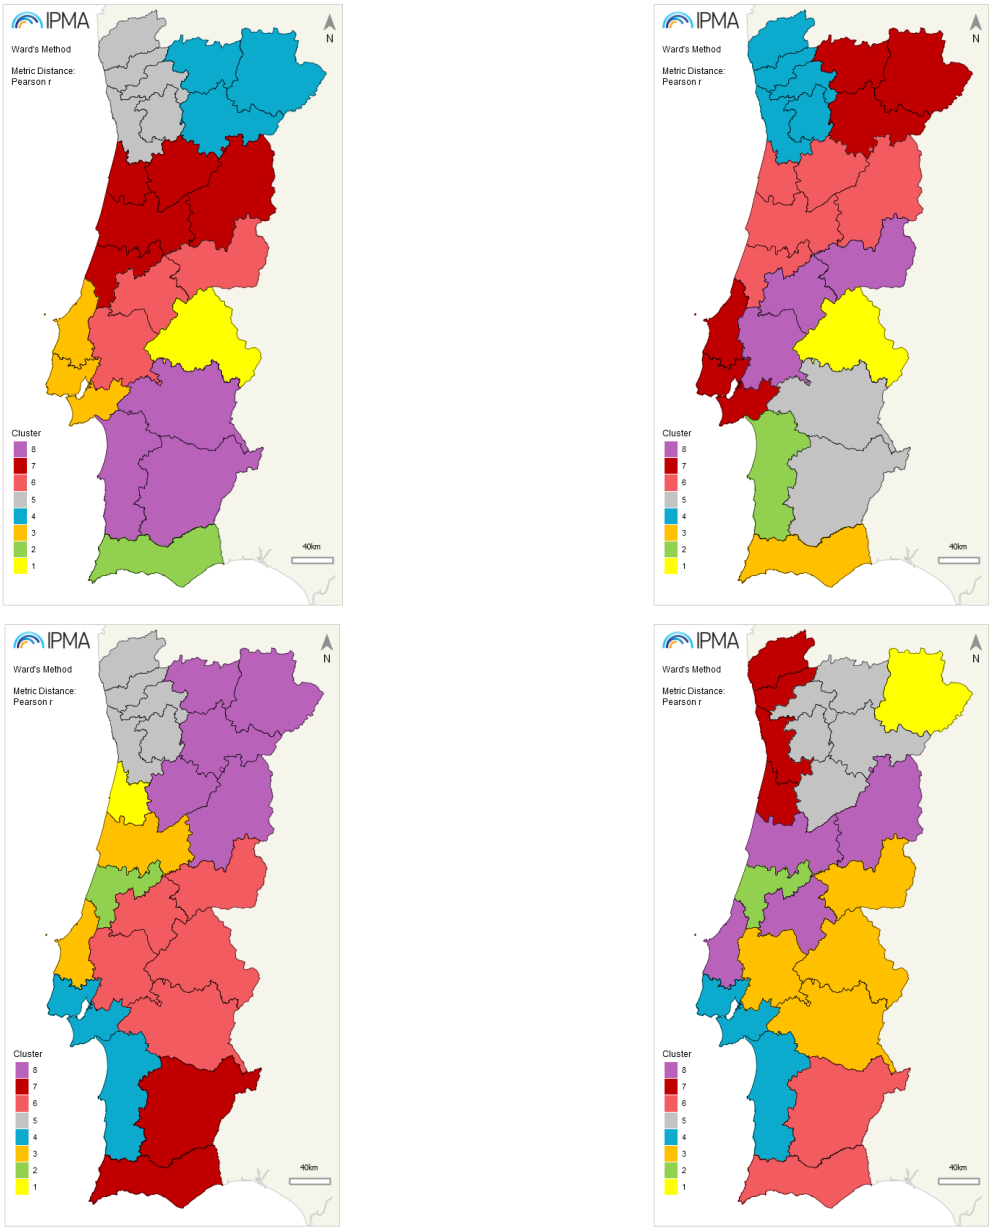

Figure 6 – NUT III aggregation in 8 clusters considering monthly values of fire occurrences (top) and burned areas (bottom) considering all months of the year (in the left) and the fire season months between June and October (in the right), applying a tree clusters analysis with Ward's method using the metric distance of Pearson r. Data from 1980 to 2018.

6. Preliminary Results for Forest Fires

Analysing Figure 6, it can be seen that for the case of forest fire occurrences there is a more homogeneous grouping in terms of NUT III spatial proximity considering both all months of the year and fire season months. The only differences between all months of the year (at the top on the left) and fire season months (at the top on the right) lies in the fact that, in the fire season months the Oeste and Área Metropolitana de Lisboa are in the same cluster as Alto Tâmega, Terra de Trás-os-Montes and Douro, and that there is an individualization of Alentejo Litoral in a single cluster, no longer belonging to Alentejo Central and Baixo Alentejo cluster (as for all months of the year).

The map for burned areas (bottom maps in Figure 6) shows a more homogeneous grouping of NUT III regions in the north and interior of the country, while for the coastal part of the country this is not the case. Anyway, it seems that grouping follows north-south guidance.

Comparing the maps in Figure 6 of the fire occurrences (at the top) with those of the burned areas (at the bottom), it can be seen that in the case of the burned areas there is less spatial consistency distribution of clusters. This suggests that there may be additional factors besides the regional proximity (on NUT III basis) that have to be considered to better understand the regional distribution of burned areas in Portugal.

Fire Danger Rating System, Fire Behaviour, AFDRS, Decision Making, Community Messaging

Abstract

The Australian Fire Danger Rating System (AFDRS) was launched on 1 September 2022, bringing a generational change to the way that Australia calculates and communicates fire danger. Its focus is improved public safety and reduced impacts of bushfires through:

- Improving the science behind fire danger predictions.
- Improving the way that fire danger is communicated.
- Providing government and industry with better decision-making tools.
- Reducing future costs associated with bushfire impacts.

The previous fire danger rating system was introduced in the 1960's by Australia's first full-time bushfire researcher, Alan McArthur, based on extensive experimental fires. While useful, the system included only two fire behaviour models (dry sclerophyll forest and grassland), was not easily updateable and fires were being experienced that increasingly exceeded its design parameters.

In July 2014, Senior Officers and Ministers agreed that the development of a new system was a national priority. The new system was developed by the New South Wales Rural Fire Service in collaboration with the Bureau of Meteorology, all Australian states and territories and the Commonwealth government. Program management and system implementation were coordinated by AFAC (Australia's National Council for Fire and Emergency Services).

The new AFDRS uses contemporary fire behaviour science, makes better use of available data and uses software infrastructure that can be continuously improved. The AFDRS starts with eight fire behaviour models representing a range of Australian vegetation types, it captures current fuel information, uses satellite data, integrates weather from the Bureau of Meteorology and calculates fire danger down to a 1.5km by 1.5-kilometer grid. These calculations are linked to tools that assist fire operational decision-making via a Fire Behaviour Index that is calibrated to operational implications for fire management.

A separate arm of the project developed a public-facing Fire Danger Rating framework, guided by one of Australia's largest social research projects. The research found that, while fire danger signage was well recognised, few acted on fire danger ratings to plan their activities. Focus groups and subsequent surveys found that the community preferred a simplified public-facing system where each fire danger rating had a distinct call to action.

The implementation of the new system required an enormous effort from all levels of government across all States and Territories as well as the Commonwealth. It required updates to legislation, policy, procedures, web pages and other IT infrastructure, as well as replacement of physical signage. However, as a result, Australia has a significantly new way of calculating and communicating fire danger, that is continuously improvable and which will bring benefits for decades to come.

1. Introduction

The 2009 Black Saturday fires that devastated the state of Victoria was a watershed moment for Australian bushfire management. It was Australia's highest-ever loss of life from bushfires and many people were left homeless (Parliament of Victoria, 2010). With at least 18 major bushfire inquiries in Australia since 1939, the

Black Saturday fires were by no means the only devastating fires (Parliament of Australia, 2022), nor were they the largest or most recent. The unprecedented fires of the 2019-2020 Black Summer saw over 24 million hectares burnt, 3000 homes destroyed, 33 lives lost, species populations devastated and accrued an estimated financial impact of $10 billion (Commonwealth of Australia, 2020).

But it was the Black Saturday fires of 2009 that galvanised contemporary efforts to improve bushfire management systems in Australia, including the first efforts to review Australia's aging fire danger rating system (Figure 1).

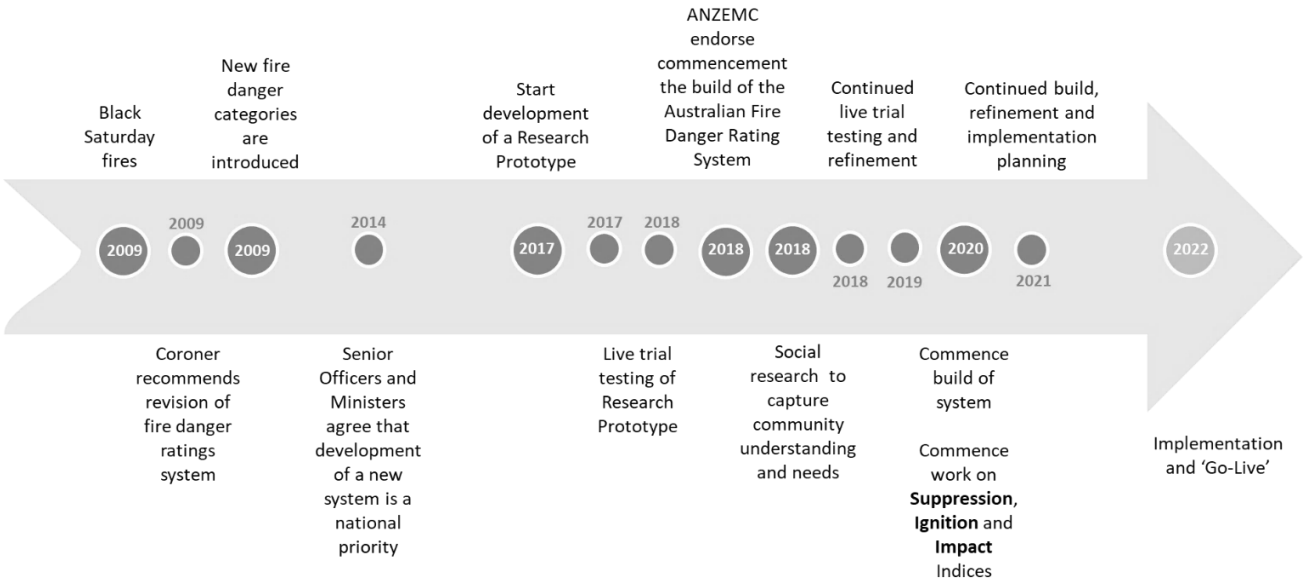

Figure 1- History of the development of the AFDRS

2. Fire Danger Ratings in Australia

Fire danger is a general term representing many factors culminating in a fire environment including ignition potential, fire hazard, risk, rate of spread, difficulty of control, fire impacts and safety. Fire danger rating is a valuable tool in communicating bushfire risk to the community, not only by increasing public awareness but also as a trigger for notification of potential threats. Importantly, because of its foundation in fire weather and behaviour, fire danger rating also provides a tool for decision-making in fire suppression operations and prescribed burning (Matthews *et al.*, 2018).

2.1. The McArthur System

Alan McArthur was the first full-time bushfire scientist in Australia, when he gained a job in 1953 working for the then Commonwealth Forest and Timber Bureau. He was tasked with developing a national fire danger rating system to suit Australian conditions. Alan and his team conducted more than 400 experimental fires that provided data to support fire behaviour models for dry sclerophyll forests, and later, for grassland. This work, together with data from high intensity bushfires, led to McArthur introducing two indices, The Forest Fire Danger Index (FFDI) and the Grassland Fire Danger Index (GFDI). These were aligned to fire danger ratings based on fire suppression difficulty (Cruz et el. 2015).

2.2. Attempts to modify the system

Although the McArthur system served Australia well for many decades, the Black Saturday Fires of 2009 underscored its various weaknesses. The 2009 Victorian Bushfires Royal Commission (Parliament of Victoria, 2010) made several recommendations that led to attempts to modify the system, including a review of the number of fire danger rating categories to provide more definition at higher danger levels, and the additional of a 'catastrophic' ('Code Red' in Victoria) category to capture fires that were increasingly being experienced beyond McArthur's original design parameters (Figure 2).

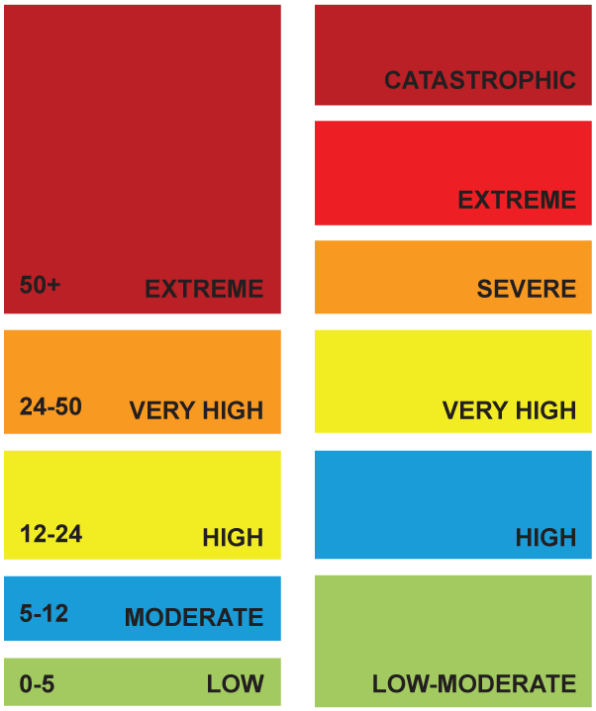

Figure 2- Changes to forest fire danger ratings after 2009

Later, there were also changes made to the ratings for grasslands, causing the GFDI and FFDI to no longer be aligned in terms of the ratings they represent.

2.3. The need for a contemporary system

Decades of research had been carried out since the McArthur system was introduced in the 1960's with countless field-studies leading to new fire behaviour models and a refined understanding of how fire behaves in a variety of fuel types. There had also been research into the impacts of bushfires, and an improved knowledge among practitioners about the implications of fires for prescribed burning, fire suppression and impacts. There had been numerous advances in weather forecasting and an improved understanding about how fire and the atmosphere interact. The quality of fuel data, satellite data and computational software and hardware had also improved (Cube, 2014).

The pressure was mounting on the McArthur system with its various design limitations highlighted (Cube, 2014):

- The design of the McArthur system did not allow for its components to be updated.
- The two fire behaviour models (one for grassland and one for dry sclerophyll forests) were not representative of Australian vegetation types and only accounted for about a third of the continent.
- Fires were being regularly experienced beyond its design considerations.
- It could not account for improved weather inputs from the Bureau of Meteorology.
- It could not account for the decades of improved fire behaviour research.
- It could not account for research into impacts of fire on assets and human lives.
- Decision-makers were forced to rely on a system with well understood flaws.
- The ratings and signage were not consistent from jurisdiction to jurisdiction.
- The system had become confusing for members of the public and did not inspire appropriate action to reduce risk.

The changes made after the 2009 fires only served to highlight the need for a new approach (Cube, 2014). In July 2014, Senior Officers and Ministers agreed that the development of a new National Fire Danger Rating System, based on new computational models, was a national priority (Matthews *et al.*, 2018).

3. The Australia Fire Danger Rating System (AFDRS)

In 2015 a roadmap was identified for the development and implementation of a new system. A national Program Board with jurisdictional and national representation was established in late 2016 to oversee development and implementation.

A key part of the development of the AFDRS was a collaborative approach involving all states and territories and the Commonwealth government. This was a considerable undertaking requiring the attention and commitment of the emergency services industry through the substantial challenges of the Black Summer fires of 2019-2020, the subsequent state and federal inquiries, various flooding events and the ravishes of the covid-19 pandemic.

Fortunately, Australia has a well-established National Council for Fire and Emergency Services (AFAC) with existing cooperative arrangements that proved useful to coordinate the program to develop and implement the AFDRS. Also, the New South Wales Rural Fire Service was well placed to take on the task of leading the science build, with help of the Bureau of Meteorology who built the fire danger calculation engine. Simultaneously, the South Australian Country Fire Service took on the task of leading one of the largest social research projects in Australia, to better understand the community's needs in relation to fire danger ratings.

3.1. The Fire Behaviour Models

Fire behaviour models in Australia are fuel specific, unlike the more unifying approach taken in the US. As fires spread and behave differently in different fuels, specific models have been built for major fuel types; e.g. grasslands, forests and shrublands (Cruz et al., 2015).

The AFDRS makes use of the best fire spread models that are available and ready for application. Table 1 provides an overview of the fire behaviour models used as guided through consultation with experts and by *A Guide to Rate of Fire Spread Models for Australian Vegetation* (Cruz *et el*., 2015).

Table 1 Fire behaviour models used for the AFDRS

Fire behaviour model	Short name	Reference	Fuel type
CSIRO Grassland fire spread meter	Grassland	Cheney et al. (1998) and Cruz et al. (2015b)	Continuous grasslands
CSIRO Grassland for northern Australia	Savanna	Cheney et al. (1998) and Cruz et al. (2015b)	Grassy woodlands and open forests
Desert spinifex model	Spinifex	Burrows et al. (2018)	Hummock grasslands
Buttongrass moorlands model	Buttongrass	Marsden-Smedley and Catchpole (1995b)	Buttongrass moorlands
Dry Eucalypt Forest Fire Model (DEFFM or "Vesta")	Vesta	Cheney et al. (2012)	Shrubby dry eucalypt forests
Mallee heath model	Mallee heath	Cruz et al. (2013)	Semi-arid mallee heath
Heathland model	Shrubland	Anderson et al. (2015)	Temperate shrublands
Adjusted Pine model	Pine	Cruz (pers. comm.)	Pine plantations

3.2. The Fuel Types

A national fuel type layer (Figure 3) consisting of a 1.5 kilometer spatial grid, was developed based on available national, state and territory vegetation mapping. Considerable knowledge and effort was applied to convert vegetation mapping into a fuel type classification useful for application within the AFDRS (Matthews, 2022).

Classification of fuel types was led by the practical need to select an appropriate fire behaviour model, and to capture the range of variation in the fuel parameters that feed the inputs to the models. Fuel types that don't have a specific fire behaviour model (e.g. rainforests, arid shrublands, wetlands, rural and urban areas) have been allocated to the model with the most similar fuel structure (as per Cruz, 2015).

There are often factors limiting the flammability, fuel availability or fuel connectivity in these fuel types. So various modifications to fire behaviour models were made to account for these variations, such as a drying factor or a wind reduction factor. This allowed for calculations of fire danger to be applied across 23 fuel types, allowing more precise results (Matthews, 2022).

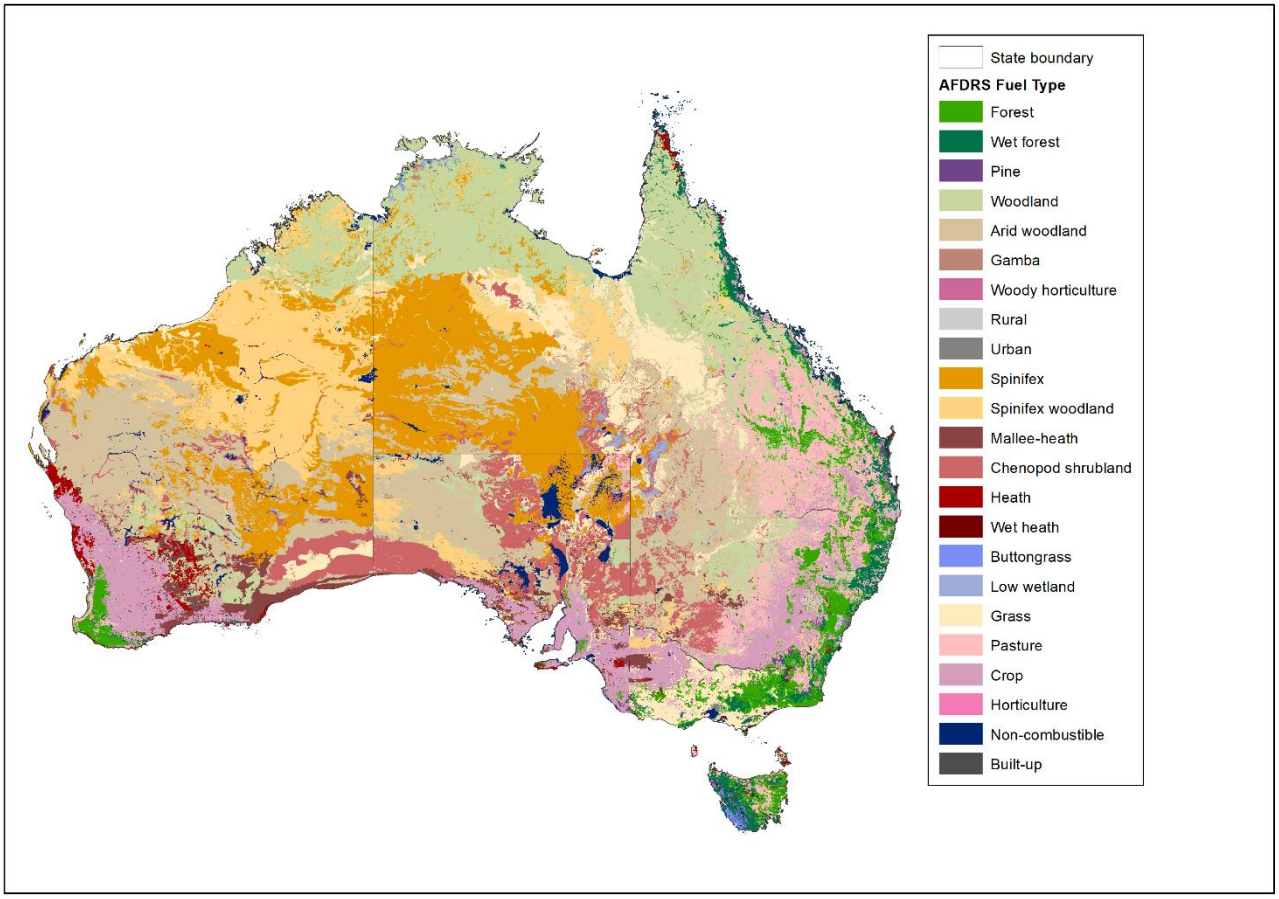

Figure 3 - Map of AFDRS fuel types across Australia

3.3. The Fire Behaviour Index

The Fire Behaviour Index (FBI) is expressed in whole numbers from 0 to 100+. It represents the severity of a fire should one occur under the forecast conditions. The FBI is divided into step-up categories controlled by table definitions (Figure 4 is an example) that represent contemporary understandings of how the underlying fire behaviour transitions create implications for prescribed burning, fire suppression and life and property loss. A step-up in FBI category is triggered by a change in (Matthews, 2022):

- Indicative fire behaviour and fire weather
- Implications for prescribed burning and fire spread
- Implications for suppression and containment
- Implications for potential impacts to life and property.

This, together with various guides produced as part of the FBI, ensures its usefulness as a decision-making tool for operational fire management.

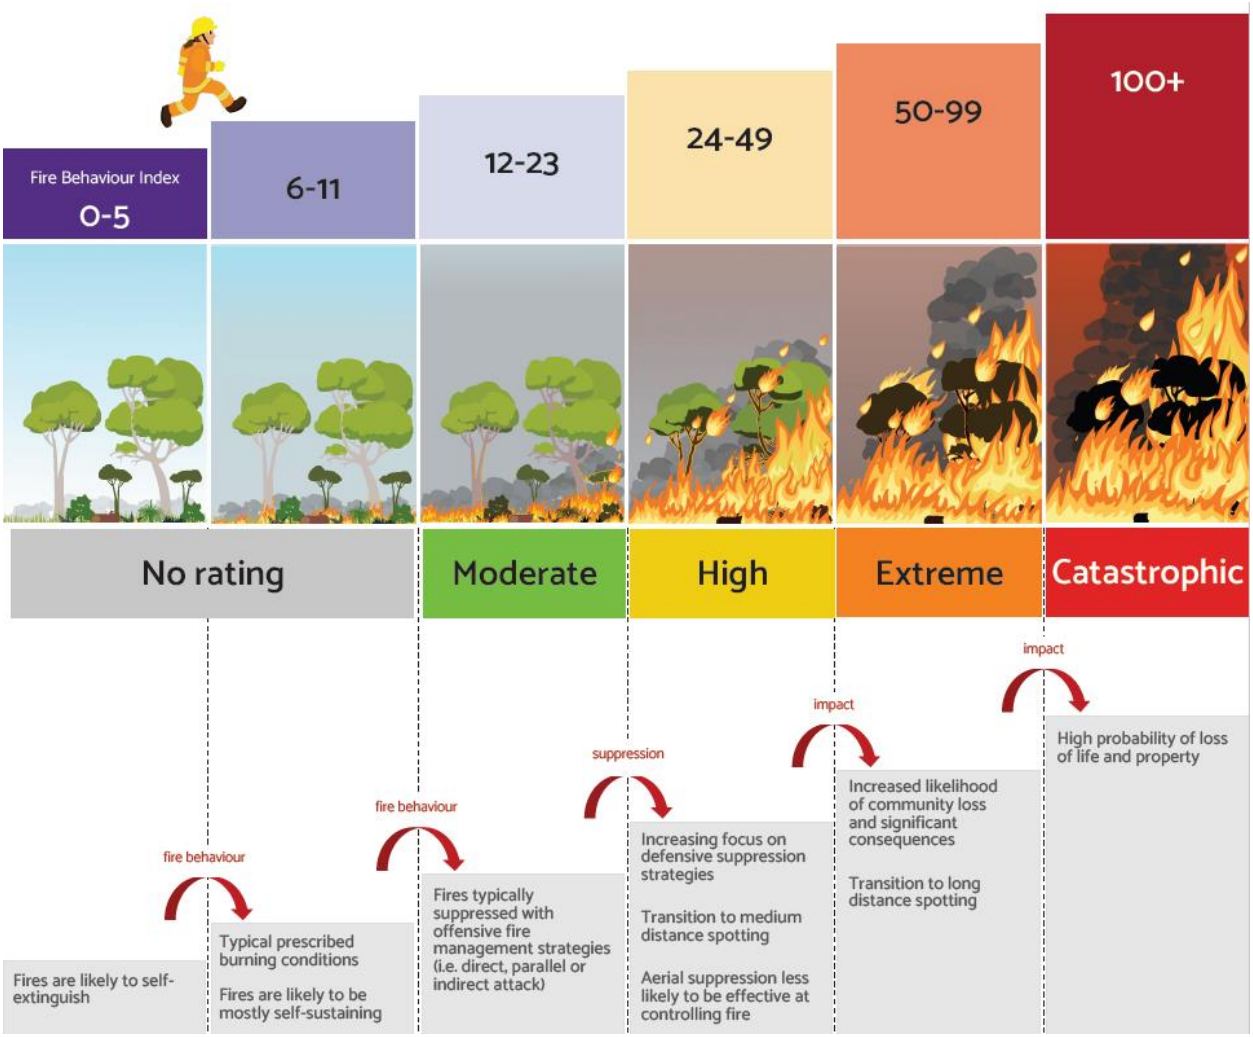

Figure 4 The Fire Behaviour Index for Forest Fuels, broken into steps that are relevant to fire operations

3.4. The Fire Danger Ratings

By contrast, the AFDRS Fire Danger Ratings are purpose built for ease of communication and comprehension for members of the community, so that members of the community are forewarned about fire danger conditions and can take appropriate action to reduce their risk exposure.

The social research conducted on the previous McArthur-based system was influential in the design of the new Fire Danger Ratings. The initial survey was the third largest ever conducted in Australia with 5,430 participants. The key outcomes were (Metrix, 2019):

- Most recognise the Fire Danger Rating system, but many didn't understand it. It was found that 93% had prompted awareness of the system but most thought it predicts how likely a fire is to occur, rather than predicting how dangerous a fire could be if one did occur.
- There is confusion over what action to take when, and it was found that few people would take action below the 'Severe' rating (refer to Figure 2 for the McArthur-based ratings post 2009).
- It was found that while the signage is recognised, most people do not use the system to plan activities and the majority have never taken action relating to fire danger ratings.

Focus groups were conducted with a broad range of communities. Locations encompassed metropolitan and rural areas as well as a variety of low, medium and high-risk bushfire areas (Metrix, 2019): It was found:

- Participants felt that each fire danger rating should be associated with a unique and distinct action-orientated message.

- Participants strongly preferred a three or four-level rating system, with more levels than this seen as confusing and counterproductive.
- Most favoured a four-stage semicircle design with intuitive names and colours.
- A green, yellow, orange and red colour set was preferred.

The finalised public-facing fire danger rating system framework is shown below:

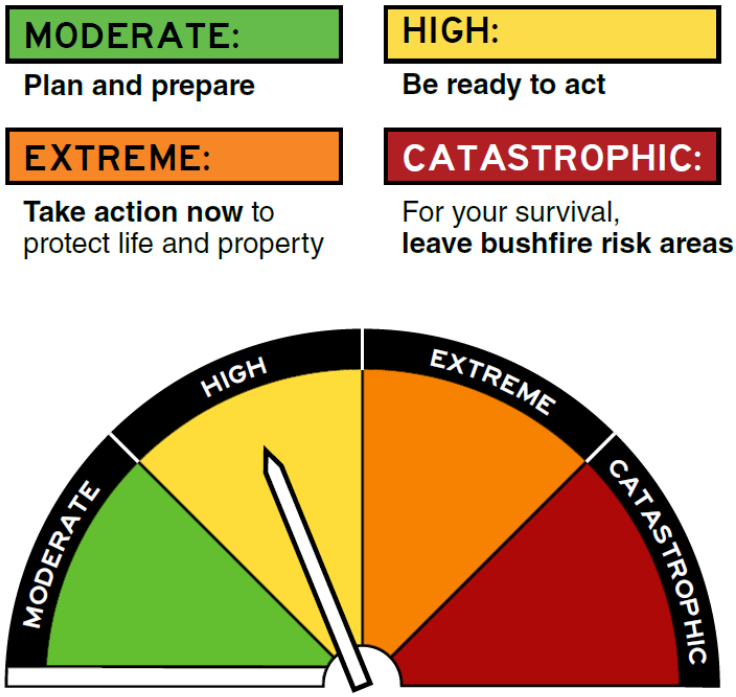

Figure 5 The AFDRS Fire Danger Ratings

The four action-orientated messages are related to underlying transitions in fire behaviour requiring different kinds of actions from members of the community. The fire danger ratings are therefore derived from thresholds in the FBI that encapsulate these transitions. This relationship was shown in Figure 4.

Climate change, fire regime, biodiversity, risk analysis, functional types

Abstract

Fire regimes are changing around the world raising important questions about the risks to biodiversity. Fire seasons are lengthening, high-severity fires are occurring more often and in unexpected places. Extensive research examines some of the fire related risks to life and property. However, in the fire risk research space there is often limited or simplified inclusion of ecological values. Future fire regimes, alongside climatic change, could have profound impacts on biodiversity conservation and ecosystem function. For example, plant population trajectories can be influenced by demographic traits, disturbance regimes and environmental variables such as climate. Climate change can affect all three and is likely to impact on plant populations through altering natural fire regimes as well as influencing species demographic traits. These changes are unlikely to be unidirectional with some plant types benefiting and others being disadvantaged. Here, we examine the impacts of climate change both on the shifts in fire regimes alone and combined with predicted climate-induced demographic shifts. We use two functional plant types (obligate seeder, facultative resprouter) in a number of case-study areas representing woodland-dominated landscapes of south-eastern Australia. We link a fire regime simulation tool with a spatially explicit population viability analysis model. We simulate fire regimes under six different future climates representing different temperature and precipitation shifts, and 16 demographic change scenarios, characterised by changes to individual or multiple plant demographic processes. Obligate seeder species were predicted to be less resilient to changes in demographic parameters. However, both resprouter and seeder species were found to be negatively affected by the combined impacts of changes to multiple demographic parameters or to a combination of a shifting fire regime and changes to demographic traits, particularly through simulated reductions in adult survival. To our knowledge this is the first study to integrate fire regime simulations with spatially explicit population viability analyses. Such an approach significantly increases our ability to identify which functional types are most at risk of population extinction under predicted fire regime and demographic changes. This flexible framework is an important first step in exploring the complex interactions that determine plant viability under a changing climate and will increase our ability to prioritise research and fire management for biodiversity into the future.

1. Introduction

Fire is instrumental in shaping plant community composition (Pausas & Ribeiro, 2017). Many plants are adapted to components of the fire regime (e.g., fire severity, inter-fire interval), through fire-adapted traits, which typically offer two main strategies in the face of fire, survive fire or regenerate following fire (Enright & Goldblum, 1999). Species that rely on one strategy are termed obligate (e.g., an obligate seeder can only regenerate through seeds), and those that are more flexible in their regeneration strategy are termed facultative (e.g., a facultative resprouter can both resprout and produce seeds, Clarke et al., 2015). Resprouting species can survive fire by producing new shoots from meristematic tissues, either above ground from buds on the trunk and branches (epicormic resprouter) or from basal tissues when above-ground tissues are killed or damaged (basal resprouter, Pausas & Keeley, 2014). Groups of species that share fire-adapted traits are often grouped into functional types, which typically describe key processes that contribute to species dynamics (Noble & Slatyer, 1980, Pausas, 1999). Responses of plant populations to fire are thus often described in terms of functional types and associated traits, including whether seeds are stored in the canopy or soil, and whether seed germination is fire cued or can occur without fire (Noble & Slatyer, 1980, Pausas et al., 2004, Pausas & Keeley, 2014).

The interactive effects of a potentially warmer drier climate alongside changes to the fire regime have the potential to increase the extinction risk of plant species through demographic changes (Enright et al., 2015). Plant demographic rates can also vary across climate gradients, with vital rates generally decreasing under warmer conditions (Bowman et al., 2014), and therefore may change as the climate changes. Many demographic traits are directly related to a plant species' fire response. For example, fire-responsive species could be at increased risk of localised extinction if future warmer drier climates decrease growth rates and associated time to maturity (Bowman et al., 2014, Enright et al., 2014, Jump et al., 2006) or decrease seed production and post-fire recruitment (Miller et al., 2019). If fire frequency were to increase alongside demographic changes, the window for population self-replacement may be reduced due to the interacting effects of climate and fire, a phenomenon termed "interval squeeze" (Enright et al., 2015). Improved understanding of the interactions among plant demographic traits, fire regimes, and climate is critical to identifying those species at most risk in fire-prone vegetation communities.

Effective conservation management of any system needs to be based on sound predictions of ecological futures. However, as we move towards the potential for new interactions without historical analogues, we cannot solely rely on past empirical data. As our climate changes and fire regimes change alongside, we need to be able to untangle how variation in plant traits influence the viability of populations. Simulation modelling provides the opportunity to expand the utility of existing empirical data to examine plant population viabilities under various combinations of traits, fires, and climates. In Australia, the empirical, demographic data around fire responsive plant species is substantive, albeit patchy. Initiatives such as Austraits, a database of plants traits from Australian flora (Falster et al., 2021) provide a means for the collation of these into the future. Previous research of fire responsive plant species in Australia has mostly focused on single species where the demographic data are often collected over many years (e.g. Auld, 1986, Ooi et al., 2004, Swab et al., 2012). These investigations are invaluable. However, detailed demographic data for many species of interest are lacking across environmental gradients. Collecting such data and attempting to measure and interpret the relationships among fire, climate, and plant populations would be infeasible for all at-risk vegetation communities.

In this study, we develop a framework for simulating ecological futures, combining a landscape fire regime model with plant demographic data in the form of a spatially explicit population viability analysis. We use this framework to examine how a changing climate might affect demographic processes and fire regimes to influence plant population trajectories.

2. Model framework

Our modelling framework involved six steps:

1. Select study area and species;
2. Create fire raster layers based on six representative climate models;
3. Construct population transition matrices for fire and non-fire years based on demographic change scenarios;
4. Create habitat suitability layers for each selected species;
5. Build population trajectory models for 100-year simulations for each combination of fire regime and demographic change scenario; and
6. Compare outputs across scenarios, functional types, and study areas (Figure 1).

The two simulation programs used in the framework are FROST (Penman et al., 2015) and STEPS (Visintin et al., 2020). FROST (Fire Regimes and Operations Simulation Tool) simulates fire regimes over decades to centuries using a combination of fire event simulation tools (PHOENIX RapidFire: Tolhurst et al., 2008) and Bayesian networks to represent uncertainty. FROST is spatially explicit and produces fire data (cells burnt, intensity, frequency) at a 180 m resolution for each year of a simulation. STEPS (Spatially and Temporally Explicit Population Simulations) is a spatially explicit population dynamics R package (Visintin et al., 2020). It models species populations as a function of species ecological and physiological requirements, and disturbance and landscape dynamics. Spatially explicit FROST outputs of fire occurrence and severity are fed into STEPS to, for example, trigger a germination or resprouting event for a plant species or to trigger mortality within the simulation cell.

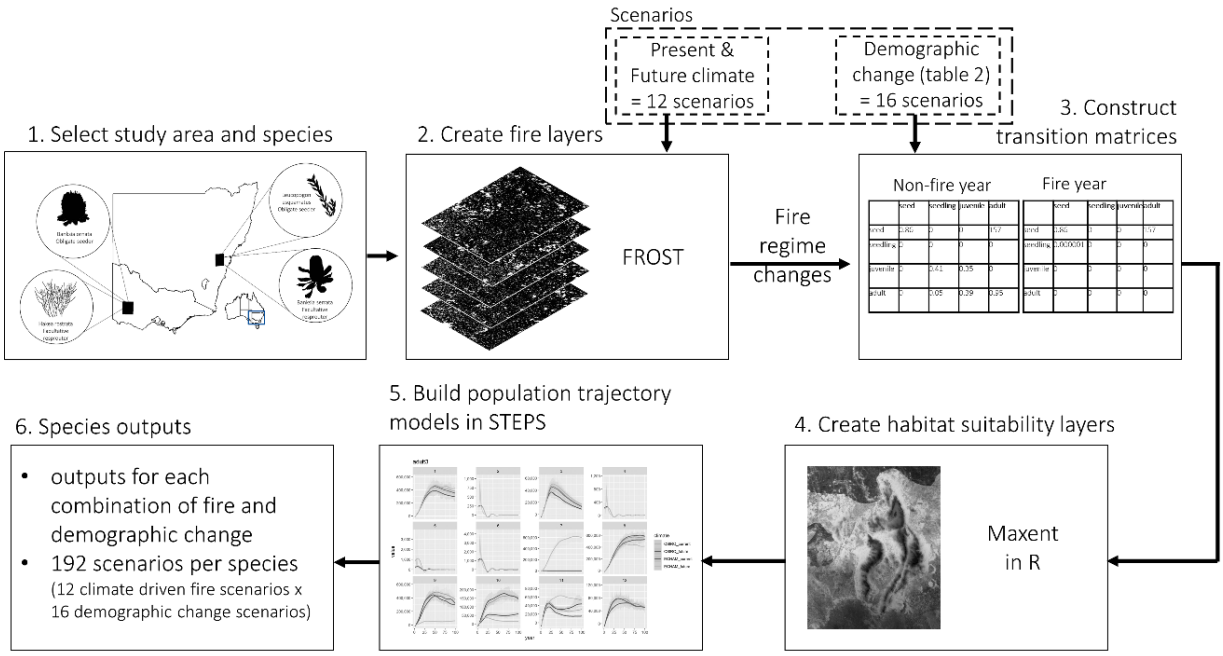

Figure 1 Modelling framework. Step 1: select the study area and species. Step 2: Create fire raster layers using FROST under six predictions of present climate and six predictions of future climate scenarios. Step 3: collate empirical data and expert advice to create population transition matrices for non-fire years and fire years for each species under 16 demographic change scenarios. The transition matrices are used to parametrise the population models with the PVAs. Step 4. Create habitat suitability layers using presence only data with the dismo package in R. Step 5: Build population trajectory models in the STEPS package in R for each combination of fire regime and demographic change scenario. Step 6. Examine species outputs under each combination of fire and demographic change scenario.

3. Implications

Demographic changes on plant population viability far outweighed impacts from a changing fire regime in our simulations. In general, obligate seeder species were predicted to be less resilient to changes in demographic parameters than facultative resprouter species. This introduces considerable challenges for management looking to improve ecological outcomes. The focus needs to shift towards management activities that relate directly to improving demographic outcomes such as protection of adult plants and ensuring adequate seed supply for active restoration. Due to the large number of interconnected mechanisms driving plant viability, there are still significant knowledge gaps that will require research to improve our understanding of how plant communities will respond to fire and demographic shifts.

4. Conclusion

The effects of future climate on biodiversity will be complex. Our study predicts changes in plant population trajectories due to climate effects on demography or climate effects on changing fire regimes and demography. The simulation results suggest we need to understand demography across climate gradients in order to prioritise species conservation. Therefore, field research that gathers demographic data is vital for protecting future ecosystems. Our PVA-fire regime simulation framework can address questions around management intervention through prescribed burning and fire suppression, and identify which demographic shifts an ecosystem may be most sensitive to. However, the importance of demographic shifts in our study emphasises the need for conservation managers to actively understand and appropriately manage at risk ecosystems to improve or promote resilience to future changes in climate.

vulnerability, natural capital, social and human capital, socio-economic damage, ecosystem services, impact mitigation and assessment

Abstract

A capitals approach deals with humans' activities and impacts on the environment and their dependencies on stocks of natural, human, social and produced capital to inform decision-making. Traditional assessments focus on one capital at a time such as natural or human capital. Conversely, a multi-capital assessment involves the analysis of more than one relevant capital and presents the results for each capital together. This paper wants to get a step further presenting preliminary findings on developing an Integrated Capitals Approach (ICA) to wildfire vulnerability considering in a holistic way the impacts on natural assets (ecological and economic values), damages on human capital (e.g., health), and the interactions between wildfires and social capital. Although some studies have recently introduced the effect of adaptation to fire, expressed mainly as the institutional capacity of improving fuel management and firefighting, the effect of social bonding and networking on training, capacity building and other actions such as volunteering activities performed at scale of community, as a means of reducing social vulnerability, is not yet thoroughly investigated. We think that it is necessary to extend the current wildfire risk frameworks proposed in the literature by adding social capital in its plurality of forms and by integrating them with the current analysis of natural, human, and economic assets as a tool to mitigate wildfire vulnerability.

1. Introduction

Although an essential disturbance for many ecosystems, wildfires affect 600 to 700 thousand ha of forest per year in Southern Europe, reaching peaks of 1,000,000 ha, and up to 100,000 ha in northern European countries (EC, 2021). These fires cause enormous impacts on socio-economic activities and population wellbeing, and their increase, magnified by climate and land use change (e.g., land abandonment), impairs the efficacy of measures implemented to contain temperature rise and adaptation to climate change. Managing the damages inflicted by wildfires requires an integrated and holistic approach, based on land-management actions such as thinning, prescribed fire and grazing (Kerns et al., 2020), investment in green infrastructures and adoption of adaptive and proactive wildfires risk prevention and management plans (Robinne et al., 2021) that account for interactions between natural and human systems (Kinoshita et al., 2016). To be effective these measures need to assess not only the likelihood that a fire ignites and propagates, but also the human, ecological and economic values potentially affected by it (in other terms, vulnerabilities) (Chuvieco et al., 2010; 2014) as well as the ability to cope with the damage through the implementation of institutional and voluntary initiatives capable of

mitigating environmental and socio-economic impacts. This paper presents a holistic view, developed under the ongoing project H2020 FirEUrisk (Grant agreement 101003890), for the analysis and valuation of vulnerability to wildfires by implementing an Integrated Capitals Approach (ICA) that embraces multiple capitals (natural, human, social, economic, and manufactured) in a common framework (Capital Coalition, 2021).

To achieve this goal, we have carried out a literature review dealing with wildfires and potential assets at risk, from forests and their ecosystem services (e.g., regulating and cultural ones), to semi-natural environments like agricultural ecosystems and wildland-urban interface, but addressing more immaterial values like human life and health, and resilience for both ecosystems and socio-ecological systems. Although institutional mechanisms to cope with wildfires are considered in the recent literature (Oliveira et al., 2018; 2020), only a few papers address human and social capitals and their relations with fire risk reduction, such as the role of information on fire and awareness of correct practices, local training, capacity building, or any volunteer measures (e.g. formalised civic, non-professional initiatives, etc.) able to limit fire vulnerability (Górriz-Mifsud et al., 2019). Analysis of the latter activities remain marginal compared to the relevant literature addressing environmental, socio-economic and health damages. We emphasise this gap and illustrate the need to integrate all the capitals in the wildfire risk analysis framework, to comprehensively assess both exposure and sensitivity and adaptive capacity of local social systems.

2. Methods

We started from a core of 30 papers on risk vulnerability and socio-economic damage proposed by the research team and then we extended our investigation through multiple searches on the online database ISI Web of Science. Search strings used are reported in Table 1. To better characterise our integrated approach to the analysis of wildfire vulnerability, we have searched for economic damage of wildfires to natural capital and socio-economic assets and explored also 1) the impact that fires have on human capital – such as risk to health and lives; 2) the contribution that social and human capitals can bring to mitigate wildfires such as training, participation in volunteer initiatives, such as clearing scrub, and information campaigns to reduce ignition and make humans less vulnerable to fire; and 3) how these themes are considered in wildfire vulnerability and risk framework. Findings from these three points let emerge gaps that need to be addressed in order to build a more comprehensive framework for wildfire risk analysis.

Table 1: List of search strings and results returned from ISI Web of Science considering as cut-off date of publications February 2022.

Search string	**Papers found**
“Forest fire” AND “economic impact assessment”	53
“Economic” AND “damage” AND” wildfire”	235
“Valuation” AND “damage” AND “wildfire”	27
“Valuation” AND “damage” AND “wildfire” AND Ecosystem services”	1
“Forest fire” AND “Willingness to pay” OR “WTP”, “forest fire” AND “choice experiment”, “forest fire” AND “hedonic price method” OR “HPM”, and “forest fire” AND “travel cost”, and “forest fire” AND “replacement cost”,	40
“Forest fire” AND “built capital” OR “manufactured capital”, “forest fire” AND “capacity building”, forest fire” AND “financial capital”, “forest fire” AND “human capital”, forest fire” AND “social capital”,	55

The full dataset of 411 documents was filtered based on the analysis of title, abstract, introduction and methods. We included papers published in English and a limited number (3) in Spanish and Portuguese. Inclusion criteria were the impacts of single and multiple fires on natural capital and human assets (in monetary and non-monetary units), as well as the analysis of vulnerability in wildfire risk framework. We also included papers clearly expressing the benefits of managing fires and dealing with resilience and adaptation to mitigate vulnerabilities. We excluded a few papers proposed in some conference proceedings of difficult availability, particularly those published in Russian, Chinese and Korean.

3. Results

Papers reflecting the inclusion criteria were 187. Notwithstanding the dominance (as expected from the key strings used) of papers addressing socio-economics issues, we found a broader range of themes referring also to Natural Capital and Risk analysis. We decided to cluster these papers in three groups: "Non-economic impacts on Natural Capital" (44 studies), "Natural Capital and ecosystem services valuation and socio-economic impacts" (95 studies), and "Risk Analysis and Vulnerability" (48 papers).

Within the first group of studies focusing on impacts of fire on natural assets, ecological values and ecosystem services, a preeminent role was played by papers addressing damages and disturbances to forest ecosystem dynamics (Wu & Kim, 2013; Aleksić et al., 2009), direct changes to dominant vegetation and biodiversity (Adams, 2013) and indirect shifts caused by grass invasion (Morais et al., 2021; Kerns et al., 2020), higher impacts of pest and diseases on plant survival, variations in traits expression (Lerch et al. 2016; Bélanger et al., 2013; Salazar et al., 2020), and reduction in forest resilience (Wu & Kin, 2013, Mouillot et al., 2005). Less investigated are impacts on water and soils. Wildfire incidents can affect water quality through increased sedimentation and erosion, causing reduction in the supply of potable water (Montagné-Huck & Brunette, 2018), alterations on the hydrology of watersheds through runoff of debris produced in response to storms (Parise & Cannon, 2017), and intensity of rockfalls in the burned area (Sarro et al., 2021). They also alter soil structural properties through mineralogical and biological impacts and their fertility through nutrient volatilization (Certini, 2005).

As regards the second group (see Figure 1), many studies focused on assessing the socio-economic impacts of wildfires on agriculture and agroforestry system by using market approaches (Molina et al., 2011; Stougiannidou et al., 2020; Fagarazzi et al., 2021), but also addressed multiple forest ecosystem services, including timber, carbon and biodiversity (Aleksić et al., 2009; Mueller et al., 2019; Varela et al., 2016), landscape amenities and recreational values (Molina et al., 2019a; Molina et al., 2018) by implementing a mix of stated (contingent valuation and choice experiments) and revealed preference methods (travel cost).

Relevant is the number of papers dedicated to health damage such as respiratory morbidity and cardiovascular diseases caused by haze (Liu et al., 2015), smoke pollutant and contamination rates (Evangeliou et al., 2015), or other physical consequences such as reduced height in adult age (Rosales-Rueda & Triyana, 2018; Sing & Dey, 2021). However, economic estimates remain sparce, focussing on cost of medical treatment and hospital admittance (Stanke et al., 2013), willingness to pay for avoiding respiratory disease (Jones, 2018; Leslie et al., 2013) and mitigating smoke exposure (Heider et al., 2019). We have also found a relevant number of studies addressing the valuation of wildfire prevention policies (categorised as "valuing decision making") (Shrestha et al., 2021; Gorriz-Mifsud et al., 2016; Allo & Loureiro, 2020), and sparse examples of macro-economic analysis of wildfires on employment (Nielsen-Pincus et al., 2014) and on the entire economy of a country (California) (Wang et al. 2021), labelled in Figure 1 as "other socio-economic impacts".

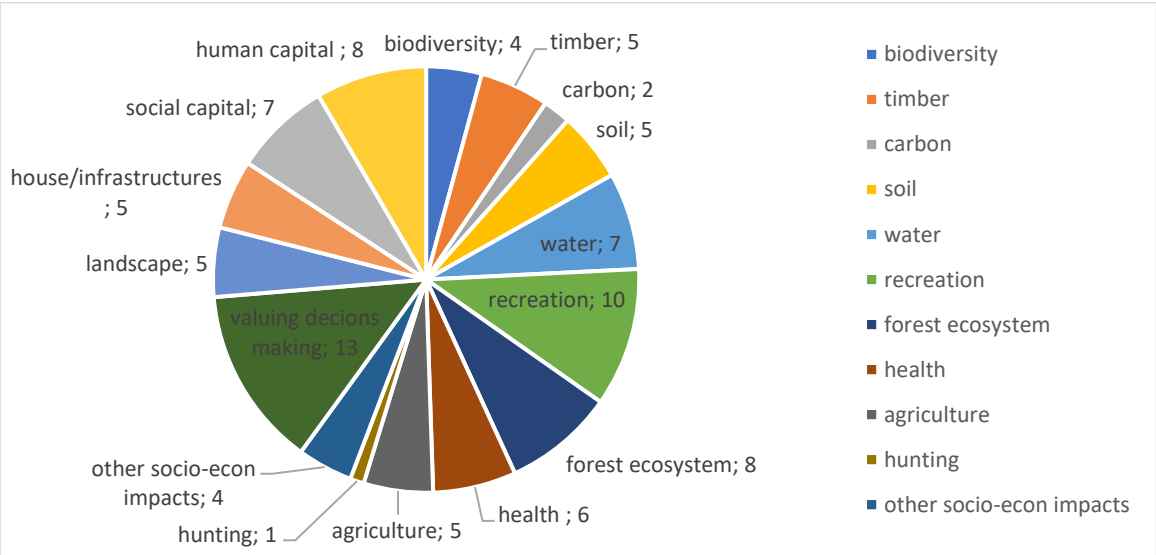

Fig. 1: Types and number of studies addressing impacts to specific ecosystem services, economic sectors and damages caused to social wellbeing and environmental values

We have dedicated attention to the interactions between wildfires and social relations. What is emerging is a limited number of studies that provide evidence of fire as a leverage to increase sound management actions to reduce wildfire risk by promoting community engagement, training and discussions. Examples from the Global South (in countries like Nepal, India, Seychelles and Indonesia – Hiratsuka et al., 2019; Chauhan et al., 2021; Etongo et al., 2021) and Western countries are found to build a stronger nexus between policy makers and scientists (Narayanan et al., 2009; Tabara et al., 2003; Huber-Stearns et al., 2021) by the integration of spatial data and models of wildfire behaviour in decision making. Relevant is the contribution that the impact of wildfires has on strengthening communities with local institutions such as municipalities and fire fighters as evidenced in Australia (Mc Dougall et al., 2014) and in developing countries like Nepal and Indonesia, where collective actions enforced rules for risk mitigation (Sapkota et al., 2015; Jalil et al., 2021). In Mediterranean countries voluntary initiatives at local levels and a series of structural and relational bonding between communities and institutions are found to statistically explain the community's operational capacity and perception of arson level (Górriz-Mifsud et al., 2019).

Finally, our search returned a consistent number of studies (48) referring to the group "Risk Analysis and Vulnerability", addressing:

1. The qualitative analysis of risk by getting information through direct interview on burnt areas, damages, local prevention and suppression techniques (Ribeiro et al., 2015; Appiah et al., 2010; Narayanan et al., 2009);
2. The quantitative analysis of:
    - fire risk by integrating spatial dataset of burnt areas and socioeconomic vulnerabilities of communities such as gender, sex, income, living conditions differences (Grala et al., 2017; Álvarez-Díaz et al., 2015; Barreal et al., 2012; Mallini et al., 2019; Andersen & Sugg, 2019);
    - fire hazard carried out through fire simulation controlling for human, biophysical, meteorological and socioeconomic variables (Guillaume et al., 2019; Molina et al., 2019b; 172- Castillo et al., 2016; Molina et al., 2019c; Castillo-Soto & Rodriguez y Silva, 2015; Rodriguez y Silva & Gonzalez-Caban, 2010; Rodriguez y Silva, 2013);
    - vulnerability as a damage function of socio-economic values (Chuvieco et al. 2010; 2014; Parente et al., 2016), resilience of vegetational types to fire intensity (Molina et al., 2018; Rodriguez y Silva, 2013; Rodriguez y Silva & Gonzalez-Caban, 2010; Chuvieco et al., 2014) and human adaptation (Oliveira et al., 2018; Oliveira et al., 2020).

Institutional aspects of coping capacity such as strengthening firefighters' activities are well reported and included in vulnerability frameworks (Oliveira et al., 2018) as well as the role of evacuation time and distance of wildfire from fire station (Oliveira et al., 2020; Oliveira et al., 2021). However, we think that many more elements making part of social capital can contribute to it and be included in the same framework. The latter can be measured, amongst others, by:

1. voluntary actions supporting fire suppression;
2. educational activities raising awareness of incorrect human behaviours (to reduce ignition causes and minimise extent of fire);
3. implementation of surveillance, patrolling and monitoring measures to reduce fire hazard (by early detection of ignition points);
4. formulation of wildfire prevention and defence plan to better manage fuel through silvicultural treatments, adoption of fire breaks and water pools.

Although recent studies are addressing some of these measures (Górriz-Mifsud et al., 2019; McDougall et al., 2014; Jalil et al., 2021), there is not yet consideration in risk analysis of the importance that training, capacity building and social bonding between citizens and institutions may have to reduce vulnerability. Ways to achieve this integration are under investigation in the FirEUrisk project at the time this paper is proposed. Below we propose an example of integrated framework between capitals, building on the investigated literature (Figure 2).

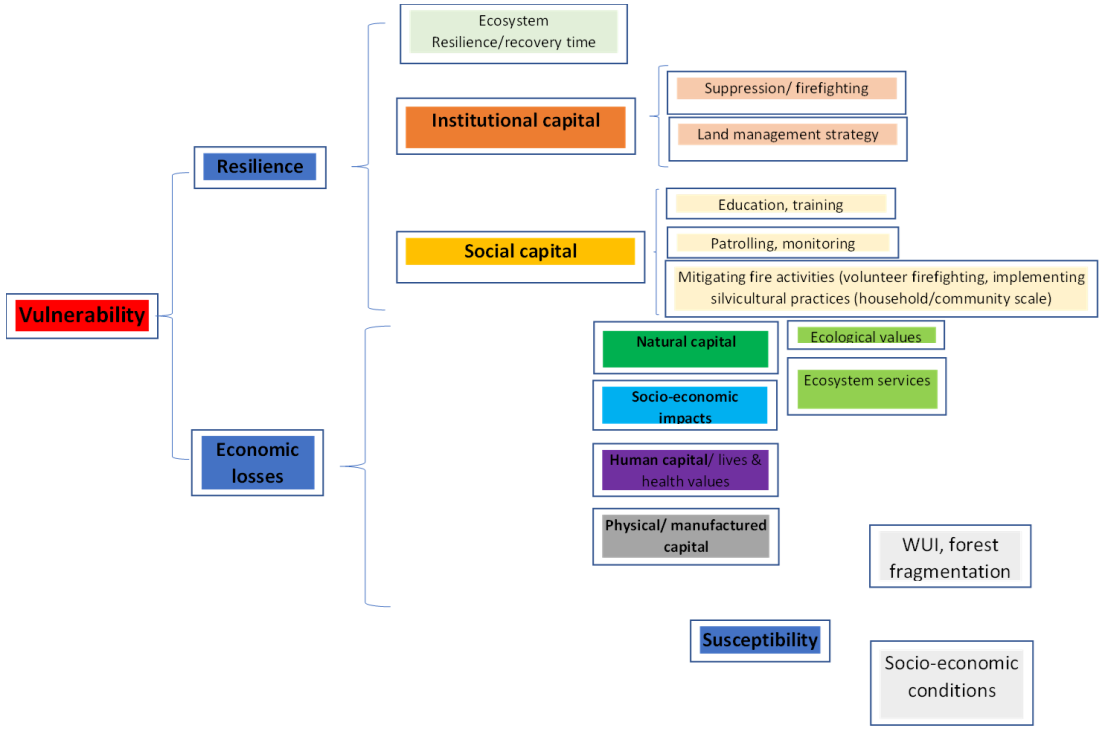

Fig. 2: A preliminary vulnerability framework to wildfires accounting for four types of capital: natural, manufactured, human and social

In the above framework we consider economic losses (as assessed in monetary units) of three different capitals (natural, human, and manufactured) corrected for the resilience of the natural and socio-ecological system. Ecosystems are in fact characterised by resistance and resilience, while societies can change their vulnerability to wildfires through the institutionalization of mechanisms such as strengthening fire suppression and addressing wise land use management strategies. Finally, educating and empowering communities may limit wildfires formation and propagation through actioning preventive measures at household scale, as well as the reduction of landscape fragmentation and other major social challenges (low income, low level of education, etc.) that are all considered relevant to explain wildfire risk.

4. Conclusion

Our preliminary analysis for the development of an integrated capital approach to wildfire vulnerability shows that studies addressing impacts on natural capital, ecosystem services and socio-economic assets are the most represented. We found also human capitals to be well proposed in terms of impacts to human health. However, gaps are evidenced by the limited analysis of social aspects such as role of communities in reducing wildfire risk, as expression of social enfranchisement emerging from the strengthening of relations in communities affected by wildfire. Other frameworks on wildfires vulnerability have introduced the impacts on ecological and economic values (Chuviero et al., 2010), stressing the importance of ecosystem resistance to fire (Parente and Pereira, 2016) and resilience to recover to post-fire conditions (Chiuvieco et al., 2014). More recently, aspects dealing with the capacity of society and communities to cope with wildfires by institutional mechanisms of fire suppression and mitigation by changes in land use management have been proposed (Oliveira et al., 2018; Oliveira et al., 2020). To bridge the gap on the holistic understanding of vulnerability, research and practice should also consider exposure to hazards/stressors, susceptibility of the system/community exposed, and its resilience and adaptive capacity (Birkmann et al., 2013; Burton, Rufat & Tate, 2018). A final consideration can be made on the importance of risk perception and how it influences fire vulnerability: perception acts indeed as a filter through which the different kinds of capital which are at risk assume specific values and/or play different roles in wildfire risk assessment, prevention and management (Paveglio et al., 2009). We consider necessary to investigate in the ongoing steps of the FirEUrisk project the integration of all these aspects in a structured index of vulnerability following the framework suggested in Figure 2.

5. Acknowledgement

This paper is funded by the H2020 Project FirEURisk (Grant Agreement Number:101003890). This research is also supported by the Rural and Environment Science and Analytical Services Division of the Scottish Government through its Strategic Research Programme (2022-2027), project JHI-D5-1 in the Natural resources Theme.

Considerations provided are the results of discussions matured between the authors and other participants of the FireEURisk projects working on the implementation of the ICA approach to wildfire vulnerability and do not necessarily reflect the point of view of the funders.

Abstract

Air quality is significantly deteriorated during wildfire events, which poses a risk for the human health of affected populations. The Mediterranean Basin was strongly impacted by wildfires in the 2021 fire-season, particularly Athens whose numerous inhabitants experienced dangerous levels of air-quality for consecutive days. It is predicted that climate change will lead to a higher frequency of this type of situations over the coming decades.

The numerical modelling system WRF-APIFLAME-CHIMERE, which comprises a meteorological model, a smoke emission model and a chemical transport model, was applied to estimate the impact of 2021 August wildfires in the air quality of Athens. The obtained concentration results were compared with data from air quality monitoring stations with a good agreement between model and measured data. Calculated values indicate concerning levels of air pollution during the days with wildfires close to the city.

1. Introduction

The fire activity around the Mediterranean basin has been increasing over the past years and the burned area in some countries is expected to increase on average by 10% a decade in some countries because of climate change (Dupuy et al., 2021). Allied to this are the lack of adequate forest management, which led during the last decades to the conversion of native oak forests into non-native tree plantations, increasing the risk of large-scale forest fires, and the abandonment of rural areas which may render the situation even worse as fields and forests are left untended, posing a significant fire risk (Corona et al., 2015).

The effects of wildfires are not limited to massive economic and human losses that are caused directly through the action of the flames. Much harm is also done by the unhealthy levels of air-pollutants released in the process such as particulate matter (PM) and carbon monoxide. A study of firefighter health parameters showed how exposure to high levels of air-pollutants released from fires, even for a short term, may lead to dangerous conditions (Miranda et al., 2012).

Greece alongside with other countries around the Mediterranean suffered unusually high levels of fire-activity during the 2021 fire-season. Reports in the media of impressive levels of smoke and ashes are supported by measurements of atmospheric pollutants during that period (Smith, 2021; EEA, 2021). Athens was especially impacted since the city and surrounding urban areas, inhabited by 4 mio people, were surrounded by two large fires in its vicinity during the first week of August.

Previous studies of extreme wildfire events have successfully employed Chemical Transport Models (CTM) and satellite data information to achieve high spatiotemporal resolution fields of species concentrations. This method was used by Péré et al. (2014) in a case-study of an event near Moscow in 2010. They used the Weather Research and Forecasting (WRF) meteorology model coupled with the CHIMERE CTM fed with emissions derived from the Global Fire Assimilation System. The latter uses the satellite derived Fire Radiative Power (FRP) and vegetation maps to estimate emissions. The authors observed a good agreement between satellite observations of Aerosol Optical Depth (AOD) and the model results, whose bias ranged from –40% to 30%. More recently Turquety et al. (2020) used the WRF-CHIMERE system coupled with APIFLAME. This system

showed good results in a case-study of Portugal in the 2016 fire season for which 5% of bias in AOD were estimated. The authors showed how the state-of-the art plume-rise model as well as the detection of small fires were important factors that allowed the reduction of the modelling biases.

This study aims at a better understanding of the emission and dispersion of smoke during extreme wildfire events, including their impacts on air quality (AQ), using the events surrounding Athens as a case study. For this, the biomass burning emissions are estimated based on a top-down methodology (using APIFLAME), and their impact on AQ is assessed based on a modelling approach. The WRF model is used to obtain high spatiotemporal meteorological conditions while CHIMERE simulates the chemical and physical processes that pollutants undergo within the atmosphere.

The validation of the chosen model parameterization and input data was done by comparing results with measurements from AQ monitoring stations from Greece.

In the following chapter the case-study is described followed by a detailed explanation of the model and its parameterization. In section 3 the model results are presented, validated and discussed. The last section deals with the conclusions of this work.

2. Methodology

The APIFLAME model was used for estimating biomass burning emissions, while other emissions, meteorology and chemical transport phenomena were handled by the WRF-CHIMERE model. The system was applied to the case study of Athens during the fires in the beginning of August 2021.

2.1. Case Study

In the beginning of August 2021 fires were detected in the region around Athens in the Terra/MODIS Fire and Thermal Anomalies satellite product (Giglio et al., 2021). The first detection was on the 4th of August due to a wildfire started 100km to the North of the city in Evia Island. The fire continued to burn for six days resulting in 51000ha of burned area (40% of the total during that fire season in Greece) as estimated by the European Forest Fire Information System Burnt Area satellite product (EFFIS, 2021). According to the same sources a wildfire started directly to the Northeast of Athens, in Attica, on the 5th ending on the 6th of August and burning 8400ha. Other significant fires were detected through their FRP signatures in western Greece and in neighbouring countries. During that period residents reported a strong deposition of ashes inside the city and authorities advised the population to stay indoors or use respiratory masks otherwise (Smith, 2021).

2.2. APIFLAME

Biomass burning emissions of trace gases and aerosols during the 2021 Greece wildfires were calculated using the APIFLAMEv2 model (Turquety et al., 2020). The estimates are based on pre-processed satellite imagery in the form of the MODIS burned scars product (MCD64A1) which uses thermal anomalies from active fires and changes in reflectance due to the charring of the vegetation to detect burned regions. This product has a 500m resolution and is released on a monthly basis indicating the estimated day of burning for each detection. For each fire and associated vegetation type, the consumed fuel was calculated, and the corresponding emissions of 46 trace gases and aerosols were derived using a list of emission factors. The module also uses the fire radiative power (FRP) from the MOD14 satellite product, which processes four daily observations at 1km resolution. This is used in the calculation of the injection height. CHIMERE then re-distributes these emissions in the vertical direction according to a plume rise profile that assigns 20% of the emissions below the injection-height and the remainder around that same height.

2.3. WRF-CHIMERE

The impact of the emissions of wildfires on AQ was quantified based on a modelling approach, using the state-of-the-art CHIMERE model (Menut et al., 2021). This model is an open-source multi-scale Eulerian Chemistry Transport Model, which includes detailed gas-, aerosol- and cloud-phase chemistry. The chosen MELCHIOR2 chemistry mechanism takes 49 species and 120 reactions into account. Additionally, 7 aerosol species are subdivided into 10 size bins, whose chemistry is also considered. CHIMERE can run over a range of spatial scales from the hemispheric to the urban scale (up to 1x1km²). It has been widely used for operational forecasts in Europe, which has allowed for extensive testing and validation over this study region (Kukkonen et al., 2012).

In addition to biomass burning, the AQ simulations considered anthropogenic, mineral dust, biogenic and sea salt emissions. Anthropogenic emissions from EMEP (EMEP, 2021) were processed to obtain hourly fluxes for the different model species (associated to the selected chemical mechanism) and the specific simulation grids. Available time profiles for specific countries were used, as well as spatial proxies such as land-use, population density, and road networks density. Desert dust, marine aerosols and biogenic emissions were estimated by the model during the simulations, taking static datasets and meteorological data into account.

The boundary conditions for the WRF meteorology driver were taken from the ERA-5 reanalysis dataset (ECMWF, 2022) with a horizontal resolution of 30km and 37 pressure levels between 1000hPa and 1hPa at six-hour intervals. Once these calculations were performed the higher resolution data was passed on directly to CHIMERE.

The whole system was run between 27-07-2021 and 06-08-2021 thus capturing the period with the highest levels of air-pollution around Athens and providing a seven-day spin-up period to stabilize all simulation variables that may be affected by inaccuracies in the initial conditions. The mesh for Greece was nested inside a larger mesh resulting in two computational domains. The coarser mesh captured phenomena at the level of the Mediterranean Basin with 95x69 cells, while the smaller one was positioned around Greece with 106x81 cells as can be seen in Figure1. The structured hexahedral mesh was created over a lambert conformal map of the computational domain with 24 cells between the surface and 200hPa.

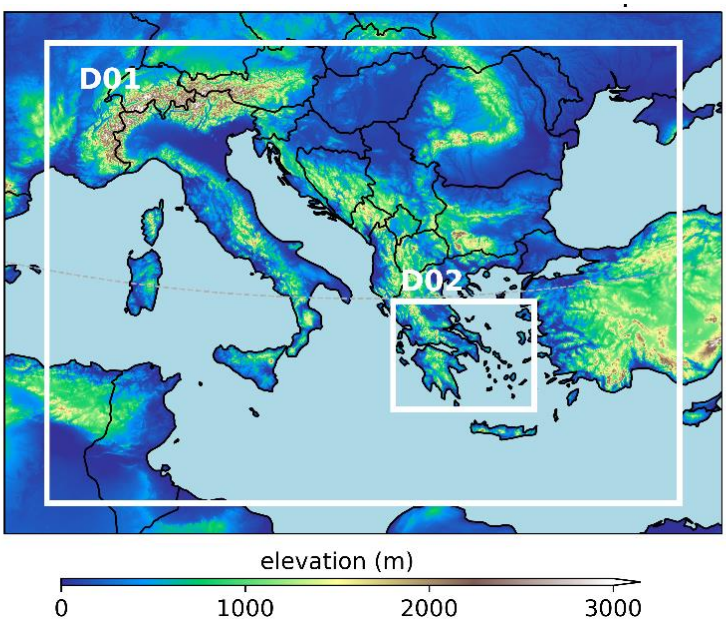

Figure 1 – WRF-CHIMERE nested domains used for the simulations plotted over an elevation map of the Mediterranean Basin. D01: coarse domain with 25km resolution. D02: small domain with 5km resolution.

3. Results

3.1. Validation

The results of the simulations were compared with data from air-quality monitoring stations which were extracted from the AQ database of the European Environmental Agency (EEA, 2021). The goal of this validation is understanding the ability of the system to model smoke emission and dispersion. Since PM and CO are consistently emitted by fires and good tracers of smoke (Schneider, 2021) these two pollutants were considered the most suitable for comparing model results.

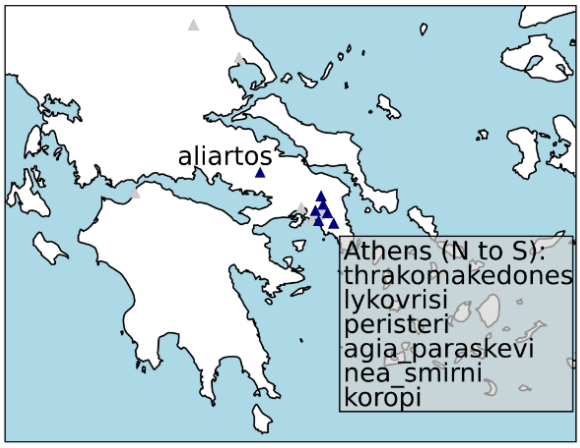

Figure 2 – Location of AQ monitoring stations within D02. Grey locations are not "background" stations and were removed.

Of the 19 available monitoring stations 7 were chosen, with their locations shown in Figure 2. These are classified as "background" stations and are more representative of a larger area around them, as opposed to "traffic" or "industrial" stations which are greatly affected by local phenomena, i.e. sub-grid phenomena for the model.

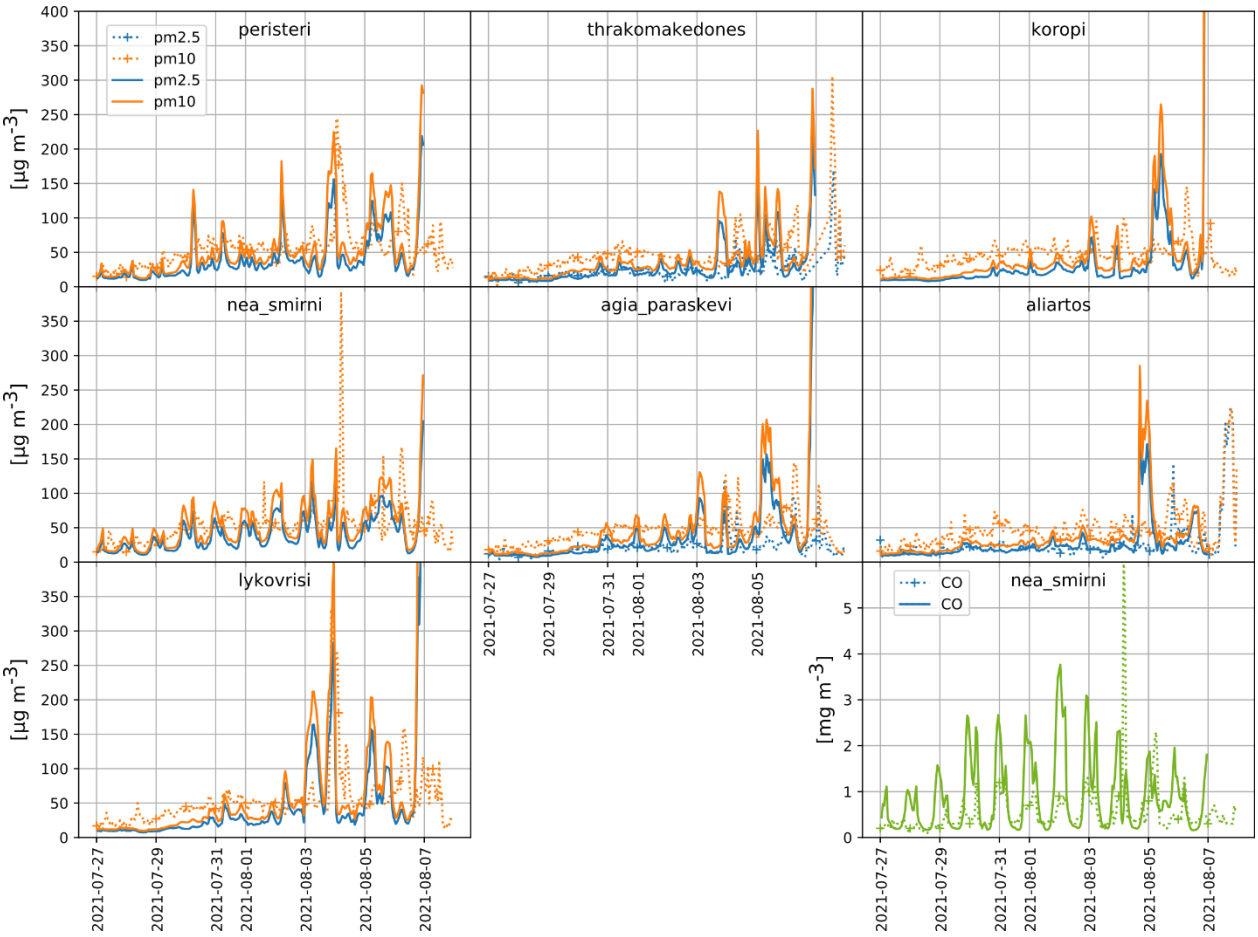

Figure 3 – Measured (dashed) and simulated (continuous) concentrations of CO and PM at the chosen sites.

Once the data was acquired, the AQ monitoring stations were associated to the grid cell of the small domain closest to it and concentration values were compared (Figure 3). Only one station measured CO concentrations, "nea_smirni". The daily fluctuations of this species are slightly underpredicted. PM concentrations, on the other hand, were widely available. Overall, discrepancies become more accentuated during wildfire periods, the

station and model concentrations follow the same trends within the same order of magnitude, and the bias is small.

3.2. Emissions

Figure 4 shows the spatial distribution (5×5 km²) of the atmospheric emissions during the fire events in Greece. It is apparent that the wildfire in Evia Island released the most amount of pollutants, not only due to high emissions by cell, but also the large area. Another four fires in Western Greece evidenced considerable emissions, together with a fire directly East of Athens.

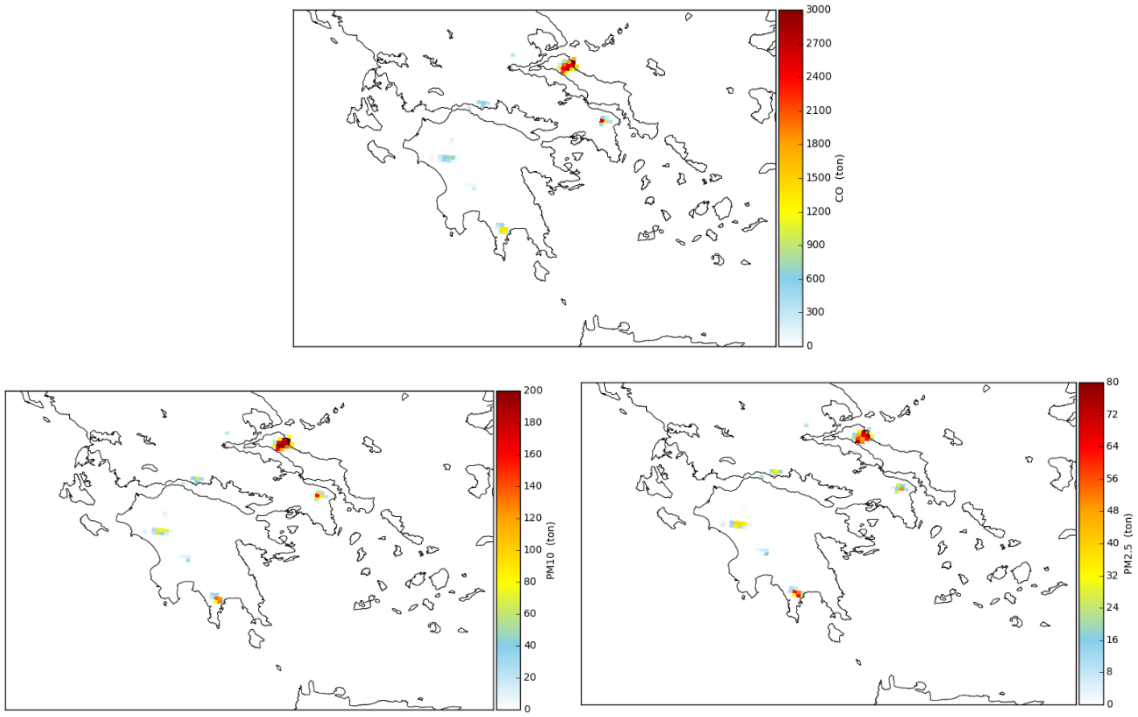

Figure 4 - Spatial distribution of the CO, PM10 and PM2.5 total emissions (ton) between 27th July and 8th August 2021.

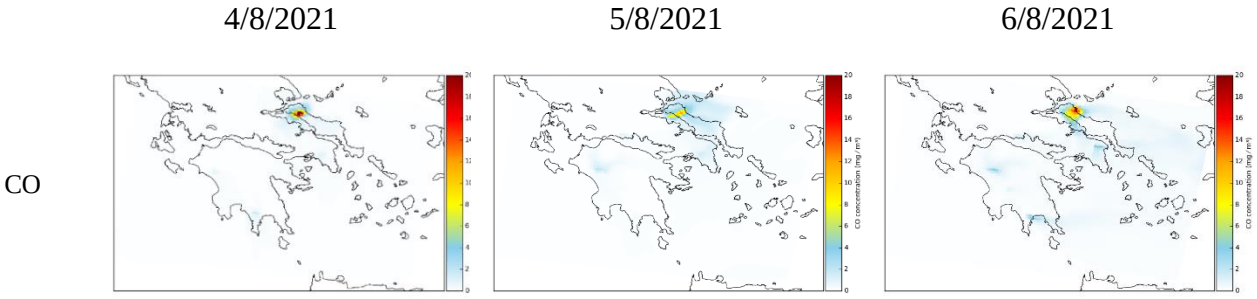
3.3. Air Quality

Concentrations of CO and PM at the surface were analyzed through time-series of maps containing the spatial distribution (5×5 km²) of the atmospheric levels. The daily averages for days 4 to 6 are shown in Figure 5. The European Ambient Air Quality Directive (2008/50/EC) sets limits at 25µg/m³ for PM2.5 (annual limit) and 50µg/m³ (daily limit) for PM10 above which considerable health impacts are to be expected.



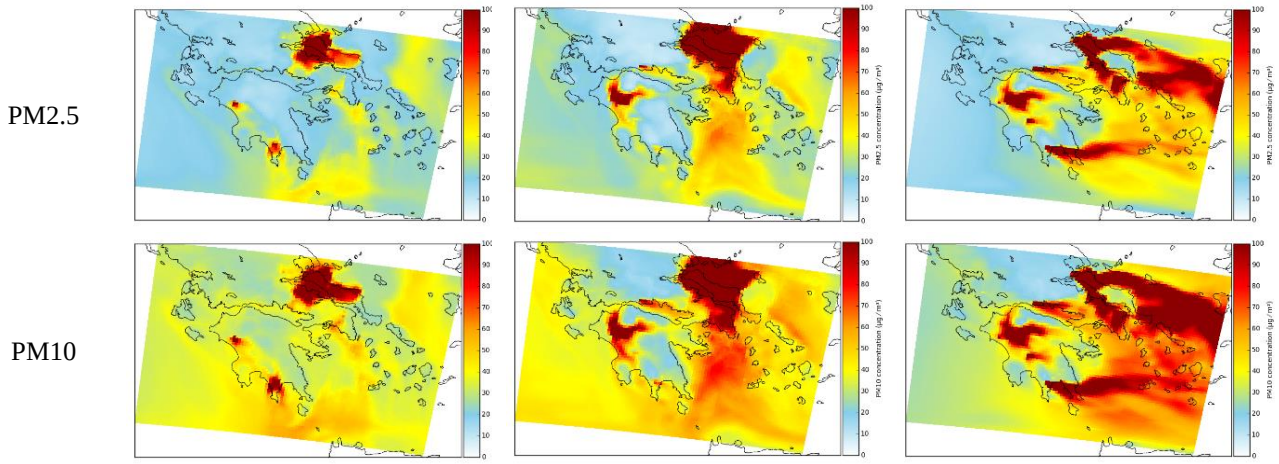


Figure 5 - Spatial distribution of the CO, PM2.5 and PM10 daily mean concentration (µg·m^{-3}) of simulated values at surface level.

On the 4th of August the fire in Evia starts early in the morning and air-pollution in the area increases throughout the day as seen from the plots, however the weak winds near the surface inhibit the dispersion of smoke and Athens is not affected. It is only during the night that PM reach dangerous levels. During the 5th of August PM levels remain high due to the ignition of the fire to the East of Athens. Atmospheric conditions are like the previous day so that PM from Evia is no longer reaching the city. Strong Easterly winds at dusk have a significant impact in cleaning the air-pollutants out of the city. This also advects smoke from fires burning to the East, however the effect on AQ is positive. Throughout the beginning of the 6th of August surface winds remain strong. By veering to the North and loosing much of their strength on the second half of the day, considerable levels of air-pollutants accumulate over Athens.

The simulation results indicate that Athens was experiencing levels of PM above the threshold before the beginning of the fires and days 5 and 6 of August were significantly impacted by the forest-fire smoke. Thus, all three days exceeded the PM thresholds.

4. Conclusions

The high spatiotemporal resolution of the calculated concentrations allowed for a more detailed analysis of the smoke plume dispersion and development, which would be unmanageable with satellite images or local air-quality monitoring stations. The model results showed a good agreement with measurements in general. However, the simulated levels of PM were clearly exaggerated during one of the events of wildfire smoke over Athens. Further analysis of the vertical profiles of the smoke and plume rise models will provide more information on how to improve model predictions during such extreme wildfire events.

Keywords

Fire radiative power, active fires, emissions estimation, forest fires, Chilean forest

Abstract

Near real-time emission estimations can be computed based on the fire radiated power (FRP) and the biomass consumption coefficients for each vegetation type. Therefore, the application of the methodology is limited by the knowledge of the biomass consumption (BC) coefficients, as the studies estimating the coefficients offer results on specific vegetation types. This study focuses on calculating biomass consumption coefficients for the most affected vegetation types in the Maule Region (Chile). We needed to estimate the biomass consumption rate to calculate the BC coefficients. Then, we computed the BC rate by estimating the biomass consumed in a specific burn time. We computed the time between VIIRS image acquisitions to assess the burning time. BC coefficients were obtained for four vegetation types: pine plantation, scrub, native oak-hualo forest, and arborescent scrub. In addition, we analyzed the variations of the BC coefficients by computing the BC coefficients on each time frame. Large variations were observed in the oak-hualo and pine plantation, which were related to the greater availability of biomass and variable fire behaviour.

1. Introduction

Forest fires are of great importance in the world because of the high emissions of aerosols and trace gases released into the atmosphere during their occurrence, directly affecting their chemical composition and the climate of the planet (Arora and Boer 2005). The increase in temperatures caused by climate change favours the proliferation of forest fires, being increasingly catastrophic (González et al. 2020). Chile has experienced an extension of the fire season in the last decade, going from 6 to 8 months. This change has produced significant impacts on CO_2 emissions into the atmosphere, biodiversity, and the country's economy (González et al. 2020).

Remote sensing has been widely used to estimate greenhouse gas, particulate matter, and trace gas emissions generated during a fire (Vadrevu and Lasko 2018; Wiedinmyer et al. 2006). These estimates have been obtained from two methods. The first, proposed by Seiler and Crutzen (1980), estimates the emissions by combining the burned area, the biomass available for burning, the consumption efficiency factors, and the emission factors by vegetation type (Oliva et al. 2019; Reid et al. 2009; Van Der Werf et al. 2017). The second method quantifies the biomass burned considering the integration over time of Fire Radiative Power (FRP) to obtain Fire Radiative Energy (FRE) (Vadrevu et al. 2019). The calculation of burned biomass is possible due to the linear relationship between the FRE and the rate of Biomass Consumption (BC) in a fire. The latter method considers within its variables the FRE and the specific biomass consumption coefficient for each type of vegetation (Wooster et al. 2005). The application of this method has shown promising results in southern Brazil (da Costa and da Fonseca 2017) in northern India (Vadrevu and Lasko 2018) and in global estimates (Vermote et al. 2009).

Visible Infrared Imaging Radiometer Suite (VIIRS) sensor provides data on active fires in near real-time thanks to its VNP14 product, which has a nominal spatial resolution of 375 m. Favouring the detection of a greater

number of fires allows a more refined mapping of the largest fires (Schroeder 2018). Therefore, VIIRS has become the new tool to continue working more accurately on emissions estimates (Fu et al. 2020; Li, Zhang, and Kondragunta 2020).

This study proposes a methodology that allows obtaining the biomass consumption (BC) coefficients necessary to estimate biomass burning emissions from the FRP product of active fires of VIIRS. The BC coefficients obtained in this study for the vegetation types of Chile contribute to the use of the VIIRS FRP for the estimation of emissions in future events.

2. Methodology

2.1. Study area

The fire called "Tabunco-El Águila Convenio" located at 35°8,862' S and 71°58,315' W in the commune of Curepto, Maule Region, Chile. We chose this fire because it has crucial characteristics for the application of emissions estimation. Among these characteristics, the presence of endemic native species stands out, such as hazel (Gevuina avellana), peumo (Cryptocarya alba), boldo (Peumus boldus), and litre (Lithraea caustic) (CONAF 2017). The event began on January 25, 2017 and was finally controlled on February 8, 2017. It burnt 4,069.7 hectares, affecting native vegetation, grasslands, thickets, and plantations. This fire also presented a rich diversity of vegetation types and detailed coverage of active fire detections.

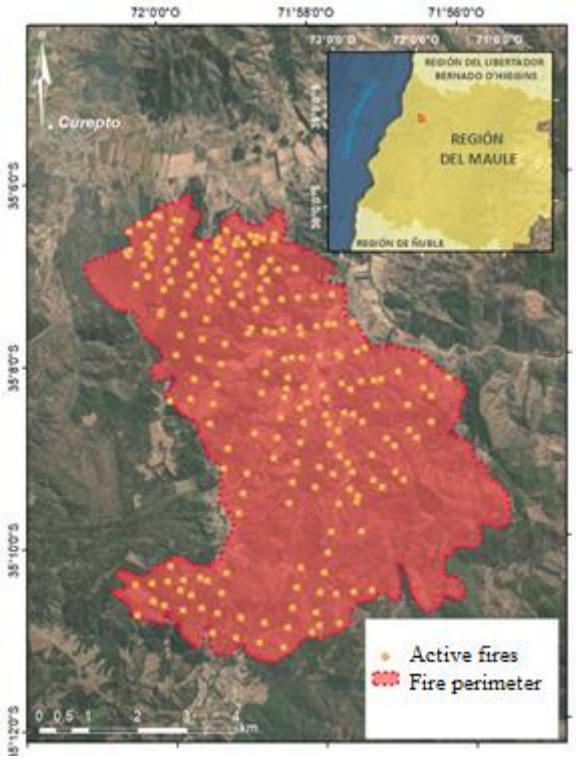

Figure 1- Location and extent of the Tabunco-el Aguila Convenio fire with the distribution of the active fires detected by VIIRS active fire product.

2.2. VIIRS active fire product

In this study we used the VNP14 thermal anomaly product of the NPP-VIIRS sensor. VIIRS active fire product provides detections at least twice a day, crossing the equator at 13:30 PM on the ascending node and at 01:30 AM on the descending node. The download of VIIRS data is done through the Fire Information for Resource Management System (FIRMS) service (https://firms.modaps.eosdis.nasa.gov/download/, last access date on February 27, 2022), from where you can access a global coverage of data from 2012 to date, in different formats.

The VIIRS active fire product provides information regarding fire coordinates, FRP measures (MW), brightness temperature in their respective bands, confidence level, date, time, and sensor characteristics. The time interval

defined for this study was based on the days of higher fire activity, which runs from January 26, 2017, to January 29, 2017.

2.3. Estimation of the biomass consumption rate

We worked over a grid o 375x375m to relate the FRP measurements with the area covered by each vegetation type. The mean FRP values for each date and time of acquisition were assigned to one cell. Subsequently, we calculated the percentages of the area for each type of vegetation, the biomass value, and the burn efficiency factor associated with each cell. The amount of biomass consumption per type of vegetation was obtained for each of the time interval measurements applying equation 1.

$$M=A\times B\times \beta \qquad (1)$$

Where M is the total amount of biomass consumed (kg), A is the total area burned (m^2), B is the dry organic matter by vegetation type (kg m^2), and β is the fuel efficiency (dimensionless).

Next, we applied the equation 2 to estimate the biomass consumption rate.

$$BCR = M / BT \qquad (2)$$

Where BCR is the biomass consumption rate, and BT is the burning time in seconds. We considered as the burning time the time between two consecutive image acquisitions. The time interval considered ranged from January 26, 2017, to January 29, 2017. In that time, eleven VIIRS images were acquired, so we computed the BCR on eleven periods.

2.4. Estimation of the biomass consumption coefficient

Following the methodology of previous studies, we estimated the BC coefficient by vegetation type applying a linear regression equation between the BC rate and the FRP measured at each burning time period. The slope of the liner regression line is assigned as the BC coefficient value. Although a variety of vegetation types were present in the fire, only four vegetation types offered enough data to compute the linear regression line: open shrublands, forested shrublands, pine plantations and native forest oak-hualo.

We also computed the BC coefficients applying the following equation:

$$C_{ex} = BCR / FRP \qquad (3)$$

Where C_{ex} is the BC coefficient by vegetation type x, and FRP the Fire radiative power measured within the burning time of each period (eleven periods considered). We called this BC coefficients, dynamic coefficients as their value change depending on the characteristics of the vegetation and the fire behaviour.

3. Results

The results of the linear regressions by vegetation type indicate that BNRH and open scrub have an R^2 of 0.6 and 0.5, respectively. This indicates that the predicted BC coefficients achieved a better fit, with respect to what is observed in the cases of pine and arborescent scrub plantation with an R^2 of 0.3 and 0.2, respectively. We also analysed the behaviour of the dynamic BC coefficients (see Table 1). We observed that, in certain cases, for the same vegetation type, these BC coefficients have values higher than the observed average. This situation affects BNRH with two high values on the second day, forested shrubs and pine plantation. These higher values are related to higher values of biomass consumption rate.

Table 1. Result of dynamic and static biomass coefficients by vegetation type. BNRH refers to the native oak-hualo forest.

Type of Coefficient	DD-HH code:MM	GNRH	Open Scrub	Shrub Arbolado	Pine Plantation

4. Conclusions

This study lays the foundation for the application of emissions calculation from FRP measurements of active fires, allowing near real-time estimates. The objective of this study was to obtain the BC coefficients by type of vegetation affected by the fire studied. This was obtained for four of the affected vegetation types. In addition, this study allowed an interesting analysis based on the dynamic BC coefficients. We could then evaluate the error that might be produced by applying the linear regression BC coefficients. The BC coefficients with the most variability was found in the BNRH and in the pine plantation. This result is related to the greater amount of biomass of these vegetation covers and the greater intensity that the fire can reach. Therefore, in those vegetation types, the BC coefficient estimated from the regression analysis does not reflect the natural variation derived from the fire behaviour and the characteristics of the vegetation.

The continuation and extension of this work on other fires and other types of vegetation present in the country are necessary to obtain the biomass coefficients by type of vegetation and use this methodology to estimate fire emissions in almost real-time throughout the country.

5. Acknowledgments

This work could be carried out thanks to the materials provided by Patricia Oliva, which were obtained within the activities of the FONIS SA18I0177 project. The authors of this work thank CONAF for its valuable information regarding the cadaster of vegetation types and the identification of ignition of the event studied.

Abstract

The lengthening of the fire season in Portugal has been understudied although there is evidence of changes in recent decades. In this study, we have focused on the complete annual cycles of fire activity and meteorological fire danger, avoiding any subjective definition of what should mark the beginning and end of the fire season. Based on the daily time series of burned areas and number of active fires collected in mainland Portugal by state services from 1980 to 2018, we have searched for changes in the monthly and daily distributions. In particular, we developed an exceedance date method to determine day-scale trends in the anticipation/prolongation of fire activity in the year. An unequivocal increasing trend in the proportion of annual burned area between January and June was found, compensated by a diminishing trend in the proportion of burned area in the summer months (July to September). Apparently, the known secondary peak of fire activity in March played an important role in these changes that should be clarified in future analyses. Moreover, the daily analysis shows a clear shift of the cumulative burned area curves to the left, which suggests an anticipation of fire activity. The evolution of the 15% exceedance date, the annual date at which the threshold of 15% of the annual burned area is reached, shows a linear variation of -1.34 days per year in 1980-2018. In order to evaluate the meteorological contribution to this found anticipation of fire activity we used the Daily Severity Rating (DSR), from the Canadian Forest Fire Weather Index System, computed from the ECMWF ERA5 reanalysis. The results show a clear earlier growth of the DSR when comparing the averages for the first (1980-1999) and second (2000-2018) halves of the period. This divergence between the two curves rises steadily from the beginning of the second half of April to the end of September. Interestingly, a closer look shows a first increase in the DSR gap in March, which almost disappears in April before steadily increasing again until the beginning of October. Finally, we argue that up-to-date knowledge of interannual and interdecadal changes in the seasonality of both wildfires and fire weather is a decisive (though not the only) aspect for comprehensive fire season management.

1. The seasonality of fire in Portugal: a brief introduction

The incidence of wildfires throughout the year, represented by the number of occurrences and burned areas, shows an uneven pattern that derives from the annual cycles of temperature and precipitation and the corresponding cyclical dynamics of ecosystems (e.g. Kwiecien et al. 2021, Viegas & Viegas 1994). This relationship between climate and fire seasonality is well embodied in the weather fire risk indices – as well exemplified by the FWI and its long memory drought subindices (Van Wagner 1974, Carmo et al. 2021) – and has received renewed attention in recent decades in the context of concomitant changes in climate and fire regimes. The focus on 'the lengthening of the fire season' in a changing climate has in Wotton and Flannigan (1993) one of the first studies and has been increasingly studied in the last few years (Jain et al. 2018, Westerling 2016, Salloum & Mitri 2014, UNEP 2022).

The present study fits these concerns and research framework aiming (i) to identify relevant changes in the annual cycle of fire activity in mainland Portugal, based on the extensive records of fire occurrences in the period 1980-2018 (≥1.0 hectare) and some previous results (cf. Carmo et al. 2021), (ii) to evaluate the meteorological contribution using the Daily Severity Rating (DSR) (Van Wagner 1987) and, finally, (iii) to discuss the interannual and interdecadal variation in wildfire seasonality in the context of fire management and the operational definition of 'fire season'.

On this last point, we must note that contemporary fire regimes are affected by human activities. Fire seasonality is conditioned not only by climatic and ecological forcings, but also by *unnatural* annual cycles of ignitions,

fuel availability, as well as changes in fire suppression approaches and means, which have specific calendars themselves changeable over time. See, for example, the secondary peak of fires in March, identified in northwestern Iberia (da Câmara et al. 2014) and in our nationwide 1980-2018 data (both in number of occurrences and burned areas, data not shown), which is associated with the (inseparable) combination of early spring agricultural practices and a recurrent window of weather conditions conducive to fire spread.

The monthly distribution of the annual burned area in Portugal in the period 1980-2018 shows a broad concentration in July, August and September (which represents on average 82.5% of the total burned area each year) (Figure 1). However, this monthly data also shows an increasing fraction of the annual burned area occurring outside those three summer months (Figure 2). In fact, there is a meaningful increase in the fraction corresponding to the months of January to June, while the fraction of July to September shows a decreasing trend (Mann-Kendall tests with $\rho<0.01$).

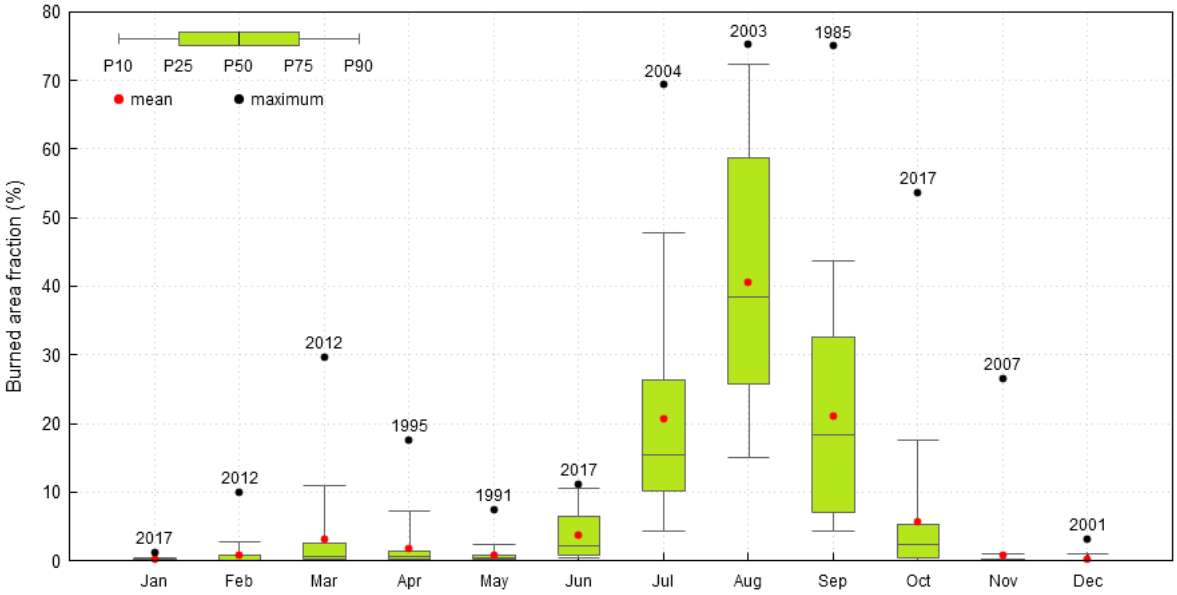

Figure 1: Monthly distribution of the annual burned area in the period 1980 to 2018, indicating the 10th, 25th, 50th, 75th and 90th percentiles (box-and-whisker plot), the mean (red dots) and the maximum monthly values (black dots labeled with the year of occurrence).

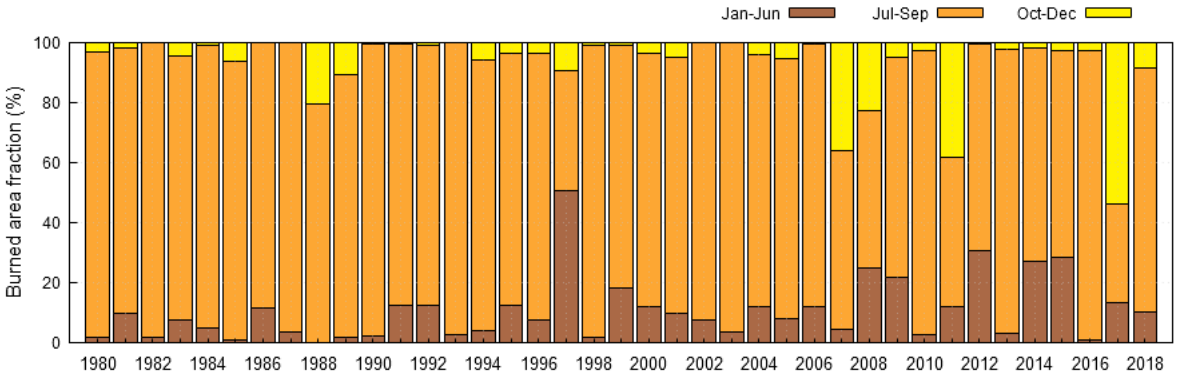

Figure 2: Distribution of the fraction of annual burned area occurred before (Jan-Jun months, brown bars), during (Jul-Set, orange bars), and after (Oct-Dec, yellow bars) the most critical months in wildfires incidence in the period 1980-2018.

2. Evolution of the burned area throughout the year: is the fire season getting longer?

The year 2017 sounded several alarm bells in Portugal: beyond the sad and unprecedented figure of 117 deaths caused by wildfires and a burnt extent never before recorded (about 540,000 ha), the two main fire events occurred before (17-22 June) and after (15-17 October) the official fire season window decreed by the

Portuguese authorities (Turco et al. 2019, Viegas et al. 2017, 2019). In 2017, 67.1% of the burned area did not occur in the three summer months (Jul-Sep, see Figure 2). To better understand the historical evolution of the annual fire cycle, we have used a simple method of determining for each year the dates (annual Julian day) at which the fractions of the annual burned area, in increments of 1%, are reached. This exceedance date method allows us to compute the annual trends for each single fraction and evaluate their statistical significance and as the advantage of being insensitive to the severity of fires in a particular year.

The two-decade averages represented by the color lines in Figure 3 show that, in the last two decades, the fractions of burned area between 1% and close to 30% are being reached earlier in the year. This suggests a widening of the annual cycle with displacement of the left tail of the burned area distribution, as a likely result of the anticipation of fire activity in the year. Trend analysis confirms the significance of early exceedance dates up to the 16% fraction (Mann-Kendall test, $\rho<0.05$). The remaining exceedance dates, including the slowing down phase of the fire cycle in late summer, show no significant trends. There was a 27-day (at the 10% exceedance dates) and 23-day (at the 16% dates) move back comparing the first and the second half-period averages. Considering the 15% fraction as a reasonable indicator of the beginning of the fire season, we obtained an anticipation linear rate of 1.34 days per year (Figure 4).

These results are in line with the expected lengthening of the fire season in Portugal during the 21st century, as detailed in Moriondo et al. (2006) and Carvalho et al. (2010). These two studies also identified a clearer signal in the fire season earliness compared to its extension into autumn. Similar trends have been obtained in the southwestern USA for recent decades, based on both fire activity (Westerling 2016) and fire weather risk (Jain et al. 2018).

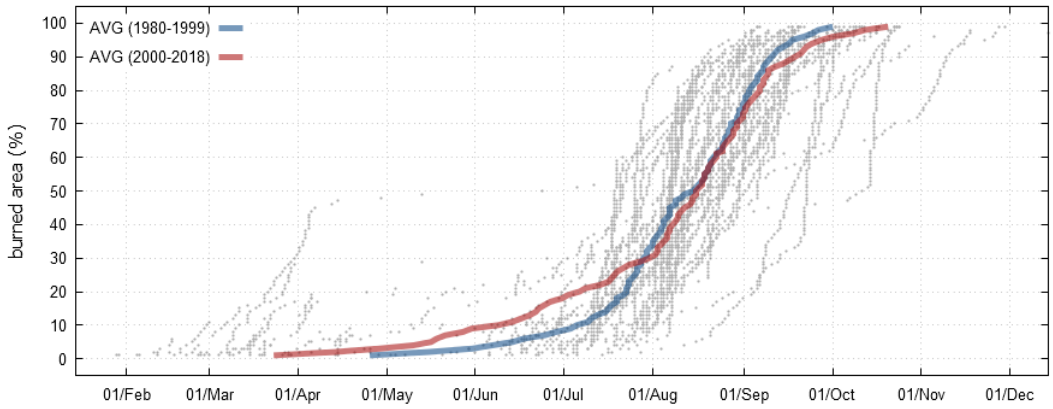

Figure 3: Exceeding dates for successive fractions (1%, …, 99%) of the total annual burned area in each year from 1980 to 2018. The grey dots represent the 39 annual dates for each fraction. The color lines represent the average dates for the first (1980-1999, blue line) and the second half (2000-2018, red line) of the period.

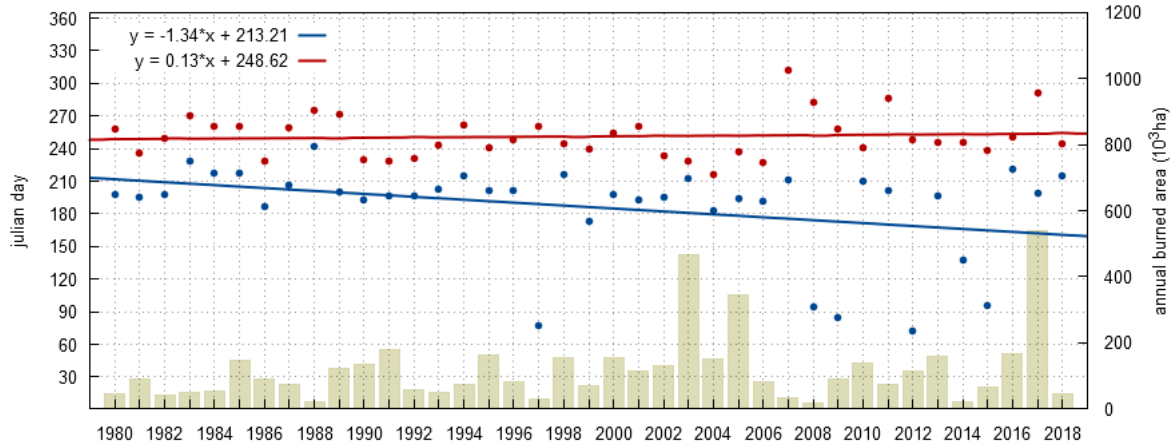

Figure 4: Evolution of the dates on which the 15% (blue points) and 85% (red points) of the total annual burned area are exceeded in the period 1980-2018, and corresponding adjusted linear regressions. The grey bars show the annual burned areas. The correlation between the 15% exceedance dates and the annual burned area is weak (r = 0.18).

3. The meteorological perspective: DSR patterns in the period 1980-2018

Changes in the annual fire cycle are related, in varying ways and intensity, to changes in atmospheric conditions conducive to fire onset and spread (e.g. Flannigan & Wotton 2001, Gouveia et al. 2016, Ruffault et al. 2018). Regarding wildfire seasonality, this relationship can be investigated with the DSR, Daily Severity Rating, which has a regular use in Portugal in the monitoring of the fire weather risk build-up throughout the year. DSR is an extension of the FWI system that transforms daily FWI values through a power expression (higher FWI values are thus emphasised) (Van Wagner 1987). In the present analysis we computed the annual cumulative DSR series, starting on January 1st, with data provided by the ERA5 reanalysis (Vitolo et al. 2020, CEMS 2019) on a grid of 163 points over mainland Portugal for 1980-2018.

Figure 5a shows the two mean cumulative DSR curves for the first (1980-1999) and second (2000-2018) halves of the study period. An increasing departure of the two curves is observed starting around April to the end of September. If we look closely at the difference between the two periods (in Figure 5b), we see a slight growth in the DSR difference as early as March, which then reduces to nearly zero in April before steadily increasing again. Considering the aforementioned secondary peak of fire activity and risk in March, this slight difference may represent a historical accentuation of that peak. In interpreting these results, we must take into account that the DSR is a good indicator of the 'sum' of fire-related weather conditions and that we are comparing average values over Portugal.

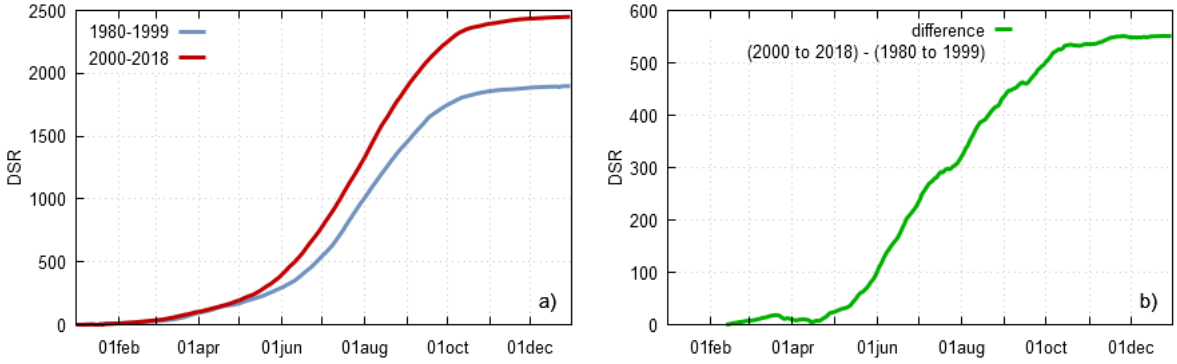

Figure 5: (a) Mean cumulative DSR values in the first (1980-1999, blue curve) and second half (2000-2019, red curve) of the study period. The DSR is cumulated daily from 1 January to 31 December in each year. (b) Daily difference between the two periods average (1980-1999 and 2000-2018); the scale on the Y-axis was changed.

4. Conclusions: Linking fire-weather and fire season management

The results presented show with confidence that the distribution of burned area has been moving progressively out of the critical period from July to September. This change is more evident during the spring period, which may be due to the combination of several factors, such as variations in human activities, in the type of machinery used in fields, in the agricultural and grazing cycles, among others, including necessarily changes in weather conditions on the scale of years and decades. Isolating social, ecological and climatic factors could be an arduous task. A good illustration of the interdependence between these factors is that the annual, operational definition of fire season, based on fire weather indicators, affects the distribution of ignitions by shifting restricted uses of fire and other fire-risk activities to the months preceding the 'season'.

The cumulative DSR showed a faster growth from the end of April when comparing the pre- and post-2000 periods, from which a direct contribution of meteorology can be deduced in the extension of the fire cycle in Portugal since 1980. This early growth must be evaluated in greater detail, both in the temporal and spatial components, in order to assess variations in the frequency of FWI values above specific thresholds and in the regional distribution of fire danger. Furthermore, the effect of March on the early season will need to be clarified, as the burned area series for this month confirms an upward trend (Mann-Kendall, $\rho < 0.01$) that does not occur in neighbouring months.

In 2017, as mentioned, 67.1% of the burned area occurred outside the 'fire season' or 'critical fire period', as legally defined by the Portuguese authorities. The term 'critical period' has gained current use since 2004, when

it replaced in legal framework the 'normal fire season', which had been established in 1981. The legal definition of the season window changed almost every year, recording the earliest beginning on May 1st (e.g. 1995) and latest ending on October 31st (e.g. 1988 and 2011). 2017 has weakened the operational role that the fixed period has had until then, in favour of greater focus on short-term forecasting of weather fire risk. We should note however that the fixed definition of 'season' included since 1981 the possibility of declaring extraordinary periods, 'when meteorological conditions that justify it occur or are expected'. This assessment was at the time based on a daily risk index given by the Angström formula (Fernandes 2015, Lourenço 1988, Decreto Regulamentar n.º 55/1981, Portaria n.º 167/2016, Portaria n.º 195/2017).

From a management point of view the seasonality of fires in mainland Portugal – presenting a well-known interannual and also decadal or climatic variability, as seen in recent decades – must be conciliated with the social and political definition of the fire season, on which numerous activities in rural areas depend.

5. Acknowledgments

Work was developed under the projects FIRESTORM, Weather and Behaviour of Fire Storms (PCIF/GFC/0109/2017) and FIREUSES, A political and environmental history of the large wildfires in Portugal, 1950-2020 (PTDC/HAR-HIS/4425/2021), both funded by FCT/MCTES. The authors thank IPMA colleagues Nuno Moreira and Paulo Pinto and FIREUSES colleagues Ana Queiroz, Joana Sousa, Frederico Ágoas, Marta Silva, and José Ferreira for rich and supportive discussions. We would like to extend a special thanks to ICNF for providing the rural fire records and to IPMA for the weather data and other facilities made available. Fire spread, drivers of fire spread, climate change, western US

Abstract

Wildfire activity in recent years not only have large total area burned but also large, single-day fire spread events that pose challenges to ecological systems and human communities. Our objective was to better understand the relationships between extreme single-day fire spread events, annual area burned, and fire-season climate, and predict changes under future warming. We employ a satellite-derived dataset of daily fire spread events in the western USA and gridded climate data over this region to assess relationships between extreme single-day fire spread events, annual area burned, and fire-season maximum temperature, climate moisture deficit, and vapor pressure deficit over a time period of 2002-2020. Extreme single-day fire spread events which were classified as single day of burning that burned more than >1100 ha (the top 16%), these could have been a part of multiple days of extreme fire behavior resulting in multiple extreme fire spread events or an isolated day of extreme behavior, regardless days with fire spread >1100ha on a single fire were analyzed separately. We then develop models to predict fire activity under a 2°C warming scenario. These extreme fire spread events accounted for 70% of the cumulative area burned over the period of analysis. Annual area burned was correlated with number and mean size of spread events, and those largest of these large fire spread events. In 2020, wildfires burned over 4 million ha in the US and we identified 441 extreme fire spread events, identified as >1100 ha burned in a single day. These 441 events in 2020, burned 2.2 million ha across our study area. In contrast, the average extreme events between 2002 and 2019 was 168 per year that burned 0.5 million ha. Fire season climate variables correlate strongly with the annual number of extreme events and area burned. Our models predict that the annual number of extreme fire spread events more than doubles under a 2°C warming scenario, with an attendant doubling in area burned. Exceptional fire seasons like 2020 will likely be more common, and wildfire activity under future extremes will likely exceed anything witnessed yet. Safeguarding human communities and supporting resilient ecosystems may require new lines of scientific inquiry, novel land management approaches, and accelerated climate mitigation efforts.

1. Introduction

Recent fire seasons in the western US and elsewhere have been characterized not only by high total area burned, but also periods of extremely rapid fire growth and very large single-day fire spread events. Throughout a fire season, short duration but extreme events may have outsized effects, vastly expanding the area burned in individual fires (i.e. "megafires"; Adams, 2013) and contributing disproportionately to cumulative social and ecological impacts (Duane et al., 2021). As examples, 4 million ha burned in the US in the 2020 fire season, mostly in western states (www.nifc.gov), with many states seeing record-setting fires. In Oregon and Washington, there were multiple days of individual fire growth over 10,000 ha (including one report of 40,000 ha), and a record-setting wildfire in Colorado that burned ca. 1500 ha/hr for >24 hours in October (https://inciweb.nwcg.gov/). Similarly, California reported a record-setting individual fire (the 400,000-ha August Complex) that exhibited extreme fire growth under high winds and low fuel moisture over several days in early September, contributing to record total annual area burned (1.7 million ha; www.fire.ca.gov).

Observations of very large single-day fire runs within the context of recent record-breaking fires and fire seasons raise a suite of research questions and hypotheses (Duane et al., 2021). New methods to calculate daily fire spread from satellite observations have catalyzed the development of datasets of daily fire spread over expanded spatial and temporal scales (Parks, 2014) and are leading to analyses that provide new insights into wildfire activity (Hart & Preston, 2020; Wang et al., 2017). At a foundational level, aggregate fire effects such as area burned represent the accumulation of thousands of single-day fire spread events. Growing evidence suggests that climate change will continue to expand fire activity in coming decades, but with interannual variability (e.g., El Niño Southern Oscillation, Pacific Decadal Oscillation; Crimmins, 2011; Trouet et al., 2009) likely resulting in climatic conditions and patterns in fire spread events outside of those experienced within recent observations. What constitutes an extreme under contemporary climate may change as once rare conditions (such as occurred in 2020) become more common. Thus, we might ask if climate and attendant fire activity in the western US in 2020 could be representative of future norms, and what kind of wildfire activity could occur during future extremes?

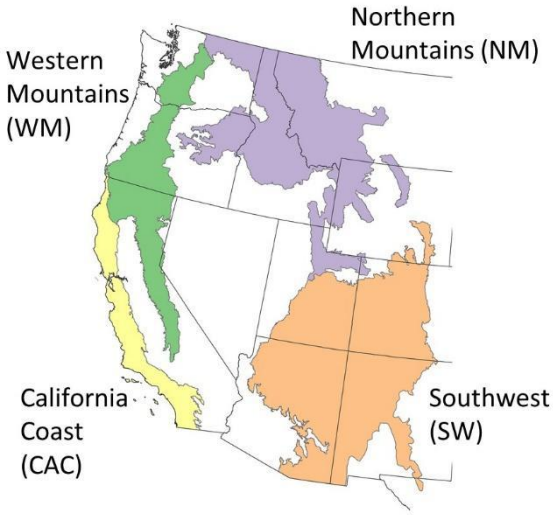

Figure 1- Western US study area, comprising four forested ecoregions.

2. Methods

Our analyses are based on measurements of daily fire spread (ha/day) for individual wildfires. Following the methods of Parks (2014), we developed spatially continuous maps depicting the day-of-burning for all fires whose centroid intersected our western US study area from 2002-2020 (Fig. 1). Briefly, this procedure interpolates VIIRS and MODIS fire detections (from https://firms.modaps.eosdis.nasa.gov/active_fire/) to map the day 1f burning within the entire area of the final fire perimeter at a 30-m resolution. This day-of-burning interpolation technique has been successfully used in several previous fire studies (e.g., Downing et al., 2021; Holsinger et al., 2016; Meigs et al., 2020; Wang et al., 2017). All day-of-burning interpolations were constrained to the final fire perimeters as obtained from national repositories; we obtained 2002-2018 fire perimeters from the Monitoring Trends in Burn Severity (MTBS) program (Picotte et al., 2020). Fire perimeters from 2019 and 2020 were downloaded from the National Interagency Fire Center (Interagency Fire Perimeter History - All Years: available at https://data-nifc.opendata.arcgis.com/datasets/); fires <400 ha were removed to match the MTBS dataset. Given minor differences between the NIFC and MTBS databases, we performed a sensitivity analysis to examine whether or not a bias correction to 2019 and 2020 NIFC fire counts and area burned would influence our findings or interpretations. We found that such a correction led to negligible increases in future projections and thus elected to use the data from NIFC without adjustments, noting that as more and better data become available, more refined future projections may become feasible. Fires with less than 10 fire detections were excluded from the analysis because of uncertainty associated with interpolating small numbers of detections. Fire detections that occurred between 12 am and 6 am were assigned to the previous day. In total, we interpolated day-of-burning for 2391 fires and 20,991 unique fire spread events ranging in size from 25 to 74,509 ha.

3. Results and Discussion

Daily fire spread followed a slightly skewed log-normal distribution, with a median value of 260 ha/day and a mean of 295 ha/day (Fig. 2). Single-day spread events >1100 ha represented the top 16% of events (1 standard deviation from the mean), and accounted for 70% of total area burned. Described another way, the top 10% of fire spread events burned 58% of the total area and just the top 1% of events burned 20% of the total area. Parameters of annual distributions of daily fire spread were closely linked to annual area burned. Number of events (P <0.001), mean event size (P <0.001), and skewness (P = 0.03) were all significant predictors of annual area burned in our best-fitting model (r^2 = 0.90, 15 d.f.). Relative contributions each term were as follows: number of events, 68%; mean event size, 29%; and skewness, 3%.

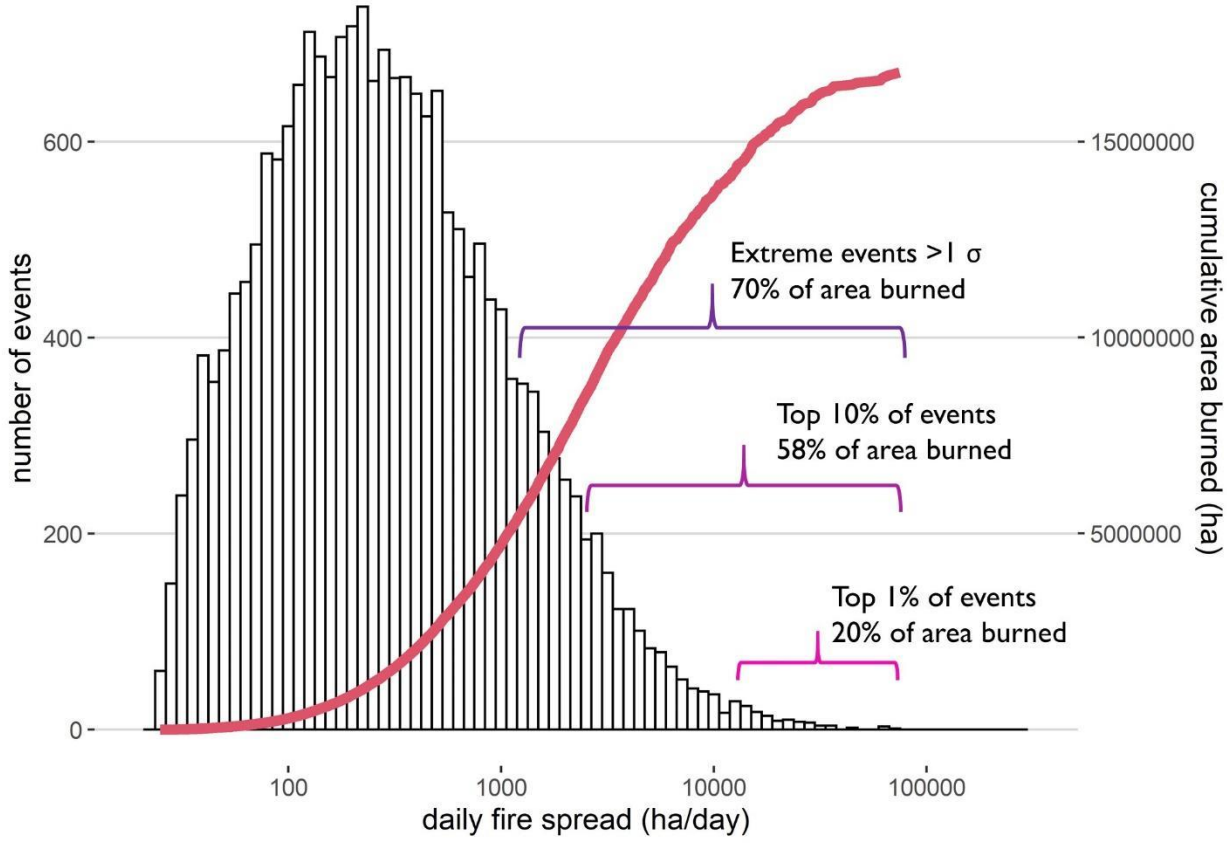

Figure 2- Distribution of daily fire spread events and the cumulative area burned during the 2002-2020 study period. Extreme events ≥1100 ha (the top 16%, 1 standard deviation) account for 70% of area burned).

A generalized linear (negative binomial) model predicting the total count of extreme fire spread events from Aridity provided robust predictions for the entire study area (P<0.001, McFadden's r^2 = 0.42); this model was then employed to predict of the annual number of extreme spread events for a 2°C above pre-industrial warming scenario in contrast to a 1986-2015 reference period, and modeled and observed activity in 2020. This model predicted a mean of 343 extreme spread events per year under the +2°C scenario, ranging from a minimum of 81 to a maximum of 815 events in extreme future years (Fig. 3). In contrast, the mean modeled number of extreme spread events in the reference period was 129, with a range of 32-302. Model predictions for the 2020 fire season climate were 324 extreme spread events; the observed number was 441.

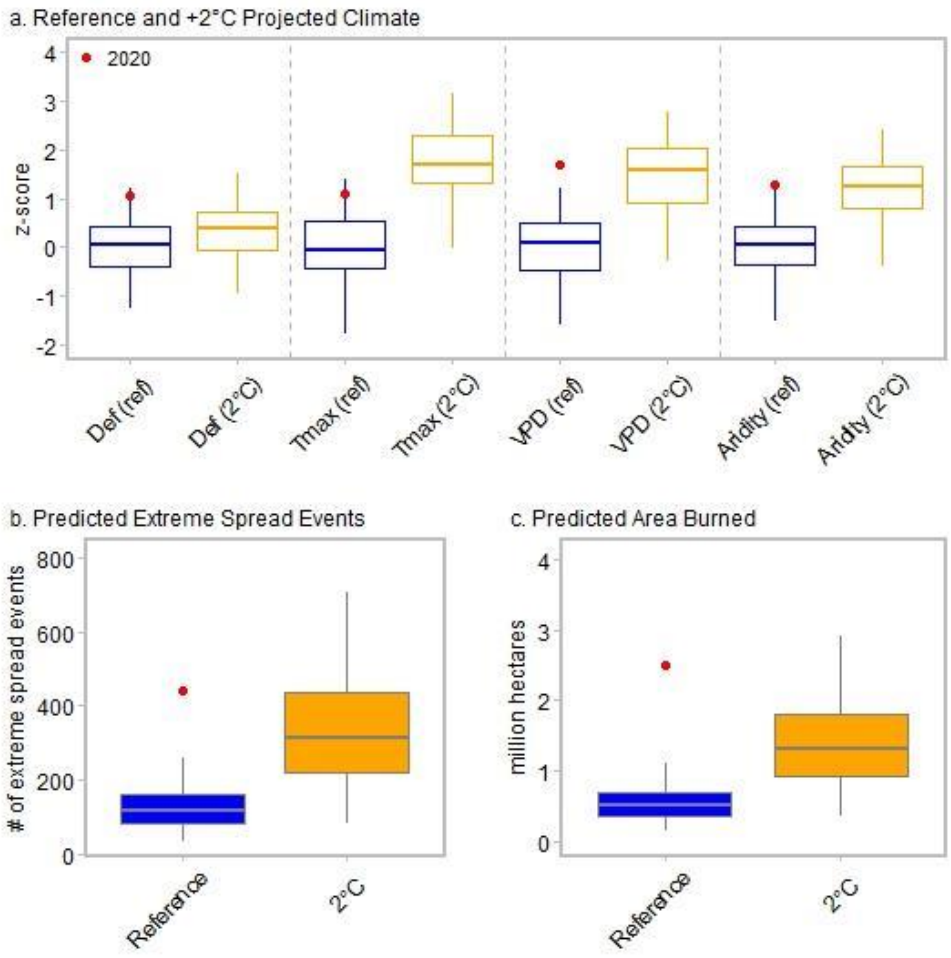

Figure 3- Reference period (1986-2015) vs. future (+2°C) projections (a) for four climate variables, Deficit, Tmax, VPD, and Aridity (defined in the text as the average of the other three variables), (b) predicted number of extreme events >1100 ha/day, and (c) annual area burned. Red dots represent observed climate and fire activity in 2020.

Better understanding the capacity for human activities to modulate the undesirable effects of extreme fire spread is also imperative. Contemporary fire management policies appear to be relatively ineffective in mitigating extreme fire spread events, which are occurring despite recent annual fire suppression expenditures of $1-3 billion in the US (data available from the National Interagency Fire Center, www.nifc.com). Explosive fire growth during extreme fire spread events can severely reduce the efficacy of fire suppression as currently practiced. Extreme burning conditions that facilitate early fire growth allow fires to escape initial attack; as these fires continue to grow, their size and potential to impact communities and other resources can subsequently overwhelm fire management resources. Given the likelihood of increasing societal and ecological exposure to extreme fire spread events, new approaches to fire management and policy may be needed (Cochrane & Bowman, 2021; Moritz et al., 2014; Smith et al., 2016). In some settings, management activities may be directed towards reducing undesirable fire effects, such as by promoting frequent but low-to-moderate severity fire to prevent anomalously severe fire and attendant ecological changes (Walker et al., 2018). In others, higher-severity prescribed fire and managed wildfire might be useful to change fuel types and reduce landscape flammability (e.g., shifts from conifer to broadleaf forest types). Enhancing community preparedness under extreme burning conditions will also be critical to safeguarding human lives and infrastructure.

ignition causes, machine learning, arson fires, southeastern France

Abstract

Knowledge about fire ignition causes and their spatiotemporal patterns can greatly enhance the efficiency of fire management and fire strategies. In France, the majority of forest fire research is based on a 2x2 km gridded database that provides amongst other information, the cause of fire ignition. According to the same database however, approximately 70% of all fires between 1973 and 2020 were recorded without a cause of ignition. Therefore, information on fire causes for a very large part of the fires that were recorded in the last 50 years is not taken into consideration and can potentially provide significant evidence on fire ignition patterns. As arson fires are of particular interest in southeastern France since they are the most frequent and account for the largest volume of burned area, this study aimed to exploit a fire ignition point geodatabase and machine learning methodologies, to create and evaluate a model that can identify whether unknown caused fires can be classified as arson or non-arson fires, based on numerous environmental and anthropogenic factors. The results of the study suggest that cause identification can be adequately accurate using such a model, although a larger fire database would increase overall performance.

1. Introduction

Fire ignition patterns can vary significantly both temporally and spatially depending on the cause of ignition (Curt et al., 2016) and can be impacted by a plethora of environmental and anthropogenic drivers (Catry et al., 2009; Syphard et al., 2008; Syphard and Keeley, 2015). Some studies have demonstrated that arson fires can potentially be predicted both spatially and temporally (Gonzalez-Olabarria et al., 2012; Penman et al., 2013). In SE France, arson (particularly pyromania and conflict/interest) is the most frequent ignition cause for large fires (100>ha) (Ganteaume and Jappiot, 2013). Recording fire causes and studying their spatiotemporal patterns is important for establishing useful fire policies (Rodrigues et al., 2014) since a better understanding can enhance the efficacy of fire prevention measures (Oliveira et al., 2012). In France according to the national fire database (Prométhée) that contains records of fire ignition causes, approximately 70% of all fires between 1973 and 2020 were ignited by an unknown cause. The percentage of non-identified causes is high, and it is an additional constraint to the already limited research conducted on fire ignition causes. As in many other disciplines, applications of machine learning methodologies have seen a significant increase in wildfire science over the past years (Jain et al., 2020). Thus, this study aims to examine whether a fire ignition point dataset coupled with machine learning methods can be used to identify the source (arson or non-arson) of unknown caused fires and evaluate the importance of several environmental and anthropogenic factors in determining the ignition source.

2. Data & Methodology

2.1. Study area

The study area covers the administrative department of "Bouches-du-Rhône", which according to the official forest fire database in France (Prométhée), ranks second in terms of burned area and fire frequency in mainland France (Figure 1, Table 1). The department is characterized by gentle slopes and low to intermediate altitudes that increase when moving eastwards. Population density (388.8 people/km^2) is higher in the eastern half of the department since that is where the second most populated city in France (Marseille) is found and because the

westernmost parts are covered by wetlands and a national park. Therefore, the westernmost section has a low potential for fire ignition and propagation but increases when moving towards the eastern half of the department.

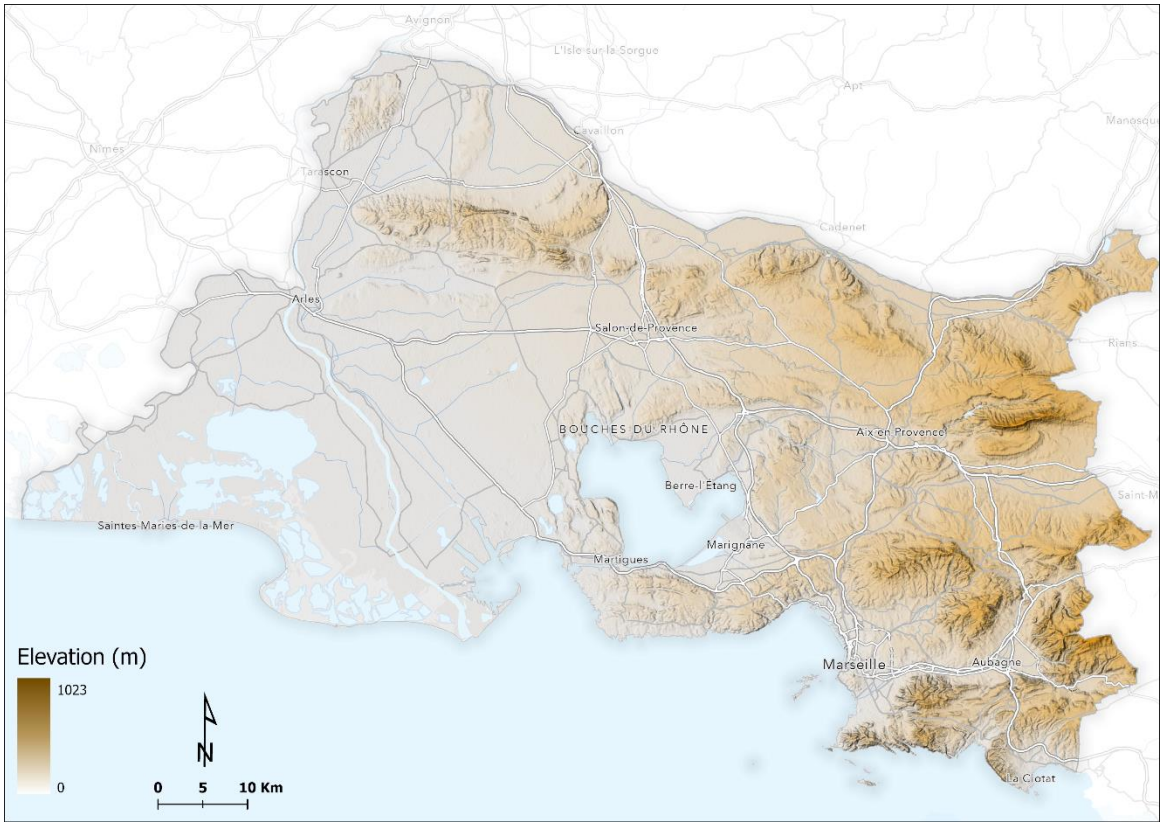

Figure 1 Departmental limits of Bouches-du-Rhônes overlaid on a 25 m Digital Elevation Model.

Table 1 Environmental characteristics of Bouches-du-Rhône.

Total area (km²)	3456
Forested area (km²)	1530
Mean slope (°)	8.8
Median slope (°)	5.7
Mean elevation (m)	142
Median elevation (m)	89

When considering only fires with a known cause, 63 % of the total burned area and approximately half (51 %) of all fire ignitions in the department are due to arson fires, according to Prométhée (Table 2). In addition, most of the large fires (>100 ha) in the study area are caused by arsonists (Figure 2). Even though negligence (professional & personal) is the second most frequent cause of fire ignition, it does not cause a proportionate volume of burned area.

Table 2 Number of fires and volume of burned area per ignition cause from 1973 to 2020 in Bouches-du-Rhônes.

Fire Ignitions (#)	Percentage (%)	Burned Area (ha)	Percentage (%)	Cause
349	3.3	3,020	3.3	Accidental
161	1.5	335	0.4	Natural
1,034	9.7	5,223	5.7	Negligence
1,556	14.7	14,493	15.7	Arson
7,524	70.8	69,105	75	Unknown
10,624	-	92,176	-	Total

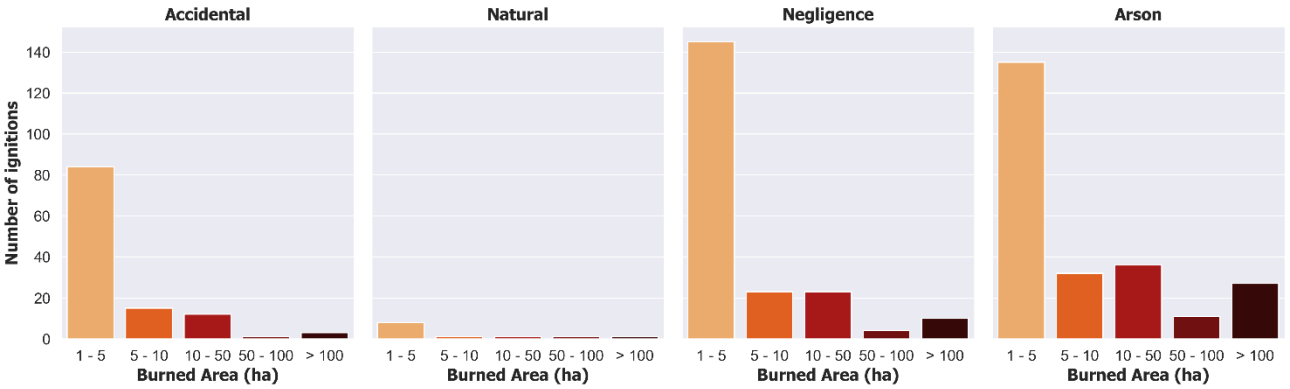

Figure 2 Number of fires per volume category of burned area (> 1ha) and ignition cause from 1973 to 2020.

2.2. Data

2.2.1. Fire database

In France, the majority of forest fire research is based on Prométhée, the national database for forest fires. The specific fire database holds records of fires starting from 1973 and it includes information such as burned area, cause of ignition, date, and approximate location (within a 2x2 km grid) for each fire. In the current study, we used a geographic database that contains exact coordinates of fire ignitions that is provided by the National Forestry Office (Office National des Forêts, ONF), which to the best of our knowledge is the second time being utilized after Ganteaume and Long-Fournel, 2015. The dataset consists of 3,234 fire ignition points ranging from 1960 to 2012, which however does not contain information on the cause of ignition. To enrich the ONF point database with the cause of ignition, two additional databases were used (Figure 3). Information from the Prométhée database was firstly merged with a polygon fire geodatabase that is described in Bountzouklis et al., 2022 and subsequently spatially joined with the point geodatabase resulting in a combined dataset that contains ignition coordinates, burn scars, and cause of ignition.

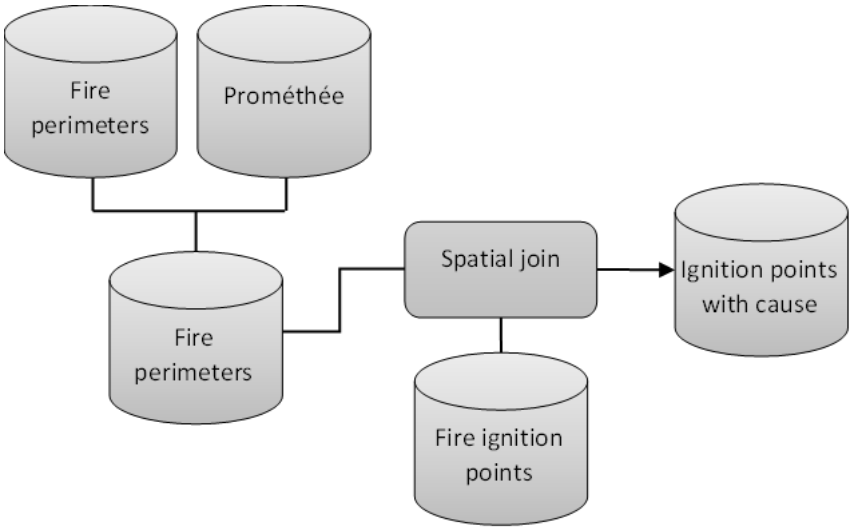

Figure 3Flow chart depicting the processing steps to generate the final dataset.

As earlier records on fire causes are considered less reliable (Ganteaume and Jappiot, 2013) only fires from 1996 to 2012 were considered, resulting in 323 fires (Figure 4). it was deemed best to classify causes into two major categories, arson and non-arson, due to the limited recorded number of fires caused by accident, negligence and lightning strikes but also due to the significance of arson fires in the specific area.

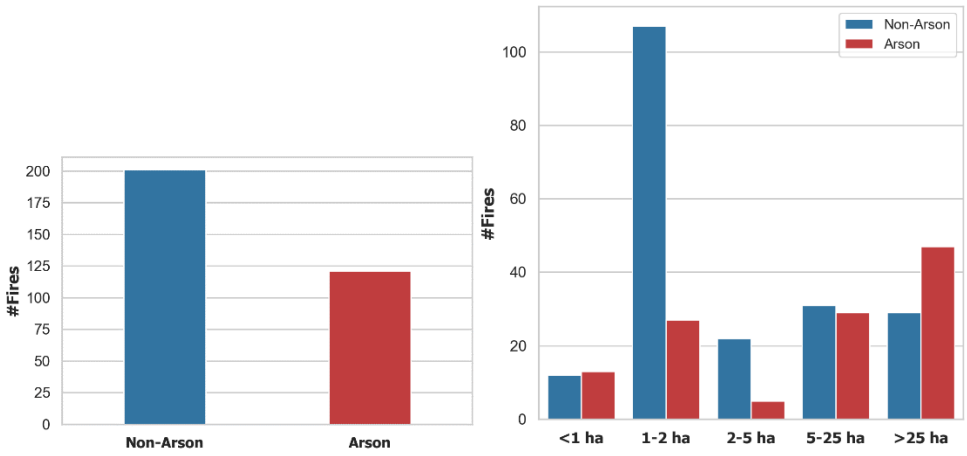

Figure 4 Number of fires per cause and burned area size.

2.2.2. Explanatory variables

Multiple environmental and socioeconomic factors (Table 3 & Figure 5) that are known to be associated with forest fires, were acquired by a combination of European and national databases, in order to train a model that can identify the ignition cause of a fire. To account for any potential geometric errors of the ignition points and more importantly to include contextual geographic information, a circular buffer zone (500 m) was created around each fire ignition point to extract relative information.

Table 3 List of environmental, anthropogenic and spatiotemporal variables considered.

Type	Name	Description	Source
Land Cover	Artificial surfaces	Percentage of cover within each zone	Corine Land Cover - 2006
	Agriculture		
	Vegetation		
	Water/ Wetlands		
Topographic	Slope inclination	Mean inclination (º)	National Geographic Institute - 5 m spatial resolution
	Slope aspect	Percentage of cover within each zone (Flat, N, E, S, W)	
	Elevation	Mean elevation (m) above sea level	
	Topographic wetness index	Topographic-driven control on soil moisture	
Vegetation type	Coniferous	Percentage of cover within each zone	National Geographic Institute - 2006
	Coppice		
	Hardwood		
	Open Forest		
	Shrublands		
Anthropogenic	Population density	Individuals per sq. m.	National Institute of Statistics and Economic Studies - Sub-municipal level - 2006
	Gini index	Inequality index	
	Income	Mean taxable income (€)	
	Unemployment	Unemployment rate (%)	
	Primary road distance	Euclidean distance from fire location (m)	National Geographic Institute - 2008
	Secondary road distance		
	Power pylons distance		
	Railway distance		
	Wildland Urban Interface distance		
	House density	Buildings per sq. m.	
Spatiotemporal characteristics	Season	Winter, spring, summer, autumn	Fire database
	Burned area size	<1 ha, 1-2 ha, 1-2 ha, 2-5 ha, 5-25 ha, >25 ha	
	Coordinates	XY coordinates of each fire	

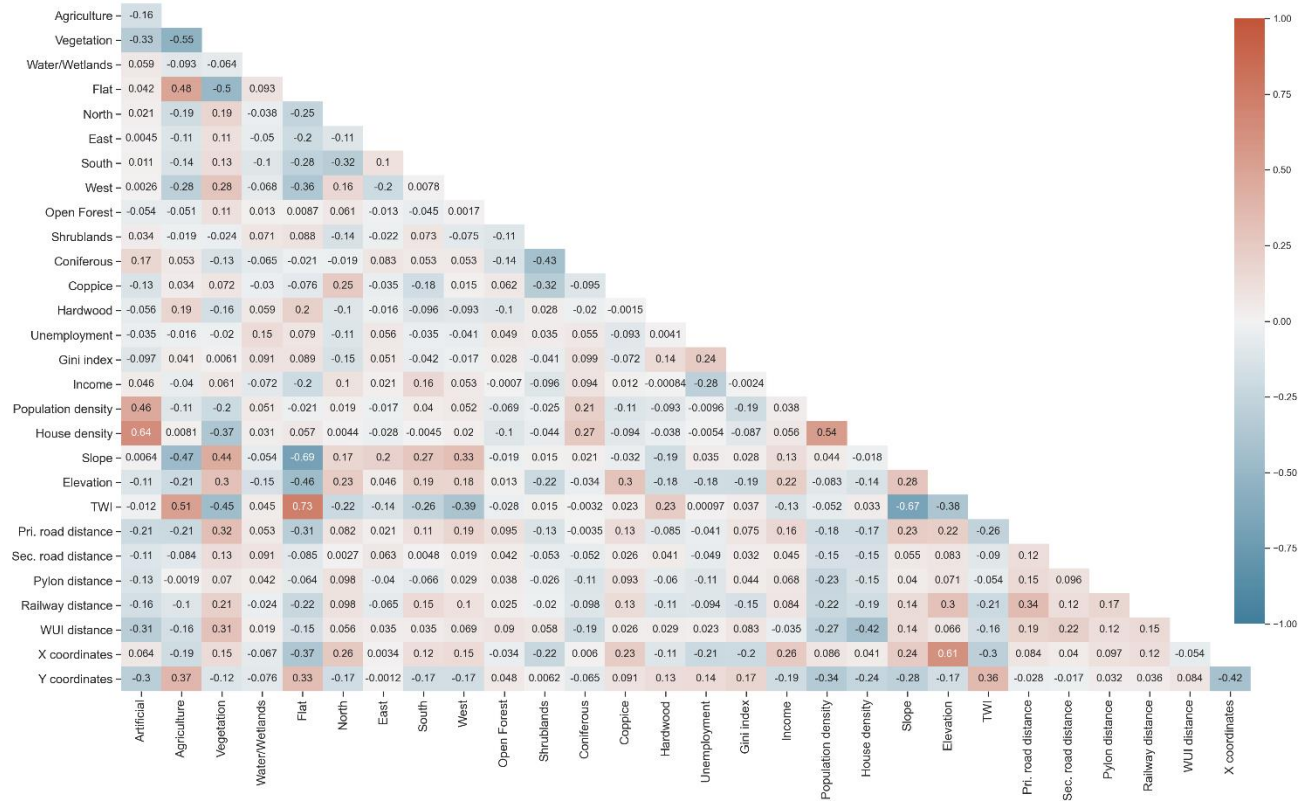

Figure 5 Kendall's Tau rank correlation coefficient heatmap of explanatory variables.

2.3. Methods

The analysis of the data is based on Random Forests (Breiman, 2001), a well-established machine learning algorithm in many disciplines but also in wildfire science (Jain et al., 2020). In order to train the model, 70% of the original dataset was utilized, while the remaining 30% was used for testing the accuracy in predicting the cause of a fire. Due to the limited number of observations, the process of splitting the data (using the same ratio) and executing the model was iterated (n=300) to have a more consistent perception of the accuracy of the model. Additionally, the processing chain included tuning the algorithm's hyperparameters as well as calculating the feature importance score for all variables. Feature importance was based on the Gini impurity method which can be used as a diagnostic which contributes to understanding which variables are driving the results of a model and which ones can be discarded.

3. Results

The accuracy of the model is illustrated in the form of a boxplot (Figure 6) that represents accuracy scores from all iterations of the model. The accuracy of the model to classify unknown caused fires can vary substantially ranging from 56% to 76% (median value 67%), due to the small size of the dataset.

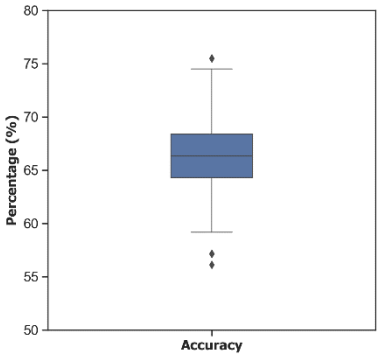

Figure 6 Boxplot representing Random Forest's classification accuracy for all iterations (n=300). (i) Bar within the box is the median value, (ii) bottom part of the box is the first quartile, and (iii) top part of the box is the third quartile. Whiskers represent observations outside the middle 50 % and points represent outliers.

Figure 7 shows the importance values of each explanatory variable used in the model. Overall, anthropogenic features (in blue) appear to surpass in importance the rest. Moreover, topographic factors (in brown) seem to be more important than land cover and vegetation type while spatiotemporal variables except for XY coordinates hold the lowest importance. More specifically, Secondary road distance, Shrublands and Unemployment rate are the three variables displaying the highest importance. Finally, several variables mainly related to spatiotemporal characteristics and others such as certain vegetation types (Hardwood & Coppice) as well as Water can be excluded to decrease model complexity and execution time.

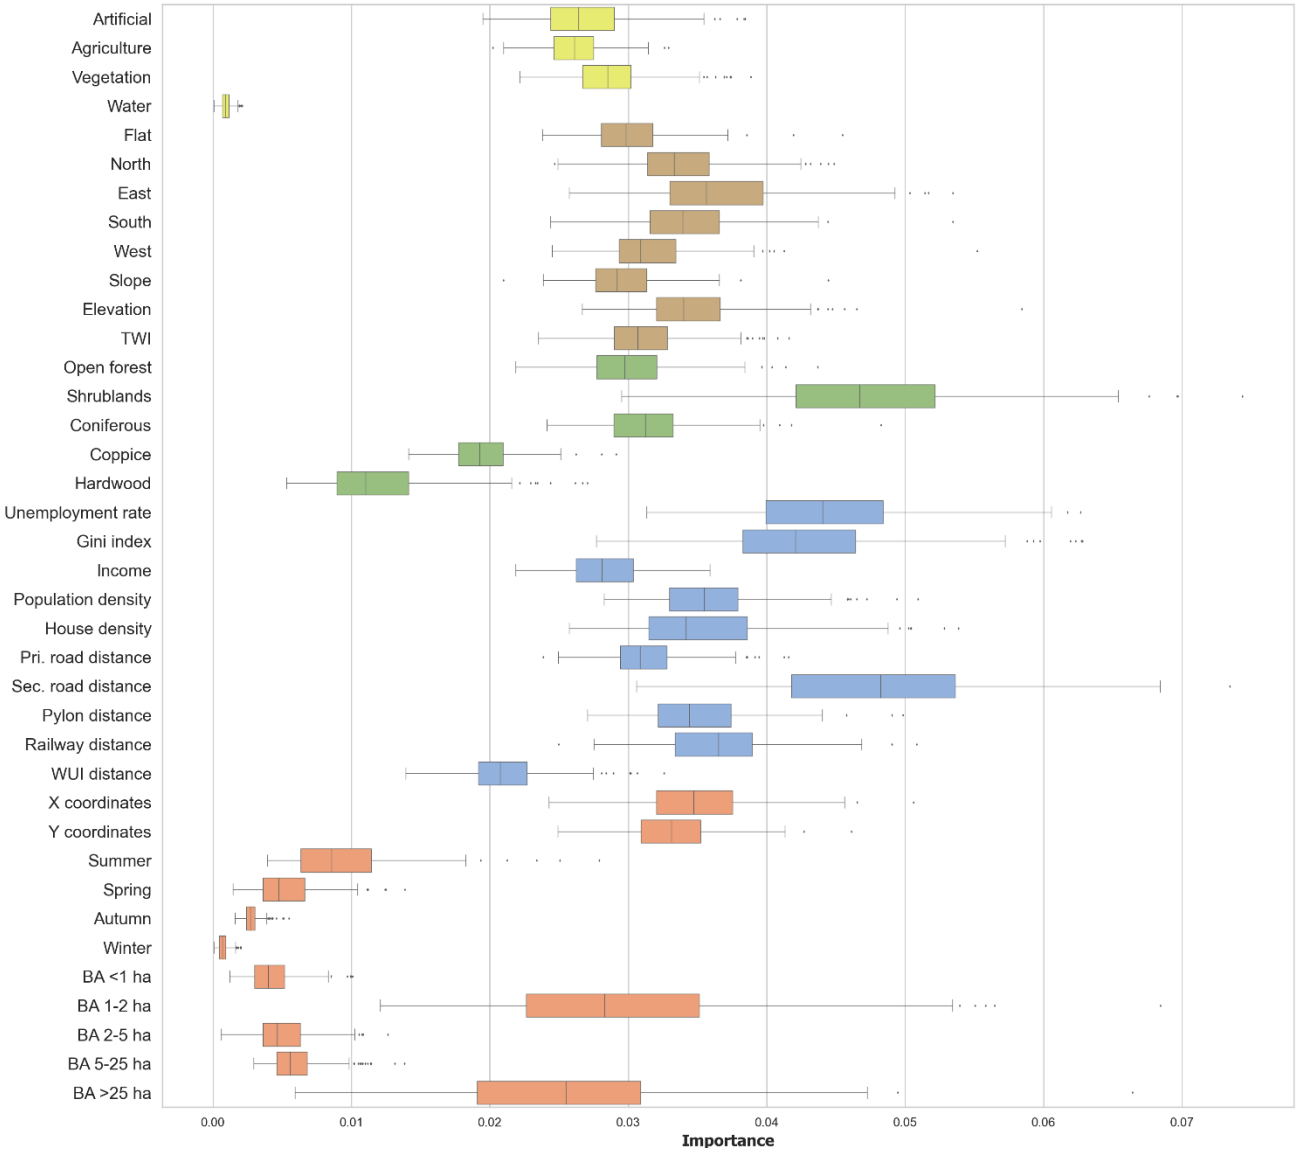

Figure 7 Distribution of the variable importance values for all iterations (n=300).

4. Conclusion

The results of the study suggest that the source of unknown caused fires can be identified at an acceptable level of accuracy even with a limited number of fires. Anthropogenic drivers such as distance to secondary roads and unemployment rate, along with higher volumes of shrublands around ignition points are the most important features in determining the classification of unknown caused fires for the specific area.
Overall performance of such models would most likely greatly benefit from the exploitation of larger datasets as well as from the inclusion of weather-related variables. Finally, as location holds particular importance over certain fire causes, spatial extensions of machine learning algorithms such as Geographic random forests

(Georganos et al., 2021) and Geographically weighted neural networks (Hagenauer and Helbich, 2022) could provide significant enhancements over the original algorithms.

Fire regime, wildfire, fire causes, pyrogeography, forest fire statistics

Abstract

Scots pine (*Pinus sylvestris* L.) covers around 60% of Poland's forests. Pine stands are considered as fire prone, which exposes a large area of forests to the risk of fire ignition and spread. This is confirmed by the statistics, among which Poland belongs to the group of European countries where forest fires occur most often. In addition, the most common cause of fires is deliberate arson. The contemporary fire pattern in lowland forests in Poland is characterised by a large number of fires with a small burnt area.

Understanding historical fire regime is important for the correct assessment of contemporary phenomena. However, compared to boreal or Mediterranean biomes, the characteristics of historical forest fires in Poland are not well researched. To fill this knowledge gap, a review of national thematic literature and historical documents was carried out. There is a limited literature describing a historical fire situation and just few studies have quantified the historical frequency of forest fires. Documentary records are often incomplete, both in time and space. In our research, to better understand the forest fire history paradigm, we took a holistic approach, integrating data from archives, historical sources (research literature and handbooks), press reports, scientific papers, and existing fire databases. An attempt to reconstruct the history of forest fires was carried out for Poland, considering that the modern borders were established in 1945. The reconstruction of fire event chronology and statistics (annual number of fires and burnt area) is presented, which will give a picture of this phenomenon in its various aspects, including periodisation in the decades, with particular emphasis on the 20th and 21st centuries.

This research allowed for the reconstruction of fire statistics in the period from 1920 to the present day. Due to historical conditions, the data for the period 1920-1945 are incomplete, mainly the information on the number of fires is unavailable. The available data show that at least 210,000 ha of forests were burnt during this period. In the years 1946-2020 in Polish forests 342,204 fires occurred, as a result of which 407,093 ha were burnt. The largest number of forest fires (17,088) was recorded in 2003, while the largest area was burnt in 1992 (43,755 ha). On an annual average, in the years 1946-2020 there were 4,562 fires on an area of 5,428 ha, and the area of a single fire was 1.19 ha. In the analysed period, it was observed that the largest number of fires occurred in the decade of 2001-2010 (approx. 9.4 thousand per year), and the largest area of fires in the decade of 1991-2000 (approx. 11 thousand ha per year). The average area of a single fire decreased from 2.35 ha in the decade of 1951-1960 to 0.44 in the last decade.

It is the first such complete study of the history of fires in Poland and it may establish the basis for further work on understanding the fire regime of Central European lowland forests.

1. Introduction

Due to the historical socio-economic transformations and development of silviculture knowledge, as well as climate and soil configuration, Scots pine became the dominant species in the Central European lowlands in the 19th century. This species finds the most suitable growing conditions in Poland. This is the main reason *Pinus sylvestris* is the dominant species in Polish forests and currently covers over 60% of the forest area. Pine stands, because of the high flammability of resins and essential oils, are susceptible to fires, which exposes a large area of forests in Poland to the risk of ignition and their rapid spread – an example of such a devastating fire was the one in 1992, during which almost 10,000 ha were burnt. This means that the species composition of Polish stands is an environment favourable to the growth of fire of considerable size.

The influence of the dominant species on the possibility of fire ignition is confirmed by the statistics, among which Poland belongs to the group of European countries where forest fires occur most often. In addition, the fact that the most common cause of fires is deliberate arson raises the problem to a higher level. Poland, Spain and Italy are the only three European countries where deliberate fires are the most representative cause. In all other European countries, outbreaks of forest fires result from human activity with no intention of causing damage (i.e. accident or neglect).

The contemporary fire pattern in the Central European lowland forests in Poland is characterised by a large number of fires (approx. 7,300 annual average in the last decade) with a small total burnt area (approx. 3,000 ha per year). This translates into low values of the average area of a single fire (0.44 ha). This characteristic places Poland in the top three in terms of the number of fires in Europe but in terms of the area around the 10th place (depending on the year).

Understanding historical fire regimes is of fundamental importance for the correct assessment of contemporary phenomena. Understanding the characteristics of fire history might help in identifying the impacts of climate change, understanding ecosystem processes, and developing fire management principles and objectives. However, compared to boreal or Mediterranean biomes, the historical characteristics of forest fires in Poland are not well researched. To fill this knowledge gap, a review of local thematic works and historical documents was carried out. There is limited literature describing a historical fire situation, and few studies have quantified the historical frequency of forest fires. Documentary records are often incomplete, both in time and space. This situation was influenced by historical events, ranging from the partitions of the country, through the First World War, the incompatibility of various forest management systems in 3 parts of the post-war country, intense warfare during World War II, and the change of the country's borders in 1945. Moreover, during the period 1945-2020, Poland has increased its forest share from 20 to 30%, planting new forests at over 3 million ha. These changes likely affected the pattern of the forest fires as well.

2. Methodology

In this study, to better understand the forest fire history paradigm, a holistic approach was used, integrating data from archives, historical sources, available literature (both scientific and branch textbooks for the forestry sector published during the analysed period), press reports, and existing fire databases.

The collected materials made it possible to systematize the historical data on forest fires in terms of numbers and area burnt, and the following parameters were calculated: **average area of single fire** – determined as the quotient of the annual sum of forest area burned and the number of fires expressed in hectares, which is a measure of the effectiveness of the forest fire protection system, **fire concentration** – the density of the number of fires calculated per 1000 ha of forest, **burnout intensity** – determined as the quotient of the burnt area in a given year and the forest area expressed in hectares per 1000 ha. The last two parameters make it possible to compare the dynamics of changes in the number of fires and the burnt area, taking into account the changes in Poland's forest cover over time.

In addition, the research also focused on the historical background that allows for understanding the context and the changing paradigm of forest fires and their significance in individual decades.

3. Results

The research carried out in this study allowed for the reconstruction of fire statistics for the entire country from 1920 to the present. The analysis of fire data over more than 100 years also provides insight and perspective into the context of changes taking place in Polish society and forest management.

The first Polish archival records referring to the issue of forest fires appear in the "Warcki Statutes" of 1423. The legal provisions contained therein prohibited lighting fires in the forest or in its vicinity under pain of death. Documents drawn up in the following centuries mainly described bans on using fire and the penalties for disobeying them. From the mid-seventeenth century onwards, more detailed instructions on how to protect forest property against fire and how to prevent it began to appear. However, there is no aggregated source material on the extent of forest fire losses in Poland before the second half of the 20th century.

Due to historical conditions, the data for the period 1920-1945 is incomplete, mainly the information on the number of fires is missing. The available data show that at least 210,000 ha of forests were burnt during this period. After World War I and the regaining of independence, Polish forests were devastated by the predatory economy of the occupying powers and as a result of prolonged warfare. The damaged, understocked and grass covered forests often felt victim to fires. However, during the entire inter-war period (1918-1939), forest fires were of little economic importance due to the species composition of forest stands at that time, their geographical location and limited penetration of forests by the public. Losses caused by forest fires in the period of World War II (1939-1945) were estimated at 150,000 burnt hectares.

In the following post-war years (1946-1950), the fire situation remained at a similar, high level. The post-war consequences and causes of the deteriorating forest fire safety situation included: people's disinclination to obey the rules, lowered sense of responsibility and negligence, explosives and mines scattered in the forests as well as partisan units stationed in the forests.

Compared to the first years of post-war history, the situation in the following decade (1951-1960) calms down and the losses caused by forest fires decrease significantly. Forest fire protection becomes a very important issue in the national economy. Between 1961 and 1970, an average of about 1,500 fires occur annually in forests on an area of almost 2,300 ha, deliberate arson is quite rare, sporadic cases have no social significance.

By the end of the 1970s, as a result of post-war afforestation of wasteland and poor agricultural land, the forest cover of the country reached 27% (compared to 20.8% in 1946). Huge forest patches of pine monocultures were created (the share of this species in the forest stand composition reached 70%), which made the Polish woodlands prone to forest fires. In the decade of 1971-1980 almost 1,900 forest fires burning 2,600 ha occurred annually.

Extreme water shortages in the summers of 1982 and 1983 resulted, inter alia, in the first catastrophic (>1000 ha) forest fire after the Second World War. The '80s also showed the beginning of a worrying trend of increasing numbers of fires from arson. It resulted in increased annual number of fires (3300) and area burned (4300 ha).

Industrial pollution contributed to the increase in forest fire danger in the 1990s, damaging, to varying degrees, up to 80% of the country's forest stands. This contributed to the overexposure of stands, the weed infestation of the forest floor, and increase of fuel load. In comparison with the previous decades, there was a clear, dynamic increase in the average annual values characterising the fire seasons. During systemic transformation in Poland (1989-1991), intentional arson became an increasingly important cause of fires. The year 1992 turned out to be disastrous, when 43,755 ha of forest (resulting from 11,858 fires) were burnt. This area represented 9.68% of the total area burnt that year in the forests of Europe. The most tragic fire occurred on 26 August 1992 in Kuźnia Raciborska - it reached in total 9,062 ha. Because of the number of forces involved in its extinguishing and the tragic death of rescuers that fire has remained to this day the most tragic wildfires in the modern history of Poland. The groundbreaking events of 1992 had a huge impact on the directions of improvement of the State Forests fire protection system, the effects of which will be visible in the coming decades. Annually, more than 8,300 forest fires started that damaged over 10,000 ha.

The first decade of the new millennium brought a record annual average number of fires – 9,300 in forests of all ownership forms. This positions Poland in the group of European countries where fires occur most frequently. The largest number of forest fires was reported in 2003, when there were over 17,088 fires in a total area of 21,500 hectares. It was record year by ignition number in Poland's post-war history, which was caused by illegal and uncontrolled agricultural burning. After joining the European Union, the problem lost its importance.

Between 2011 and 2020 there were 72,785 forest fires with a total area of 31,674 ha. This means that in Poland we are dealing with a large number of small incidents. In the last decade, no further upward trend in the number and area of forest fires has been observed, which allows us to conclude that the forecasted upward trend in these characteristics, related to the effects of climate change, has not yet taken place in the area of Poland.

In the years 1946-2020, 342,204 fires occurred in Polish forests, as a result of which 407,093 ha were burnt.

Table 1 - Forest fire statistics in decades from 1951 to 2020

Years	Forest fire no.	Mean	Median	Area burned [ha]	Mean	Median	Single fire avg area	Fire concentration	Burnout intensity
1951-1960	14 998	1 500	1 585	35 294	3 529	3 423	2.35	0.20	0.48
1961-1970	15 134	1 513	958	23 388	2 339	1 607	1.55	0.19	0.29
1971-1980	18 728	1 873	1 765	26 459	2 646	1 990	1.41	0.22	0.31
1981-1990	32 929	3 293	3 431	43 220	4 322	4 085	1.31	0.38	0.50
1991-2000	83 649	8 365	8 172	109 146	10 915	7 652	1.30	0.95	1.24
2001-2010	93 909	9 391	8 979	57 833	5 783	3 572	0.62	1.04	0.64
2011-2020	72 785	7 279	6 882	31 674	3 167	2 793	0.44	0.79	0.34

4. Summary

On an annual average, in the years 1946-2020, there were 4,562 fires on an area of 5,428 ha, and the area of a single fire was 1.19 ha (table 1). In the analyzed period, it was observed that the highest number of fires occurred in the decade of 2001-2010 (approx. 9.4 thousand per year), and the largest area of fires in 1991-2000 (approx. 11 thousand ha per year). The average area of a single fire decreased from 2.35 ha in the 1950s to 0.44 in the last decade. Taking into consideration changes in forest area, fire concentration was stable until 1980s and peaked in 2001-2010, whereas burnout intensity is now very low compared to 1990s.

It is the first such complete study of the history of fires in Poland and it may make up the basis for further work on understanding the fire regime of Central European lowland.

FRISCO: Managing fire-induced risks of water quality contamination

Fire assessment and modelling; burnt area hydrology; hydrological ecosystem services; water resources management

Abstract

Fires can contaminate streams with fine sediments, nutrients, and ashes, threatening aquatic ecosystems and water supplies. Recent research on sediment and contaminant mobilization processes in burnt areas exists but linking mobilization with water contamination processes at larger scales remains challenging. In the FRISCO project, we argue that recent advances in understanding fire behavior and post-fire landscapes can overcome the major challenges in assessing and managing post-fire contamination risks. Links between fire characteristics and hydrologic impacts can be assessed by combining remote sensing and modeling tools with studies on fire severity and impacts on vegetation and soils. The impacts of fires on contaminant transport pathways can be assessed by combining landscape connectivity and hydrological modeling of burnt areas with field research on contaminant mobilization and transport. Overall, FRISCO researchers want to investigate the vulnerability of Mediterranean streams and water resources to contamination by fires. Our main results include: (i) map of post-fire sediment and ash transport pathways using satellite imagery; and (ii) statistical analysis of relation between fire characteristics (e.g., burnt area and fire severity) and water contaminants. We hope that the results help stakeholders in the development of the best practices for post-fire contamination management.

1. Introduction

Land abandonment in the Mediterranean has led to the combination of fuel build-up with widespread afforestation and an increase in the frequency and severity of wildfires (Moreira et al., 2020). Post-fire processes can contaminate streams with fine sediments, nutrients, and ashes (Verkaik et al., 2013), threatening aquatic ecosystems (Martin, 2016) and water supplies (Shakesby et al., 2016). Recent research focuses on sediment and contaminant mobilization processes in burnt areas (Nunes, Doerr, et al., 2018), but difficulties in linking mobilization with water contamination processes at larger scales persist (Santín et al., 2016).

We argue that recent developments in understanding fire behavior and post-fire landscapes can overcome most of those difficulties (Santín et al., 2016), such as: (i) the relationship between fire spread descriptors and hydrological impacts (Nunes, Doerr, et al., 2018; Sá et al., 2017), using the combination of remote sensing techniques and modeling (Benali et al., 2017; Chafer et al., 2016; Sá et al., 2018) tools with studies on burn severity and impacts on vegetation and soils (Cardil et al., 2019; Keesstra et al., 2018; Moody et al., 2016) to

estimate the hydrological impacts of fires at large scales; and (ii) the impacts of fires on contaminant transport pathways (Martínez-Murillo & López-Vicente, 2018) using the latest methodologies of landscape connectivity (Martínez-Murillo & López-Vicente, 2018; Nunes, Naranjo Quintanilla, et al., 2018) and hydrological modeling of burnt areas (Campos et al., 2016) combined with field research on contaminant mobilization and transport (Hawtree et al., 2014).

The FRISCO project takes advantage of these advances to answer the question: How vulnerable are Mediterranean streams and water resources to contamination by fires? This study aims to present the current developments of the project on developing the information and tools needed to address this question.

2. Data and Methods

The FRISCO project focuses on Portugal as representative of the Mediterranean region. Portugal has an extensive forest cover and has experienced frequent and recurrent forest fires since the 1970s under two distinct fire regimes (Santín et al., 2016). It also has a large and open-access historical water quality database (SNIRH; http://snirh.pt).

This project has 72 main study areas that: (i) represent key water supply sources, e.g., direct water uptake from streams, low-capacity reservoirs, and large volume reservoirs; (ii) represent different fire regimes; and (iii) have available water quality data from the SNIRH network.Currently, we are working on 3 of 5 main tasks of FRISCO:

Task 1 - Characterization of fire impacts on vegetation and soils**:** with the main objective of combining satellite imagery and field data to characterize the fire impacts on vegetation and soils in mainland Portugal, in the last 20 years (2001 to 2020);

Task 2 – Characterization of fire impacts on contaminant mobilization and transport to streams: with the main objective of combining the information produced in task 1 with the new developments in connectivity theory and modelling, to characterize the contaminant mobilization and transport to streams for key water supply sources;

Task 3 - Identification of post-fire contamination episodes in key water supply sources and their main drivers: used historical water quality data and statistical analysis to identify post-fire contamination episodes in the key water supply sources in the last 20 years and assess their main drivers in coordination with water managers.

3. Results and discussion

The results of the 1st stage of FRISCO project show the new state of the art in the study of post-fire water contamination and in the establishment of the relationship between port-fire processes and post-fire hydrology. In particular, (i) the modelling of post-fire sediment and ash transport pathways using satellite imagery datasets; and (ii) the improvement of knowledge on the relations between fire, vegetation, soils, and water, which was done through statistical analysis of relation between fire characteristics (e.g., burnt area and fire severity) and water contaminants.

4. Conclusion

The FRISCO project had advanced the state of the art in the development of new knowledge on the relations between fire, vegetation, soils, and water, overcoming the main limitation for further progress (Santín et al., 2016); help understand and assess the impacts of fire on the provision of hydrological services by forests (Campos et al., 2016); and take fire into account in the assessment of the impacts of climate and land-use changes on water resources, addressing a major uncertainty in adaptation to climate change planning (Santín et al., 2016). As future work, we hope to (i) model a contamination risk index, which will arise to an operational tool that will allow qualitative risk for each water body; and (ii) a combined fire and contamination model that will help to get an operational risk mitigation manual for water managers.

5. Acknowledgements

This work was financed by the project FRISCO - managing Fire-induced RISks of water quality Contamination (PCIF/MPG/0044/2018). This work was also supported by National Funds through FCT - Foundation for Science and Technology under the project UIDB/04033/2020, and funding attributed to the CE3C research center (UIDB/00329/2020).

Keywords

Wild fire, burned area, random area, probability density function, Riemann integral of a random function.

Abstract

We show that the probability density function (PDF) of a burned area enclosed by a random fire-perimeter is driven by the PDF of the bounding-box sides. In particular, the random value of the area emerges to be proportional to the random position of the bounding-box sides times an averaged coefficient dependent on the geometry of the burned area. Therefore, the two PDFs are functionally equal. This means that the PDF of the burned area is driven and functionally equal to the PDF of the position of the head of the fire. The displacement of the head of the fire is given by the rate of spread (ROS), thus the PDF of the burned area results to be driven and equal to the PDF of the ROS. This result holds in general whenever the fire exhibits an advancement along a main direction. The main theoretical result has been tested by different families of stochastic processes. This study can be understood as a start for the development of a theory of stochastic dynamics of wildfire propagation with the aim, for example, to provide physically-grounded initial perturbations of wildfire perimeters for ensemble forecasting.

1. Introduction and Motivation

The determination of the spreading of wildfires is affected by large errors because of such predicting and modelling difficulties. As a consequence of this complexity, the evaluation of fire spreading predictions relies on scoring methods (Filippi 2013, Filippi 2014). Because of such unpredictability, in analogy with the weather forecast, ensemble forecasting has been formulated for wild fires, see, e.g., (Finney 2011, Allaire 2021), together with the application of data assimilation procedure, see, e.g., (Mandel 2008, Rochoux 2014, Rochoux 2015, Ferragut 2015). The idea of ensemble forecasting is based on the concept of stochastic dynamics that describes the evolution of the probability of certain observables. This limit is often associated with the rapid growth of uncertainty originating in the initial conditions; these arise both from imperfect and incomplete observations, and from inaccuracies in the formulation of the model both in terms of its physical processes and its computational representation. Ensemble prediction is a practical method to find a single, deterministic forecast with an estimate of the probability of nearby forecast states. Uncertainties in prediction by fire simulators are statistically related to the simulators' dependence on the required parameters, such that sensitivity analysis is considered for improving the reliability of predictions (Trucchia 2019, Prieto 2015, Asensio 2020) and also on the regional-scale weather prediction. Thus, such uncertainties are covered by probabilistic predictions in terms of ensemble forecasts through a proper distribution of input parameters (Allaire 2018, Allaire 2020, Allaire 2021).

The present research goes in the direction to establish the stochastic dynamics of wild fire spreading. In particular we show that the probability density function (PDF) of a burned area enclosed by a random fire-perimeter is driven by the PDF of the bounding-box sides.

2. Methods

We study the Riemann integral

$$A(t) = \int_0^{a(t)} y(x,t)\, dx,\ y(x,t) \geq 0\ \forall x, \forall t \geq 0$$

when $y(x,t)$ is replaced by a random function and $a(t)$ is replaced by a nondecreasing stochastic process. We show that, under quite general conditions in the random setting, the randomness of the outcome of the integral depends only on the randomness of the upper-bound of the integration interval such that the PDF of the random counter-part of $A(t)$ is ruled by the PDF of the random counter-part of $a(t)$. The same holds for the governing equations of the corresponding PDFs. Hence, we finally provide the PDF of the burned area in terms of the PDF of the ROS with the aim to start the development of a theory for stochastic dynamic predictions of wildfire propagation.

Observable $A(t)$ can be understood as an area that evolves in time and then its interpretation as the burned area of a wildfire is straightforward. In particular, if *x*-axis is aligned with the wind, the point $a(t)$ describes the motion of the head of the fire and then it is driven by the rate of spread. In the context of wildfires, the equation states that the evolution of the statistics of the burned area is determined by the evolution of the head of the fire times the mean value of the function enclosing the area. We report that that the exact shape of the function is not important and we don't account for it in this work. The perimeter of the fire perimeter is assumed to be a noisy ellipse and we use six models of random perturbations in order to capture the stochastic nature of it on each realization. Examples of the random functions enclosing the area for the six models of random perturbations are shown in Figure 1, focusing only on the first quadrant.

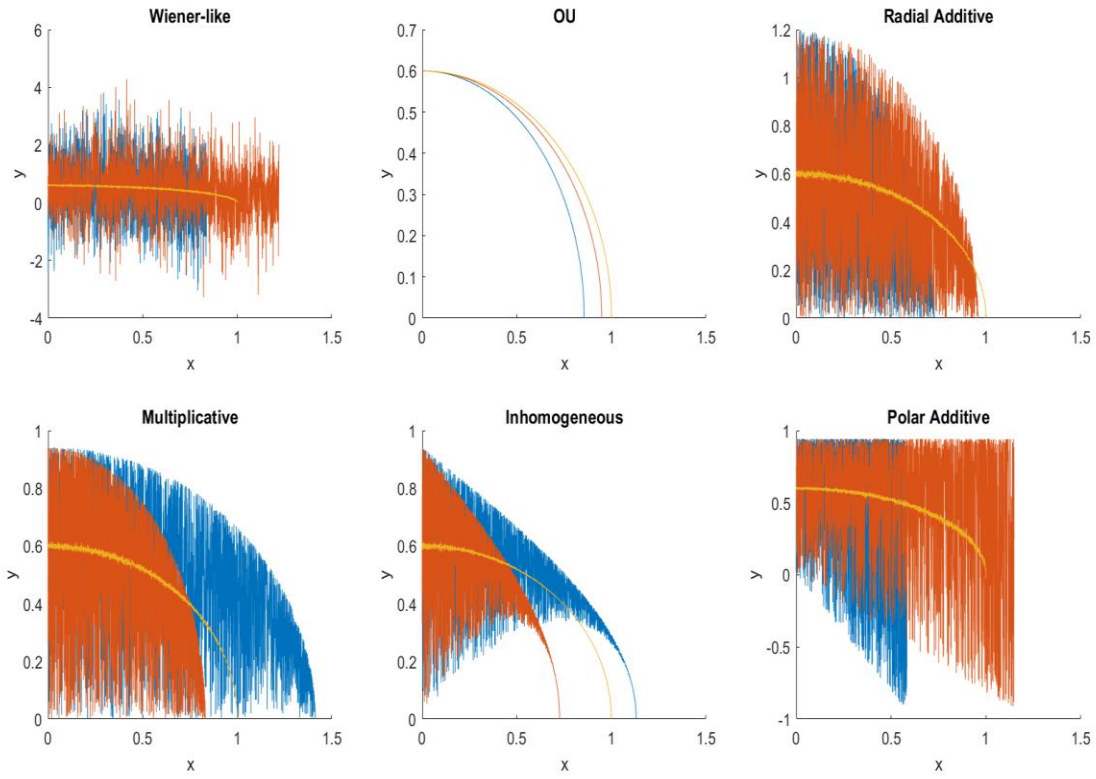

Figure 1 - Two realizations (blue and orange) of the noisy ellipse for the six random perturbations. The mean fire perimeter is also plotted (yellow).

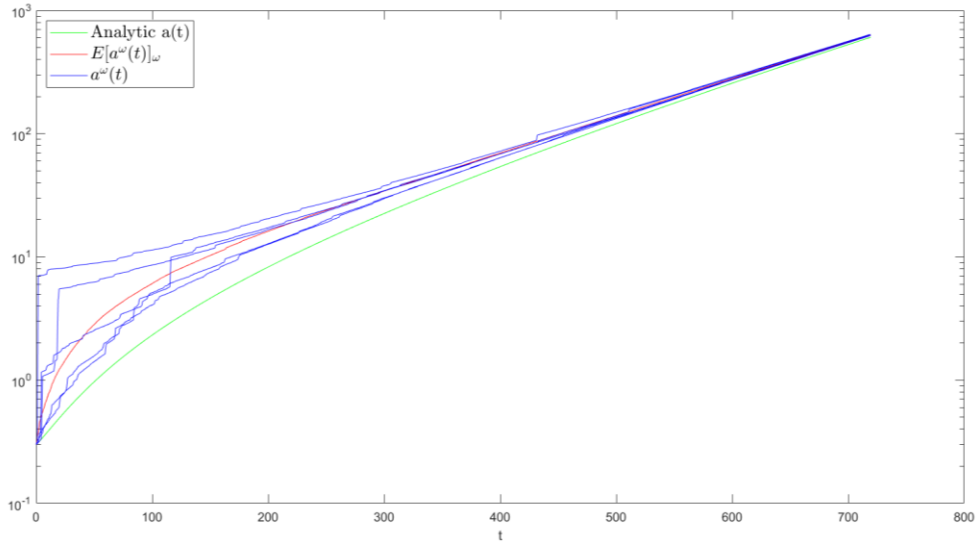

Figure 2 - Five trajectories (blue) of the head of the fire following Viegas' evolution model and lognormal perturbations and the expected value over all the realizations (red). The lowermost line (green) corresponds to the analytic value without noise. Logarithmic y-axis.

The time evolution of the head of the fire is modelized using Viegas' ROS model for eruptive fires (Viegas 2005, Viegas 2006). We use the differential equation and parameters as presented for herbaceous fuel (Viegas 2006), being R the rate of spread. The evolution of the perpendicular direction (the vertical semiaxis in the case of an elliptic-like curve) is taken as propagating with constant ROS. We take a convenient numerical value based on (Rothermel 1972) and (Catchpole 1998). For each realization a perturbation is applied to the analytical value of the head of the fire by using a lognormal PDF. All the realizations are initialized at the same point and we let them evolve as it follows. Some trajectories of the head of the fire are shown in Figure 2 together with the noise-free value and the expected value among all the realizations.

3. Results and Conclusions

We now present and analyse the qualitative results obtained by running simulations as described above and we show that the developed equality holds numerically under different conditions of the random motion of the fire front and for different PDFs of the position of the head of the fire.

First, for the six noisy-model of the front perimeters, we consider and ensemble of realizations of the head of the fire that are distributed according to a Beta distribution $B(2,2)$. In Figure 3 we see that the distribution of the area divided by the mean value of the fire front function clearly follows the distribution of the head of the fire. It can be shown that for every well-behaved PDF mapping the position of the head of the fire, the equality is fulfilled.

In particular, looking at Figure 2, we roughly distinguish three regimes on the evolution curve of the mean head of the fire: An early regime before than $t \approx 15$, a final regime after $t \approx 300$, and the transition between them. Hence, in Figures 4, 5 and 6 we show PDFs of a and $A / \overline{Y}$ for times $t = 10$, $t = 70$ and $t = 700$. We see that both PDFs are equivalent at any time, and for wildfires this shows that the statistical properties of the burned area are driven by the statistics of the position of head of the fire.

The application of this approach to real systems is limited to the existence of a main direction of advancement of the fire that is characterized by large fluctuations among independent realizations, here it is identified by a which corresponds to the head of the fire ruled by the rate of spread, and of a perpendicular direction that is characterized indeed by negligible fluctuations among independent realizations. Actually, this approach is limited, for example, to wind driven fires or fires with similar dynamics.

Abstract

Land managers use models to understand potential fire behaviour, which provide insight into the social, economic and environmental implications of fire. Although combustion is a fundamental process, numerous fire behaviour models exist across the world, each with model-specific inputs and outputs. While these are useful for local-level fire management, vegetation- or country-specific fire behaviour models, they do limit knowledge-sharing between jurisdictions – largely because model inputs (particularly fuel arguments) and outputs differ, meaning they cannot be readily compared. At the same time, advancements in remote sensing techniques have resulted in accurate methods to estimate fuel for current fire behaviour models that have not been fully integrated.

This project has two key aims: a) to develop a comprehensive set of model parameters that can be used to universally characterise fuel attributes fundamental to fire behaviour, and b) based on knowledge gaps identified, undertake expert elicitation to identify fuel attributes for fire behaviour not currently utilised in models, and propose methods to estimate these values using remote sensing. To achieve this, we reviewed 25 fire behaviour models to identify similarities and differences in model inputs and outputs. We then subset model inputs to the fuel parameters and linked each to current remote sensing methods. Following the review, and in conjunction with an expert elicitation process, we developed a list of fundamental fuel attributes missing from current fire behaviour models. From this list, we developed novel fuel parameters that fully utilise information contained within remote sending datasets. The final step in this process is to validate the importance of each fuel argument using further expert elicitation and field burning experiments.

We found many common parameters across fire behaviour models. Most models require parameters that describe fuel, short- and long-term fuel moisture, temperature and wind variables, however, the physical fuel parameters are typically where models diverge. Models across the world use fuel inputs that describe the amount, horizontal and vertical arrangement of fuel, bark hazard and the importance of crown fuels. Preliminary expert elicitation identified shared and divergent opinions related to fuel characteristics that drive fire behaviour. While common parameters related to horizontal and vertical arrangement of fuel were important, gaps exist in our capacity to describe ladder fuels. From these results, we have developed novel remote sensing metrics to describe vertical and horizontal connectivity. Throughout 2022, we aim to validate these preliminary results through further expert elicitation and field observations of fire behaviour.

Through this work, we have developed a complete list of fuel parameters for fire behaviour and related these to remote sensing methods. This provides a framework for current models to shift to remotely sensed inputs, and a basis for future fire behaviour models. Overall, we argue that this work provides the foundation for a universal fuel assessment methodology to be developed, that is scalable and captures change over time, that can link physical fuel structure and remote sensing techniques to accurately capture fuel dynamics.

1. Background

In many regions across the globe, fires are becoming increasingly frequent and severe (Pausas & Keeley, 2021). With the effects of climate change likely to continue to amplify this pattern into the future, jurisdictions around the world model fire behaviour to make high-consequence decisions both during the response phase of wildfire management and for the estimation of risk by simulating a set of bushfires across the landscape and observing the associated environmental, economic and social impacts (Gazzard et al., 2020; Kramer et al., 2019; Ladds et al., 2017; Yu et al., 2020). Differences in vegetation across the world have led to independent fire behaviour models being developed (Sullivan, 2009a, 2009b). Consequently, descriptions and systems of measurement for fuel are also unique with the intention to characterise the necessary parameters for the associated model (T. Duff et al., 2017; Keane, 2013). Although this has been useful for local-level fire management, this has limited our capacity to share fire behaviour knowledge across different jurisdictions because the model inputs differ.

Remote sensing products derived from active sensors have been shown to provide an accurate, objective means of measuring fuel attributes. (Gale et al., 2021). Active remote sensing methods utilising LiDAR to measure the 3D structure of fuel have been the focus of the research (Calders et al., 2015; Cooper et al., 2017; Greaves et al., 2015; Kramer et al., 2014; Rowell et al., 2016; Wallace et al., 2016, 2017). A range of platforms have been used to derive measurements including terrestrial, Unoccupied Aircraft Systems (UAS), fixed wing and satellite (García et al., 2011, 2017; Hillman et al., 2021).. Limitations to using these approaches have been highlighted in the ability of these sensors to measure surface fuel characteristics (i.e. vegetation in contact with the ground) (Wallace et al., 2020) due to the inability of sensors to differentiate between ground and surface fuel. Despite this limitation, the information content within remote sensing products provides the ability to describe complex 3D attributes of fuel that are beyond those which are currently utilised in fire behaviour models (Hillman et al., 2021).

2. Knowledge gap

The fuel parameters that are used in current operational fire behaviour models are derived from research at the time of their development. Given advancements in both fire behaviour modelling and remote sensing techniques, there is a clear need for an extensive review of fundamental fuel characteristics that influence fire behaviour, combined with remote sensing techniques that can be employed to assist in the characterisation of complex fuel characteristics.

3. Aims and Objective

This project has two key aims: a) to develop a comprehensive set of model parameters that can be used to universally characterise fuel attributes fundamental to fire behaviour, and b) based on knowledge gaps identified, undertake expert elicitation to identify fuel attributes for fire behaviour not currently utilised in models, and propose methods to estimate these values using remote sensing

4. Methods

To achieve the aims of this project, we firstly reviewed 25 fire behaviour models (empirical, semi-empirical and physical fire behaviour models) across the world. For each model we made note of the input parameters utilised and the outputs derived. For each fuel parameter we identified the scale, units of measure and the minimum levels of precision and accuracy required. Common parameters and outcomes were identified through this process.

Building on the considerable body of work completed by Gale et al. (2021) who reviewed remote sensing research in relation to the fuel attributes that influence fire behaviour, we directly identified the remote sensing research pertinent to each fuel argument identified in part one of this review.

A process of expert elicitation was then undertaken to review the current parameters utilised within fire behaviour models and identify attributes that are fundamental to fire behaviour but not currently measured. Three guiding principles were employed to develop novel metrics that leveraged the full capability of the remote sensing information. Firstly, the attributes had to provide an understanding of the vegetation at the time of

measurement and be able to identify why things are changing over time. This builds on the concepts highlighted by Duff et al. (2012) and Keane et al. (2012). Secondly, a hierarchical system was used to describe the fuel attributes. Wherever possible primary fuel attributes that can be directly linked to fire behaviour were extracted. Thirdly, attributes had to be scalable with the associated remote sensing method able to provide the necessary precision and accuracy. By focussing on developing attributes that can be continuously mapped across the landscape, simulation models should be able to process the values directly.

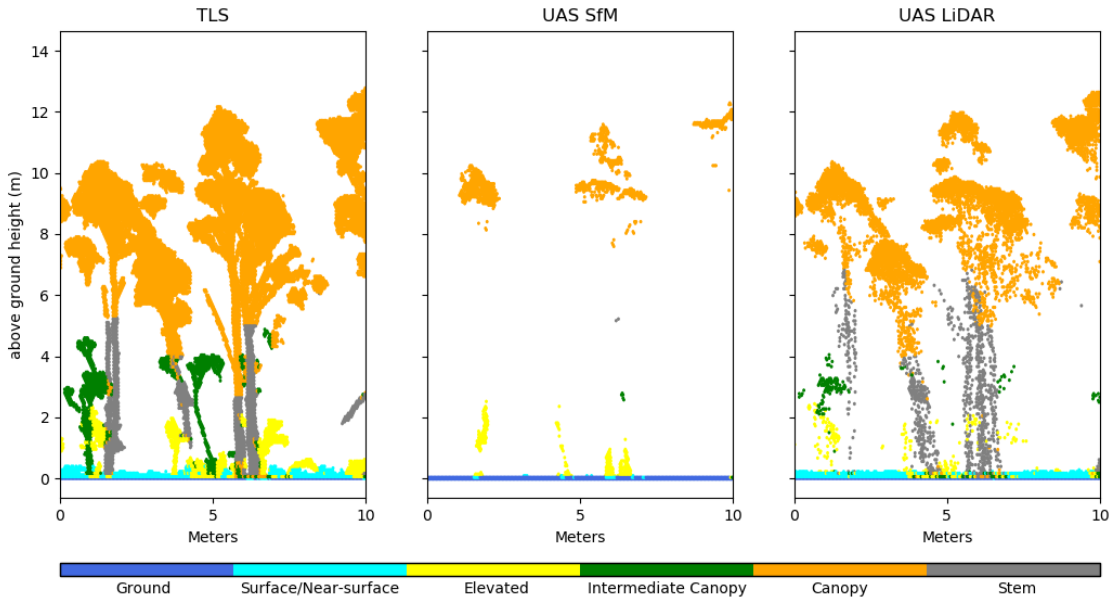

Figure 1. Side view transect through a section of a study area near Hobart, Tasmania demonstrating the capability of 3D remote sensing and novel classification approaches to automatically classify vegetation into canopy, stems intermediate canopy, elevated, surface/near-surface and ground layers (Hillman et al. 2021).

5. Results and Discussion

Preliminary results suggest that broad overlap in the inputs and outputs exist between empirical and semi-empirical fire behaviour models across the world. This is a logical outcome given the fundamental principles of fire behaviour. Most models utilise input arguments describing long term dryness, wind, temperature, short term fuel moisture (as temperature and relative humidity) and a fuel value. The main differences between models can be seen in the fuel parameters. Most models require parameters that describe the horizontal and vertical distribution of fuel at different strata in combination with the amount of fuel. Similar outputs from empirical and semi-empirical models include descriptions of the rate of spread and height, angle and the depth of flames at the head of the fire are observed across fire behaviour models. This contrasts with physical fire behaviour models which enable observations of fire behaviour in greater detail and consequences of multiple fire interactions and connectivity in vegetation to be analysed at the expense of longer running times.

With respect to the alignment of remote sensing literature to describe fuel variables - consistent with previous findings of Gale et al. (2021) most research has focussed on extracting measurements describing overstorey and understorey variables. This suggests that fuel variables at the fuel assemblage scale which are currently utilised in operational fire behaviour models could be measured using remote sensing methods. However, factors which limit wider implementation of such technologies include the inability of active sensors to measure surface fuel properties in contact with the ground and the patchwork nature of these datasets. The incomplete coverage of datasets is also at odds with operational fire behaviour models which need to be run at a regional scale. Potential opportunities to bridge this gap have been demonstrated in recent research which has shown ability to scale up point-based measurements across the landscape (Jenkins et al., 2020; McColl-Gausden et al., 2020). It was also noted through this manuscript that remote sensing derived datasets have the ability to characterise complex 3D fuel attributes (Figure 1).

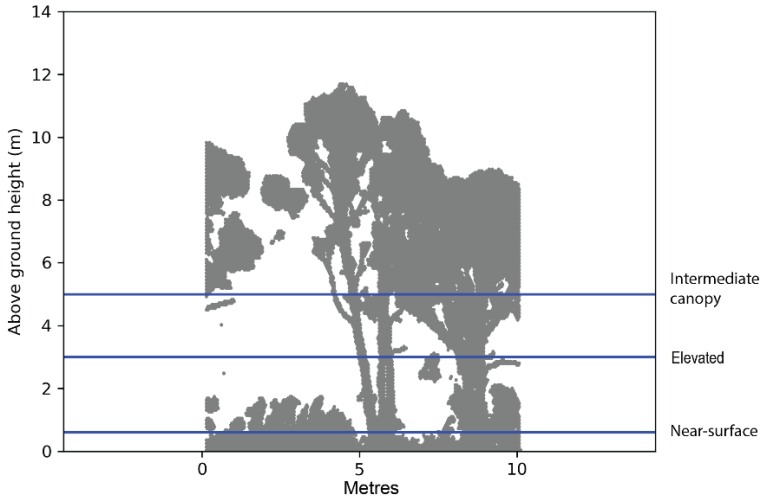

Figure 2. Height thresholds used to extract different fuel strata (based on Hines et al. (2008) and Gould et al. (2012)). Expert elicitation highlighted difficulties in the utilisation of remote sensing to extract vegetation at different strata due to the high variability of vegetation in different areas.

Preliminary results from the expert elicitation process highlighted shared and divergent opinions about the fuel characteristics that drive fire behaviour across the world. Consistent with current fuel inputs used in fire behaviour models, metrics that describe the horizontal and vertical arrangement of fuel are considered important to be measured. In contrast to current fuel hazard measurement systems, there were suggestions to move away from defined strata layers due to the complexities of defining strata using both in-field and remote sensing techniques (Figure 2). Instead, metrics describing the connectedness of fuel across the "ladder" was seen to be an area of opportunity for active 3D remote sensing. Work has begun on developing a metric to describe the vertical and horizontal connectedness of fuel from 3D remote sensing that will also allow changes in the arrangement of fuels to be observed through time. Further metrics of interest derived from the expert elicitation process include the development of an approach that allows for assessment of vulnerability of a site to stand-replacing fire and the fusion of structural and moisture information). Whilst the aforementioned fuel attributes are universal across fuel types, expert elicitation highlighted cases where fuel attributes that influence fire behaviour were unique to the vegetation type. An example of this, is the need to describe canopy fuel properties in coniferous and deciduous trees (e.g. canopy base height, canopy fuel load) which were observed to be of lower relevance in eucalypt dominated systems. Similarly, the properties of different bark types in eucalypt dominated systems were seen to be of great importance to potential fire behaviour and less important in deciduous forests. Future work completed as part of this project will validate the metrics developed through remote sensing with further expert elicitation and field observations of fire behaviour.

6. Conclusions

Overall, we make two key recommendations from this manuscript on the assessment of fuel attributes for fire behaviour in models used across the world. Firstly, we recommended that current operational models (e.g. PHOENIX, RapidFire, and FARSITE) undertake a trial to utilise fuel parameters derived from remote sensing approaches outlined in this manuscript and compare outputs from this approach with current input parameter outputs. Secondly, the complete list of fuel attributes derived from this manuscript are validated in their ability to represent fuel hazard in forest types around the world. This would enable greater confidence in the attributes ability to represent fire behaviour and identify fuel change over time. Overall, we argue that this work provides the foundation for a universal fuel assessment methodology to be developed, that is scalable and captures change over time and can link physical fuel structure and remote sensing techniques to accurately capture fuel dynamics. This work will be undertaken through a Fulbright exchange (Samuel Hillman with Rocky Mountain Research Station, Missoula, Montana).

Plume simulation; fire behavior; airborne observation, Experimental Fire.

Abstract

Coupled fire-atmosphere systems are currently developed to respond to the need of operational system in air quality and fire attack management. This work participates to this effort by proposing a simulation strategy where the plume is simulated using fire observation. Such approach can provide reference test case for more complex coupled fire-atmosphere simulation. Using the Forefire-MesoNH system, we simulate the plume evolution of a landscape scale burn where the fire is not simulated as a spreading front but rather prescribed from multiple fix burners controlled with observation data. The simulation of the plume formed from a 7-hectare savannah fire conducted in Kruger National Park in 2014 is demonstrated using helicopter-borne observations georeferenced at 1-m resolution and post-processed to extract information of heat fluxes at pixel level.

1. Background

Over the past 20 years, the development of earth observation (EO) satellite product enable the observation of wildfire at the global scale and show an increased of fire activity in fire-prone regions such as western USA or eastern Australia (Andela et al., 2017), most probably because of the high population living in Wildand-Urban Interface (WUI) in those regions (Doerr and Santín, 2016). To mitigate wildfire effects, operational forecast systems have been developed with either focus at fire scale for application in fire operational attack like the fire growth model FARSITE (Finney, 1998), or at plume scale for application in air quality like the Smoke Research Forecast (SRF) system BlueSky (Larkin et al., 2009).

More recently, coupled fire-atmospheres systems have been developed to resolve simultaneously the plume updraft/smoke dispersion, the propagation of the fire front, and their mutual interactions. Several coupled systems are now making references: CAWFE (Coen et al 2013), WRF-SFIRE (Mandel et al 2011) and MesoNH-ForeFire (Filippi et al 2013). While still mostly used as research tools, they are intended to become operational (Kochanski et al 2016). They are design to simulate landscape-scale (>100m) propagating fire, and therefore forced to rely on highly parameterized fire model as current computational resources cannot resolve such domain size at the resolution required to capture combustion processes that responsible of the fire front dynamics (<1cm). In atmospheric model grids, fires are set as front lines with associated Rate Of Spread (ROS) and sensible heat flux predicted according to local orography and local modelled atmospheric variables (ie wind speed, humidity).

To the authors knowledges, apart from the recently released Rx-Cadre experiment dataset (Ottmar et al 2016), no other dataset exists that can provide simultaneous information on both the fire and the atmosphere states, and therefore can be used to run detailed validation of coupled fire-atmosphere system. Unfortunately, the prescribed burns of the Rx-Cadre experiment were set in non-homogeneous vegetation and with complex ignition pattern that make them difficult to simulate as detailed vegetation map and fast return observation of the front propagation are then required. Nevertheless, validation exercise against observation already exists for MesoNH-Forefire (Filippi et al. 2013) and WRF-SFIRE (Kochanski et al 2013). They are both based on the simulation of the Fire-Flux field work campaign which took place in 2006 (Clements et al. 2007) in a homogenous grass field in Texas. The fire was set with a single front ignition. However, no comprehensive fire behavior data were collected for this experiment, and the model validations were conducted against turbulent flux measurements acquired with an instrumented mast located along the propagation of the fire front.

2. Objective

To improve the validation of coupled fire-atmosphere system and assess further the impact of the fire model assumption on simulated fire behavior we need validation datasets for scenarios in which the fire induced winds influence fire front behavior (Liu et al 2016) as for example fire front acceleration induced by front merging. In such scenario, plume dynamics point measurement like in Clements et al. 2007 and Clements et al. 2019 are much more difficult to perform due to the more complex predictable location of best measurement point.

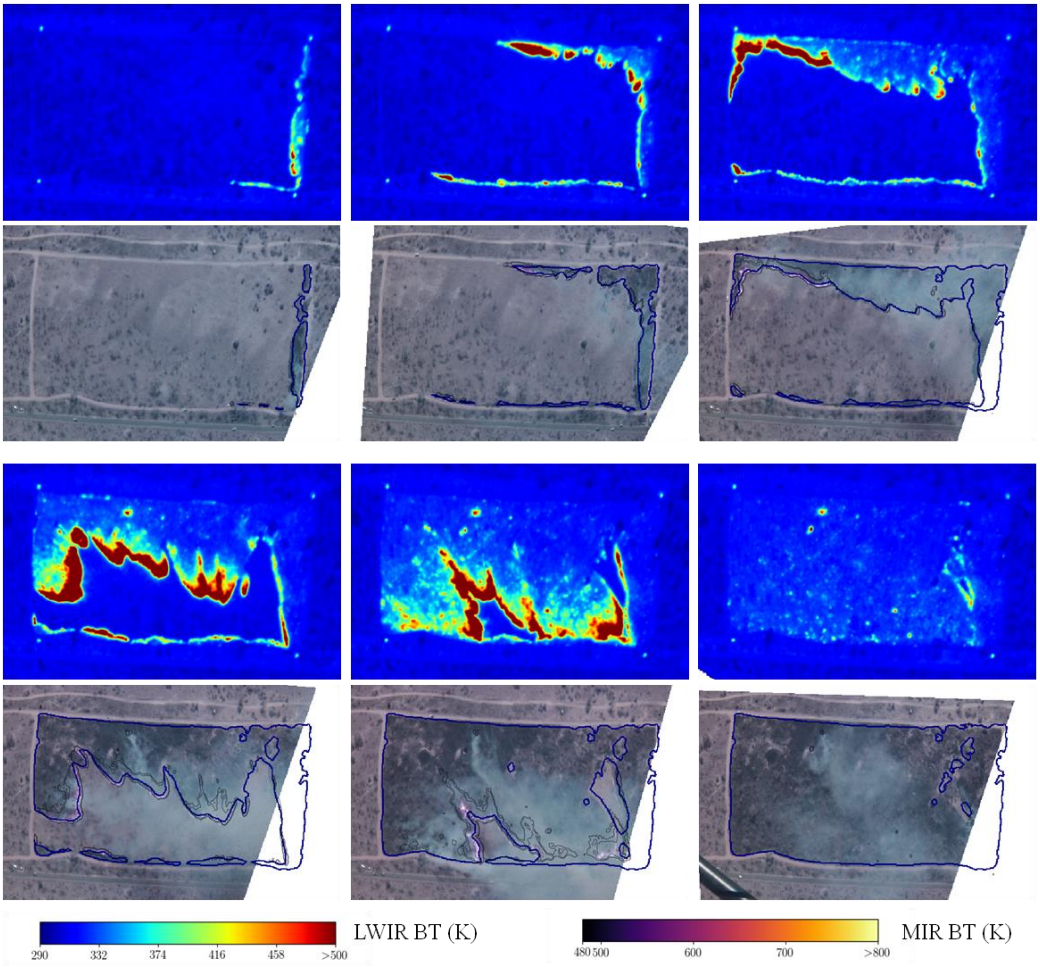

Figure1: Time series of LWIR, and combined MIR/VIS images for 6 times along the 20 minutes of the duration of the Skukuza6 fire conducted on the 26th of June 2014 in Kruger National Park (South Africa). The spatial resolution is 1m for all images. Time after ignition are t=249, 419, 556, 656, 750, 931 s from top left to right bottom. Corner fires are visible on the LWIR images but were not used in the georeferencing. The VIS images show the perimeter of the active fire contour (blue line) as segmented by Convolutional Neural Network trained on the KNP dataset, and the MIR contour plot extracted from the MIR images.

In situation of high variable fire behavior and potential complex front geometry structures, infra-red high temporal and spatial resolution observation have shown capability to capture fire front dynamics (Paugam et al 2021, Paugam et al 2022). To help continuing the development of fire-atmosphere system, we show here the potential such airborne high-resolution observation to force plume simulation.

3. High resolution experimental fire observation

We use here the orthorectified IR image data set of experimental 7-ha savannah fire processed in Paugam et al 2021. The epxeriemtal setup required to produce such data set require to have a set scene (no wildfire), but the common constraint on having bone fires presence on every image is released (Pastor et al 2012, Paugam et al 2013), hence making easier high frequency observation. The set of algorithm developed in Paugam et al 2021 are built on background feature tracking and image to image correlation optimization (Evangelidis and Psarakis 2008) for application on Long Wave Infra-Red (LWIR) and Middle Infra-Red (MIR) images. Orthorectifucation of visible image time serie are also possible if the plume is not too dense.

Results of orthorectified images collected during a fire conducted on the 26th of June 2014 on the KNP plot named Skukuza6 are shown on Fig 1. Hereafter this fire is referenced as Skukuza6. During the KNP fieldwork three cameras were operated simultaneously from a hovering helicopter:

- a visible camera (GOPRO Hero1, 1Hz, 3849x2880 pxs) with its IR filter removed to better capture flame location,
- a Long Wave Infra Red (LWIR) camera (OPTRIS 400, 7-13µm, 1Hz, 382x288 pxs, $T \in [250,1700]$
- and a Middle Infra Red (MIR) camera (FLIR AGEMA 550, 3.9 µm, 3Hz, 320x240pxs, $T \in [473,1073]$.

Fig 1 shows, for 6 times along the 20 minutes of the fire duration, LWIR images together with quasi-simultaneous combined MIR/visible images. The hovering altitude of the helicopter and the sensor resolution of the LWIR and MIR cameras allow a spatial resolution of 1m.

The second step to the image postprocessing tasks is the segmentation of the fire front. Among the 3 cameras available, we decided to base our approach on LWIR images only. This choice is explained by: (a) using only one band avoid potential problem related to time-synchronization, (b) VIS images can be masked by smoke, and (c) the MIR camera used here is not as widespread in the scientific community as the LWIR camera. The LWIR image front segmentation is based on a deep learning approach, it is described in Paugam et al 2022. Using a limited number of manually tagged front, a series of Convolutional Neural Network (CNN) is designed to develop a multiple step learning methodology gradually including information from 4 different burns. Based only on 10 initial manually segmented images, a series of 14 CNN learn front features from each other, using cumulative knowledge and manual annotation adjustment from previous front prediction. Transfer learning techniques are used to improve CNN response when including new burn to reduce overfit inherent to the first learning steps. Results of the final CNN is shown on the visible images of Fig. 1 (see blue line).

4. Plume Simulation

Using previous high-resolution fire front observation, this section intends to simulate the plume triggers by the heat flux and the emissions induced by the spreading fire front and the cooling trail located behind the front. We proposed here to use the MesoNH model (Lafore et al 1998) to simulate the atmosphere above the fire while the fire is simulated as a multitude of fix burner (one per cell of the atmospheric grid) that are switched on and off with a set strength accordingly to the fire observation (Mell and Linn 2017). The fluxes conversion from the observation resolution (1m) to the atmospheric grid (10m) is done via the ForeFire model (Filippi et al 2013). The front spread prediction of ForeFire are not used here, ForeFire control each cell as a burner where the heat flux activation is set using maps of arrival time, time of residence and total energy released. This latter is computed from the measurement of the Fire Radiative Energy (Wooster et al 2005) and an assumed radiation to total energy ratio of 10%. To better model the evolution of the fire spread each burner differentiated the phases of flaming and smoldering, so that a burner is defined with the inputs of arrival time, flaming residence

time, flaming FRE, total burning time and smoldering FRE. See Fig 2 for inputs associated with the Skukuza 6 fire introduced in the previous section.

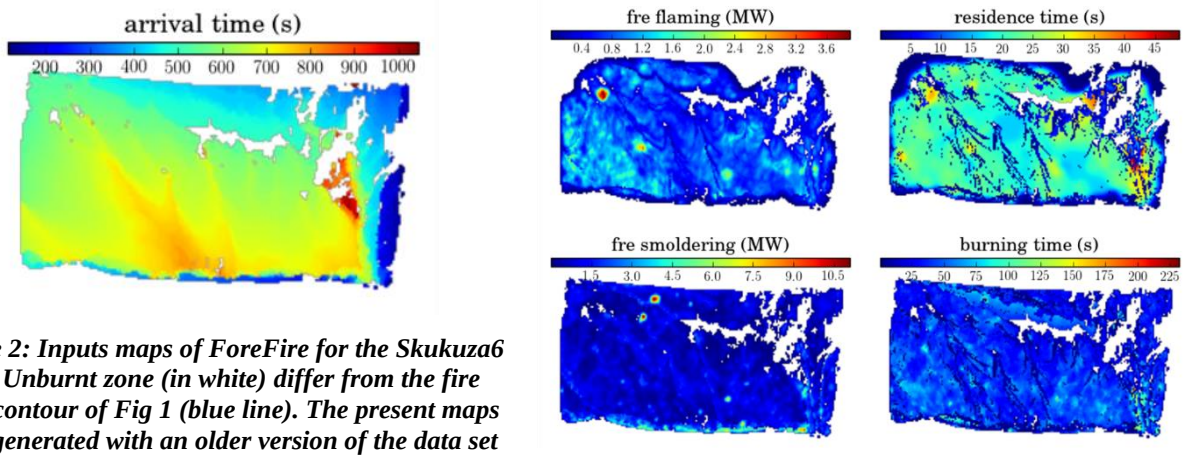

Figure 2: Inputs maps of ForeFire for the Skukuza6 fire. Unburnt zone (in white) differ from the fire front contour of Fig 1 (blue line). The present maps were generated with an older version of the data set presented in Fig 1.

The arrival time map concatenates information from all the fire front CNN prediction to map the time of first appearance of the fire front in a pixel. FRE is computed from the time integration of the Fire Radiative Power that is evaluated using the MIR images following the formulation of Wooster et al 2005. The flaming residence is defined as the time is takes to a pixel ($1m^2$) to cool down below a certain threshold (here we used a MIR brightness temperature of 600K). The total burning time is the time it takes for a pixel to cool down to background temperature.

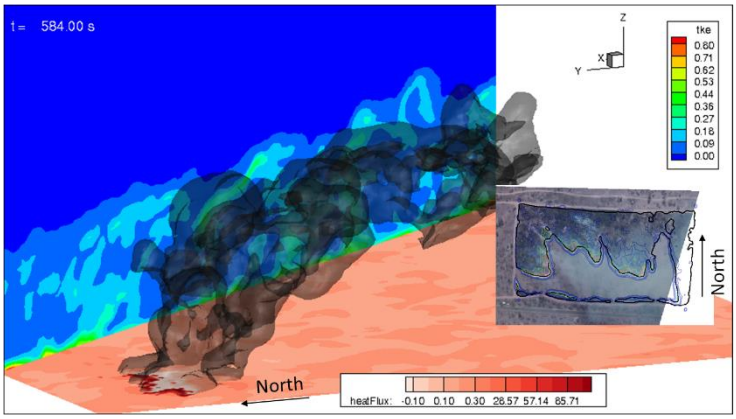

Figure 3: perspective view of the simulated plume of the Skukuza 6 fire a time t=584s after ignition.

Emissions linked to the heat flux is also passed to MesoNH via the FRE formulation (Wooster et al 2005) with a conversion factor of 0.4 (kg/s/MW) and emission factors set for the flaming and the smoldering phases. In this first simulation, only a passive tracer is set. It uses emission factor of 0.05 and 0.01 for flaming and smoldering, respectively.

The MesoNH simulation uses a 10 m spatial resolution and a 4 second time step. It is run in LES mode. The initial condition is set using a radio sounding and a spin-up time of 1500 seconds that was necessary to generate the boundary layer (see tke profile on Fig 3). The radio sounding was generated from a MesoNH simulation using 3 nested models and forced with ERA interim reanalysis data. Fig 3 shows a perspective view of the plume simulated by MesoNH that was induced by fix burners set accordingly to the Skukuza 6 fire observation. The heat flux map generated by ForeFire and pass to MesoNH is seen on the ground level of the MesoNH grid.

Fig 4 shows the 10m wind data from the first level interpolated on the 2m fire data grid for 2 times of the fire evolution: at the start and end of the large ellipsoidal front spreading on the left of the plot. The fire shows a wind dominated dynamics with wind passing through the front (Finney et al 2015, Frangieh et al 2010). The wind field a ground level is significantly alter downwind to the front, see left shift southward of the front at t=600s, or the acceleration in the unburnt area at t=700s. To analyse the impact of the coupling between the fire dynamics and the wind field, Fig 5 shows correlations between the cross product of the ROS and the wind field and (a) the norm of the ROS and, and (b) the Byram's Fire Intensity (FI). FI is computed following the approach of Johnston et al (2017). In the correlation we only select point from the fire front with ROS greater than 0.2m/s to focus on the spreading part of the fronts and remove the back fire and dead front.

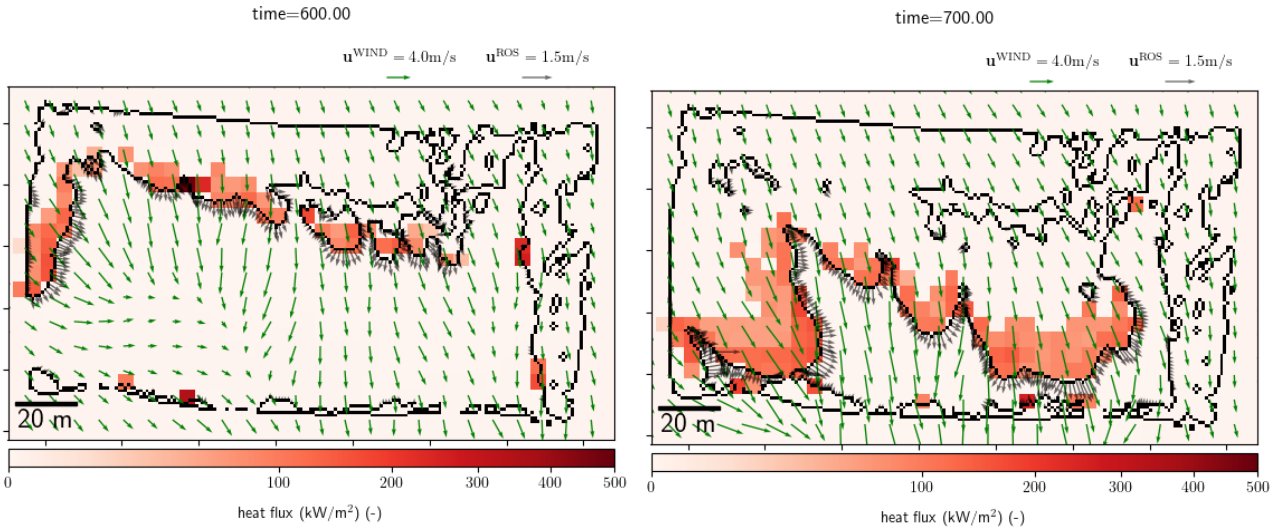

Figure 4: Wind vector field at 5m heigth in green (first MesoNH level) and fire front ROS in grey at 2m resolution for 2 times of the fire evolution: start and end of the main ellipsoidal front spreading on the left of the plot. The black line shows the fire front while the convective heat flux computed by the forefire flux scheme is reported in the background at the 10m MesoNH resolution.

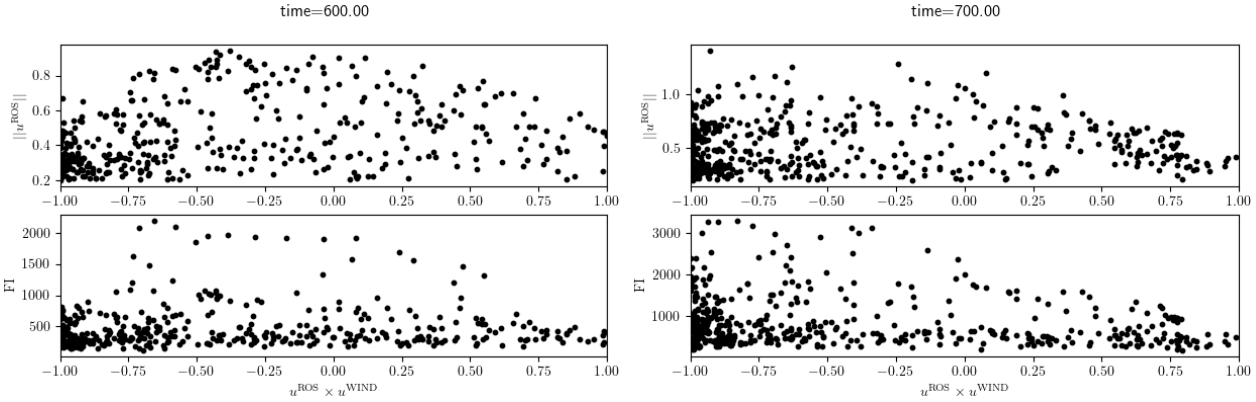

Figure 5: Correlation of the cross product of the ROS vector (uROS) and the wind field (uWIND) with the norm of the ROS (top panels) and the Fire Intensity (FI) for the same two times t (left and right panels) as Figure 4.

No clear correlation appears from Fig 5. The dynamics of the front does not seem to impact the wind speed near the front. This is probably due to the ambient wind direction variability that can be seen in Fig 1, for example at time t=656s, and t=750s. The ambient wind oscilates between west and south during the fire evolution as shown by smoke released by smodlering spots in the back of the fire. This variability is not taken into account in the MesoNH simulation that uses a single radio sounding and a spin-up time to build its boundary layer. As a result the ellipsoidal front spreading from the left of the plot edge is spreading in the MesoNH simulation with a southwards wind (see Fig 4 left panel) when visible image shows a clear eastwards wind at this time. This issue shows also with a right shift of the the wind field from the ROS direction in Fig5, see the large number of negative cross product at t=700s. Improving the ambient wind input will be investigated in future work as well as the impact of the heat release scheme use in forefire. Comparison with the default nominal flux of Filippi et al (2013) will be considered.

5. Conclusion and Perspectives

This work presents the development of a methodology to simulate fire plume from airborne IR observation. Unfortunately, as no atmospheric data or plume sampling were collected during the burn we simulate, no validation of the simulated plume can be run. Furthermore, no details fuel load was performed, hence making fully coupled fire-atmosphere simulation more challenging. This first attempt to simulate a plume from fire

observation is therefore only a proof of concept that emphasize use of airborne IR observation in the on-going effort of the fire community in developing fire-atmosphere coupled models. Details knowledge of plume structure and composition also shows potential application in current effort in 3D radiative transfer simulation in fire scene (Paugam et al 2021b).

Abstract

Forest fires are among the most catastrophic natural hazards threatening human lives, properties and infrastructure. In recent years, these events keep rising both in frequency and severity mainly due to climate change, constituting fire risk assessment a critical priority. Scientific and technological bloom, during the last decades, offers the required contemporary tools and data for innovative frameworks on risk assessment leading to operational action-plans for prevention, during-the-event management and post-event mitigation actions. This study illustrates an integrated approach, for high-detail fire risk assessment (at building-block level) and management planning in peri-urban areas that are prone to forest fires, through coupling of geoinformatics, machine learning techniques and field observations. The methodology combines fire hazard modelling, vulnerability and exposure assessment. The fire hazard scenarios refer to spatiotemporal simulations of fire spread (generated by applying the adapted FlamMap model), based on the most probable ignition points for possible fire outbreaks (derived by the BEYOND's daily fire risk forecasting machine learning model modified for seasonal forecasts) and on the analysis of the meteorological regime (wind intensity, directions, frequency) of the area of interest. The vulnerability layer was produced by coupling population (density and age) and building characteristics, based on 2011 census data. The exposure layer refers to land value (€/m2) and works as an indicator for the qualitative estimation of possible economic effects in the study area, in case of a fire event. The high-risk areas resulting from the fire risk map, were visited in-situ for validation and update if/where needed. Throughout the field campaign, important areas and critical points (high-risk buildings, traffic congestion areas, population gathering areas etc.) were recorded and included in the mitigation suggestions and management planning. This integrated and iterative process (office-to-field and field-to-office) forms the basis for the synthesis and recommendation of effective and operational mitigation actions, protective measures and coping/management strategies. The methodological framework is developed by BEYOND Centre of EO Research & Satellite Remote Sensing (National Observatory of Athens) and applied in Vravrona, Chamolia and Porto Rafti settlements (pilots) of the Attica Region in Greece, under the project "Seismic, Fire & Flood Risk Assessment in Attica Region, Greece" funded by Attica Region.

1. Introduction

Climate change has led to increases in the vulnerability of forest ecosystems, as it is a major contributor to the rise of forest fires and tree species' inability to adapt to the intensity and frequency of summer droughts (Prodromou et al., 2020). Peri-urban zones, mainly due to uncontrolled urban-sprawl and lack of proper planning, are more vulnerable to wildfires leaving people's lives and properties, as well as the surrounding natural environment and ecosystem, exposed to increased disaster risk. Attica region, Greece, where the country's capital is located and almost half of the country's population along with critical infrastructure, is characterized by a plethora of peri-urban settlements surrounded by intense morphological relief with steep slopes, and with pine forests being the dominant land cover type. Moreover, the region's rich natural landscape results in the intrusion of dense forest parts inside a significant number of settlements. Fire risk assessments are

necessary to reduce the impact of natural disasters and support decision making (protective measures, mitigation actions, emergency evacuation procedures, etc.). A cornucopia of fire risk assessment methodologies can be found in scientific literature. The Analytic Hierarchy Process (AHP) is highlighted among them and is usually combined with Geographic Information Systems (GIS) (Gheshlaghi et al., 2019). Several studies also used satellite imagery and GIS (Kanga et al., 2014), fuzzy approaches (Erdin and Çağlar., 2014), artificial neural networks (Goldarag et al., 2016) and LIDAR data (González-Olabarria et al., 2012). The methodology presented in this work, is an integrated approach for fire risk assessment and management planning in peri-urban areas that are prone to forest fires, through machine learning techniques, geoinformatics and field observations. It was developed under the umbrella of the national research project "Seismic, Fire & Flood Risk Assessment in Attica Region, Greece", led and coordinated by the National Observatory of Athens (NOA) and specifically the Centre of EO Research & Satellite Remote Sensing – BEYOND, of the Institute for Astronomy, Astrophysics, Space Applications and Remote Sensing (IAASARS).

2. Material and Methods

2.1. Study Area

The study area (Figure 1), concerning the fire risk assessment, includes the settlements of Vravrona, Chamolia and Porto Rafti of the Municipality of Markopoulo Mesogaia. It has an average altitude of 140 m and borders the Athens International Airport, the settlements of Markopoulo Mesogaia, Artemida and Kouvaras in the wider area of Mount Merenda (614 m), while it is limited from the east by the Southern Gulf of Evia. The area is mainly covered by hardwood vegetation and coniferous forest (~ 50% of the total surface), fruit trees, meadows, vineyards and natural pastures (~ 32.5% of the area) and urban fabric, non-irrigated arable land, bare rocks, etc. concerning the 17.5%. It is worth mentioning the cultural and environmental importance of Vravrona as it brings together an archaeological monument and a NATURA region.

Figure 1- Study Area.

2.2. Methodological framework

The approach (Figure 2) is a fusion of the research team's expertise (EMSN041, 2017[20]; EMSN059, 2019[21]; FireHub[22]; (Apostolakis et al. 2021; Girtsou et al. 2021) and of extensive literature review (Darvishi et al. 2020; Gheshlaghi et al. 2019). To assess the fire risk, were taken into account: i. Selected fire hazard scenarios, ii. The composite spatial layer of fire vulnerability and iii. The spatial layer of land values. According to the fire risk assessment map that has been produced, targeted high risk areas were visited for validation/modification purposes and further important observations were recorded for the development of management plans.

Figure 2- Flowchart of the methodology.

3. Fire Hazard

3.1. Analysis of wind characteristics

For the analysis of wind characteristics of the study area, wind velocity and direction data were derived by the ERA-5[23] mission (from 1990 to 2020) as well as by the METEO[24] platform (from 2013 to 2020). The two aforementioned data sources were combined through the "Q-Q plot mapping" methodology so that the gridded ERA-5 data follow the same distribution as the point observations from the meteorological station of Porto Rafti (Figure 3).

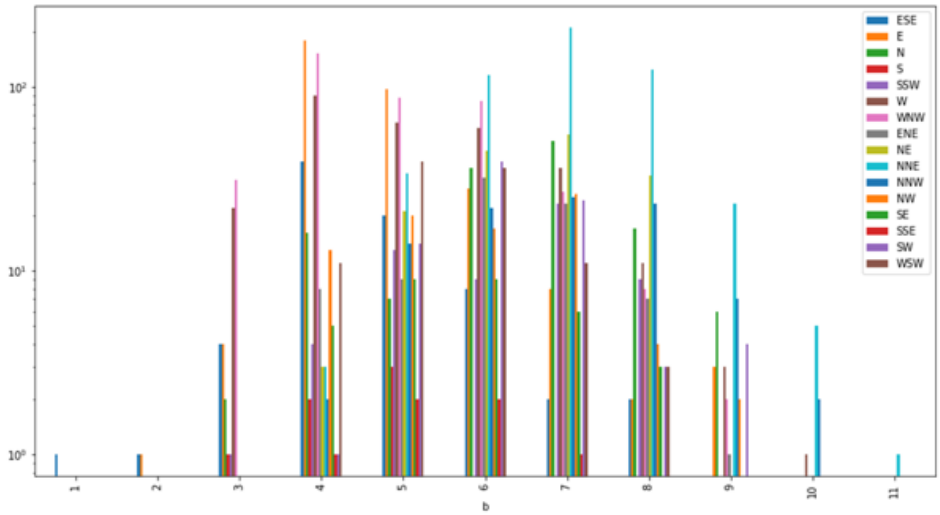

Figure 3- Wind intensity per wind direction in the study area.

[22] http://ocean.space.noa.gr/FireHub
[23] https://climate.copernicus.eu/climate-reanalysis
[24] https://www.meteo.gr/

3.2. Determination of fire ignition points

For the determination of the fire ignition points several datasets have been utilized such as the DEM[25] and its derivatives (aspect, slope), ERA-5 and METEO data related to temperature, wind (velocity, direction), rainfall, along with the adjusted Corine Land Use / Land Cover[26] product and other satellite based spectral indices (e.g. NDVI, EVI). The selection of ignition points is critical to simulate the start and spread of fire scenarios. For this purpose, the Machine Learning model of daily fire risk forecasting, which was developed by the BEYOND Centre, was utilized (Apostolakis et al. 2021). The resulting output (Figure 4) is a set of high fire ignition probability cells (red), based on the model's knowledge gained through the correlations of the input variables with past fire events. Based on these results and the analysis of the worst case wind scenarios in the area, the ignition points were combined with the respective wind intensity and direction that could possibly harm residential areas.

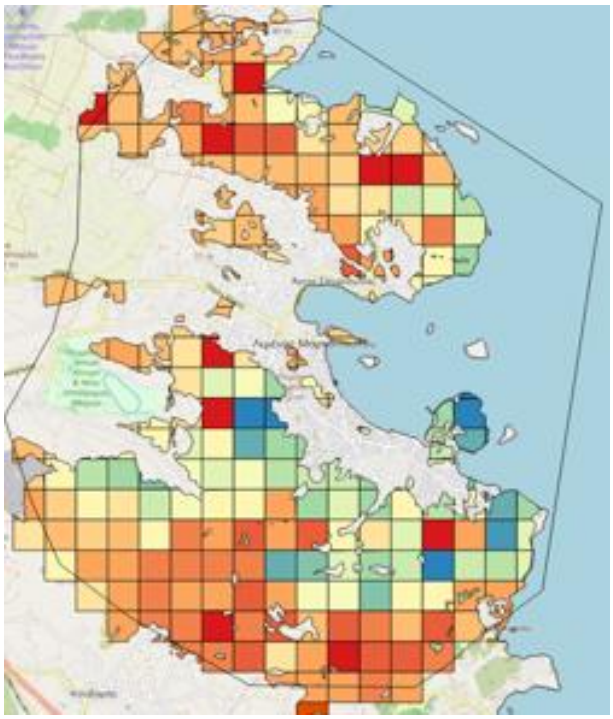

Figure 4- Fire ignition probability cells.

3.3. Fire spread simulations

FlamMap[27] is an open source application that runs in a 64-bit Windows Operating System environment and simulates possible fire behaviour characteristics, such as the rate of spread and its intensity under constant environmental conditions at a given time. By adapting FlamMap in a Linux environment, it was possible to simplify the number of input layers from 8 to 5 as follows: DEM, Aspect, Slope, Fuel and Density. The elevation, the aspect and the slope layers were created through GIS. In this study, the surface fuel, the moisture content of the fuel and the vegetation characteristics of the area, were determined by using an adjusted land use/cover map through GIS, high resolution satellite imagery and photo-interpretation. Each fuel model was assigned to a vegetation type as a combination based on the works of Kalabokidis et al. (2013) and Scott & Burgan (2005). The layer of Density represents the amount of available fuel per unit volume of the surface covered by the canopy space. It is an important factor that affects the probability of starting a fire and the rate of crown fire spread (Johnston, 2012). For the area of interest, this layer was categorized into 4 different classes, concerning the estimated timber volume of the available fuel per m^3.

[25] https://www.ktimatologio.gr/
[26] https://land.copernicus.eu/pan-european/corine-land-cover
[27] https://www.firelab.org/project/flammap

Various hazard scenarios were simulated, based on extensive combinations of ignition points and wind characteristics (direction, speed). Finally, all these scenarios were co-assessed and combined, leading to 4 fire hazard assessments, one per ignition area (ignition areas refer to groups of ignition points depending on their place and impact on the study area).

3.4. Vulnerability

For the estimation of the total vulnerability of the study area, the generation of the population density/age and the building materials datasets from the Hellenic Statistical Authority[28] was a necessary prerequisite. For the generation of the above mentioned datasets, the 2011 Census data were processed along with the support of very high resolution satellite images and orthophoto maps.

3.5. Exposure

The economic exposure layer was generated by using land use and land values data (€ / m^2), very high resolution satellite images and orthophoto maps. These data were obtained from the Ministry of Digital Government[29] and contained polygons with the land value zones. In order to handle areas with no information on land value, polygons of these areas were created and values were manually assigned, through an exhaustive analytical process were the neighbouring land values and the photo-interpretation of high-resolution satellite images and orthophotos were assessed and combined.

3.6. Fire risk

For the risk assessment, the datasets of a) hazard, b) total vulnerability and c) exposure, derived in the previous stages of the methodological approach were fused. Each one of the 4 spatial layers concerning fire hazard were combined with the layer of total vulnerability and economic exposure and the final risk maps were produced for the area of interest.

4. Results

4.1. Fire risk maps

Fire risk maps (e.g. Figures 5, 6) depict the fire risk per building block according to the socio-economic characteristics, the resistance of the buildings and the spatio-temporal spread of fire. Two fire risk maps were produced for each one of the 4 fire ignition areas, with the former presenting the fire risk and the population gathering areas (social and cultural sites, such as schools, museums, etc.), while the latter the fire risk and the essential infrastructure and services of the area (road network, fire brigade, etc.). It is emphasized that building blocks that are shown in red and orange colour are of the utmost importance and priority, as these are of the highest risk during the 1st and the 3rd hour of the fire spread respectively.

[28] https://www.statistics.gr/
[29] https://www.minfin.gr/

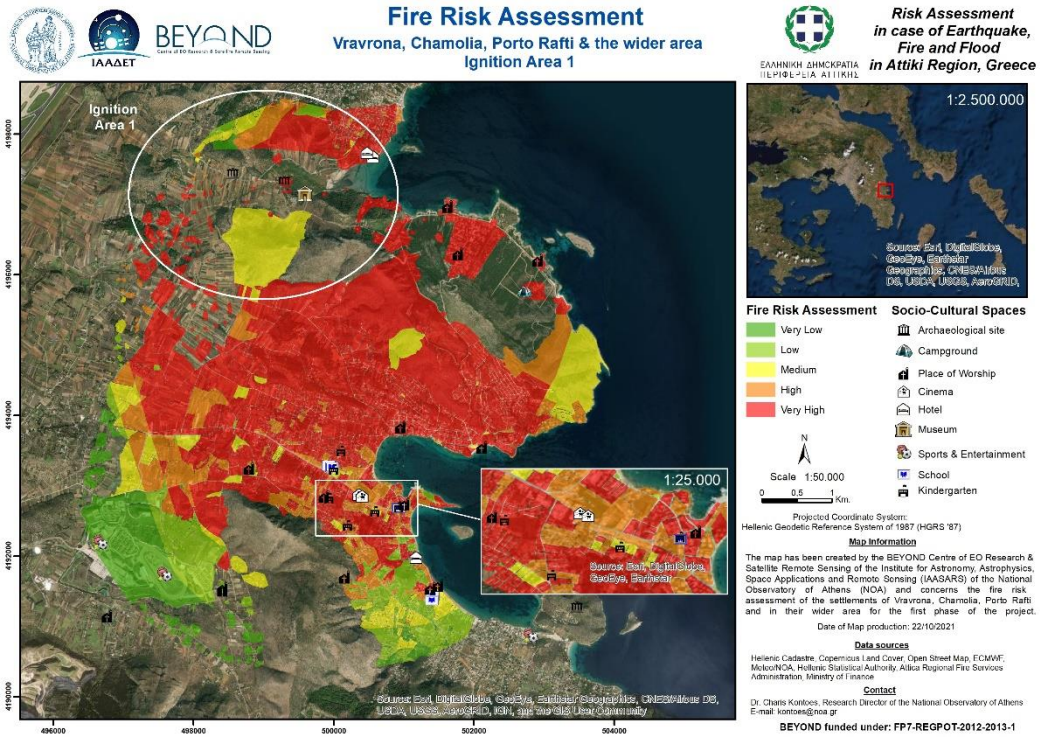

Figure 5- Fire risk assessment for the ignition area 1 (Socio-cultural Places).

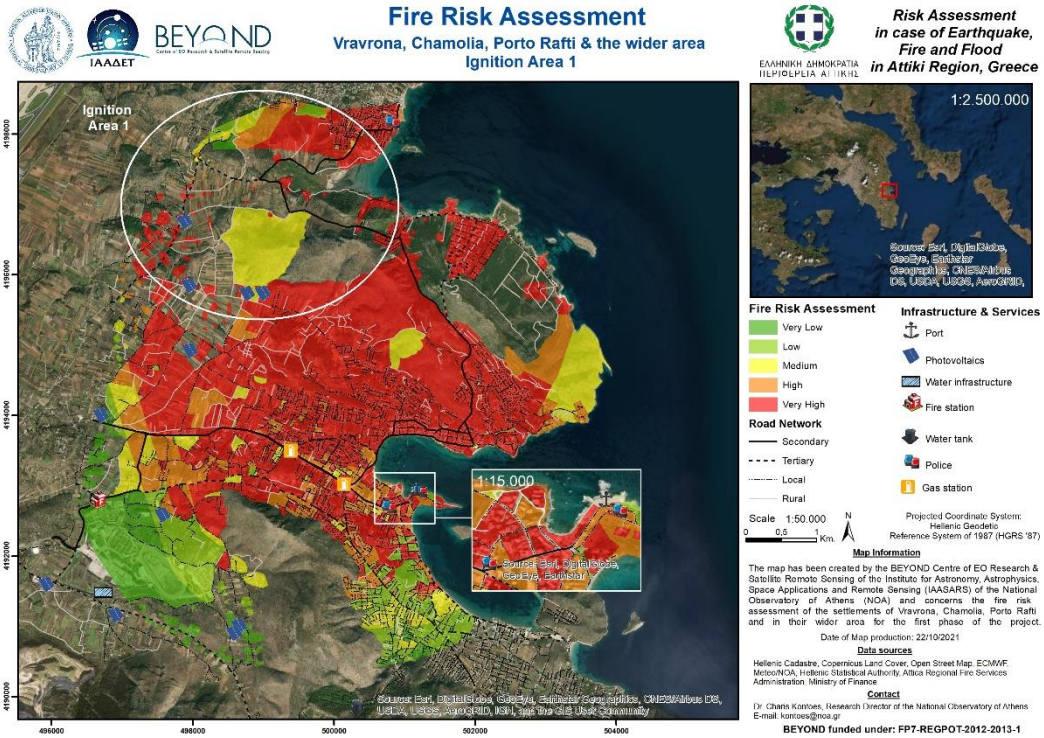

Figure 6- Fire risk assessment for the ignition area 1 (Infrastructure & Services).

4.2. Field observations/Management planning

The study area was divided into sectors for the optimization of field work and the proposed management plans. These sectors were selected according to the produced risk maps and autopsies as the most prone to fire in the area. Priority in each sector was high population gathering areas such as schools, hospitals, nursing homes, etc., as noted in the fire risk maps presented in the previous section. During the field-work, several critical characteristics of the area were recorded like for example road dead ends, high slopes, suitability of roads, possible escape routes, existence of fire protection infrastructure, properties that are surrounded by trees, yards

and roofs covered by pine needles or waste, etc. All these contributed to the creation of evacuation maps (e.g. Figure 7) for the defined ignition areas, with assembly points in case of emergency and escape routes. Moreover, proposed fire protection zones were also mapped as an extra measure of fire protection followed by a list of management suggestions such as the placement of fire alarm and protection systems and cleaning of roads and properties.

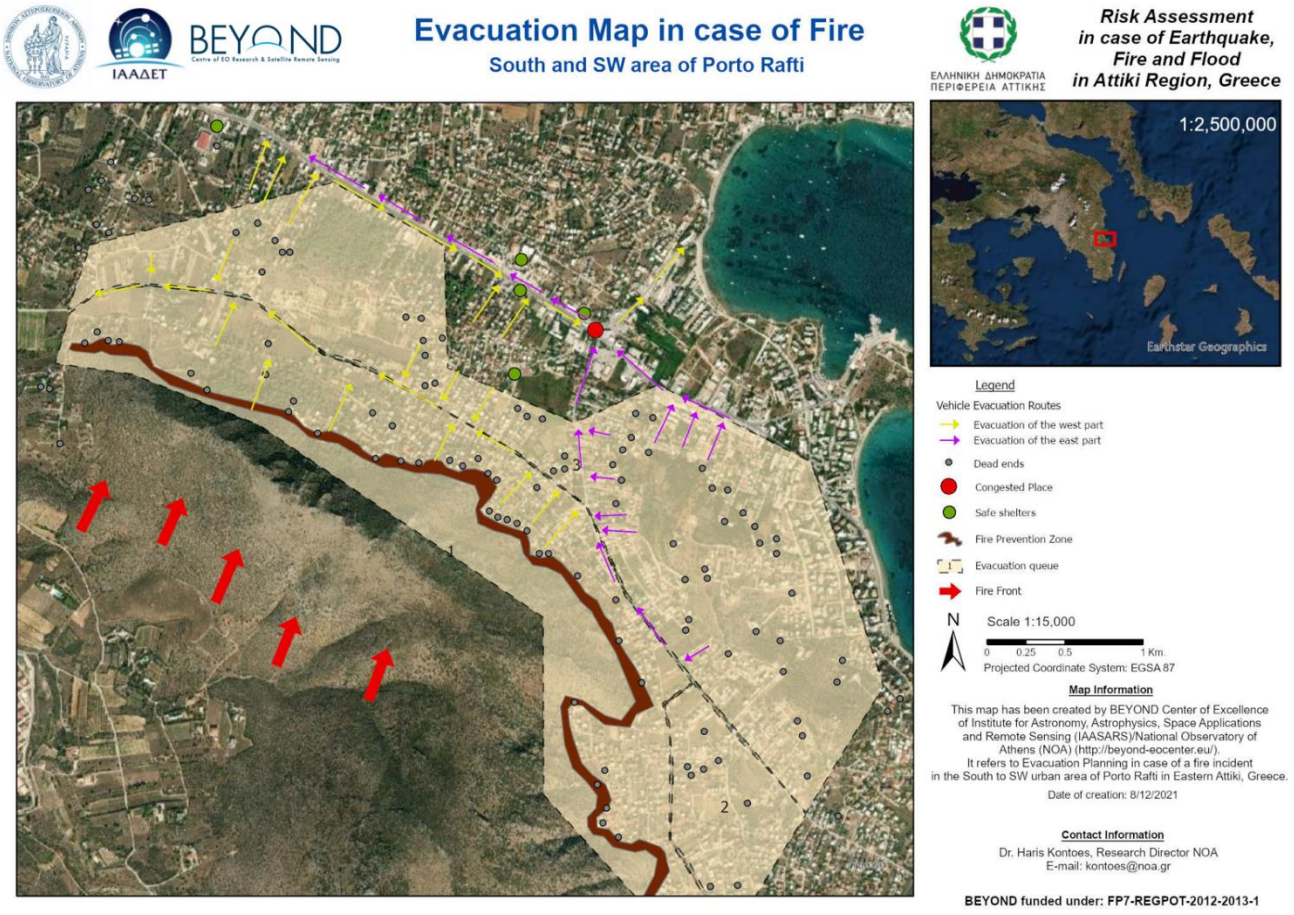

Figure 7. Example of evacuation map.

5. Conclusions

Demographic data, such as population density and age distribution per building block and the buildings' fire resistance characteristics yielded the foundation for a robust approach to estimate the fire vulnerability of each block. In addition, the combination of vulnerability with land values (as a level of economic exposure) composed a comprehensive socio-economic assessment of building-blocks in the event of fire. The combination of the above with the numerous simulations of fire spatio-temporal propagation scenarios led to the overall fire risk assessment of the study area. The two settlements of augmented fire risk, identified through the risk maps and distinguished during the field campaign are the eastern part of the settlement of Hamolia and the settlement of Vravrona (mainly south of Vravronos Avenue on the slopes of the hill). Both of these areas are in direct contact and within the forest, which penetrates into the properties and is adjacent to roofs, power cables, etc. The road network of the areas consists of poor quality roads with significant slopes and many dead ends. In addition, the roads are covered by pine needles, dry side grasses and many of them are used as parking lots. No, or poorly maintained, firefighting and fire protection systems were recorded in those areas. Finally, it is crucial that all civilians take the necessary precautions (e.g. cleaning their roofs and yards from foliage) and follow the instructions of the responsible actors in combination with the development of the appropriate fire preventive measures and fire protection infrastructure.

The presented methodology signifies the importance of coupling innovative technologies (ML modelling, geoinformatics, etc.) and contemporary data (e.g. EO data) with field-work, in service of human life and

infrastructure protection. It is an integrated approach of fire risk assessment and management at a very high-resolution level of analysis (building-block), that is produced for Greece and sets a precedent for the first time.

6. Acknowledgements

This research has been supported by using data and resources from the projects "Seismic, Fire & Flood Risk Assessment in Attica Region, Greece" funded by Attica Region and "CLIMPACT: Flagship Initiative for Climate Change and its Impact by the Hellenic Network of Agencies for Climate Impact Mitigation and Adaptation" funded by the Greek Government – Ministry of Development & Investments.

Fire modeling, burn probability, extreme fires, wildfire risk, Europe

Abstract

This research shows the potential use of cross-boundary fire modeling systems at the pan-European level. Despite the growing interest in building fire-resilient cultural landscapes, European Union (EU) level efforts have been reactive and focused on early detection, fire propagation monitoring, and perimeter mapping rather than predicting where the disaster can potentially occur to develop a comprehensive wildfire management strategy. We propose a modeling system that integrates wildfire occurrence models and observed fire-weather scenarios with a fire spread model to generate the probabilistic risk components, i.e., wildfire likelihood and hazard estimates. We selected four NUTS-2 level administrative division pilot sites from different fire-prone countries to implement the modeling system. The European-level pyromes were first delineated based on ecoregions and historical wildfire activity. We then generated human and lightning wildfire occurrence models to display the ignition points. Remote sensing products were used to derive fire spread modeling spatial input data such as surface fuels and canopy metrics. Global atmospheric products were used to calculate the fuel moisture content with physical models and determine the most frequent wind scenarios for each pyrome. We then used the Minimum Travel Time algorithm to model the fire footprints that correspond to 10,000 years or synthetic iterations. This modeling approach accounted for the spatial variation of ignition locations and the changing weather conditions across the different pyromes within each pilot site. The modeling results include the annual burn probability and fire intensity rasters, and fire perimeter vector outputs. Modeled burn patterns showed a close agreement with observed fire size distributions. We compared this modeling system with previous works to explain why stochastic fire modeling is essential to assess wildfire exposure of natural values at risk and human communities. Our results may help predict future catastrophic fires and provide quantitative estimates to identify high-priority management areas within vast regions. The probabilistic predictions generated in this work represent the foundation for developing long-term adaptation strategies to better coexist with fire. This work is also a demonstration of how this modeling system is replicable in any European country.

1. Introduction

In the European Union (EU), some 72,500 fires burned about 450,000 ha annually from 1990 to 2019, and Mediterranean countries alone (i.e., Portugal, Spain, France, Italy, and Greece) accounted for 86% of the total burned area (San-Miguel-Ayanz et al., 2021). Despite the high effectiveness in suppressing most ignitions, the few extreme fires escaping initial attack overwhelm firefighting efforts and burn vast areas (Rodrigues et al.,

2019a). These wildfire events show very high spread rates, exhibit extreme behavior and produce massive amounts of embers showered at long distances (Tedim et al., 2018). The 2007 fire season in Portugal and the Greek fires of 2021 (e.g., a single mega-fire burned 45,000 ha) are the most recent extreme wildfire manifestations (Ribeiro et al., 2020). Increasing fuel loads in cultural landscapes and more frequent severe droughts are the main factors explaining the increase of severe wildfire episodes in Mediterranean areas. As a result, the European Commission promoted the development of early detection and fire risk monitoring systems that facilitate a coordinated emergency response among the EU members. However, as the fire exclusion policy fails to protect socioeconomic and natural values at risk, wildfire managers request a paradigm shift towards a management-oriented, more preemptive strategy (Wunder et al., 2021).

The wildfire risk assessment integrates burn probability estimates with fire effects at different fire intensity levels (Finney, 2005). On the other hand, the wildfire exposure analysis describes burn probability and fire intensity but ignores potential effects. Fire intensity and burn probability show complex patterns across landscapes due to the interaction between fire spread direction, weather scenarios, topography, and heterogeneous fuels. Moreover, a given location will show a variable fire intensity depending on the changing interactions between the previously mentioned factors. Therefore, understanding wildfire exposure and spatial risk patterns is paramount for strategic management in extensive areas (Palaiologou et al., 2022).

Fire simulation modeling is essential to generate a large sample of fires, reduce uncertainty, and capture the stochastic variation in fire ignition location and changing weather conditions (Finney et al., 2011). Observed extreme fires are rare episodes, rearrange fuels over large areas, and represent a far too limited sample of the potential burn patterns. Modeling the fire footprints for thousands of years or iterations from a sufficiently large set of plausible scenarios allows for describing the magnitude of the next "black swan" event. In this line, recent fire modeling studies showed strong capabilities for predicting catastrophic wildfires (Ager et al., 2021).

In this study, we generated the spatial dataset of probabilistic wildfire risk components for three NUTS-2 level fire-prone administrative units from different EU countries. Our previous works implemented fire modeling systems in Mediterranean areas at regional and national levels (Alcasena et al., 2021; Palaiologou et al., 2021; Salis et al., 2021). We demonstrate in this work how probabilistic modeling systems can be replicated at the pan-European level using a harmonized set of input data. The outcomes showed a high potential to allocate management efforts efficiently at the continental level from science-based consistent fire exposure and risk metrics.

2. Material and methods

2.1. General framework

This modeling system parallels previous works conducted in the US (Finney et al., 2011; Short, 2017). The system includes a wildfire occurrence module to predict lightning and human ignitions across the landscape, and weather conditions are sampled from the most frequent observed scenarios during the wildfire season (Fig. 1). The landscape file contains spatial data for fuels and terrain. The outputs include the annual burn probability, flame length probabilities, and modeled fire perimeters for the NUTS-2 fire-prone selected sites.

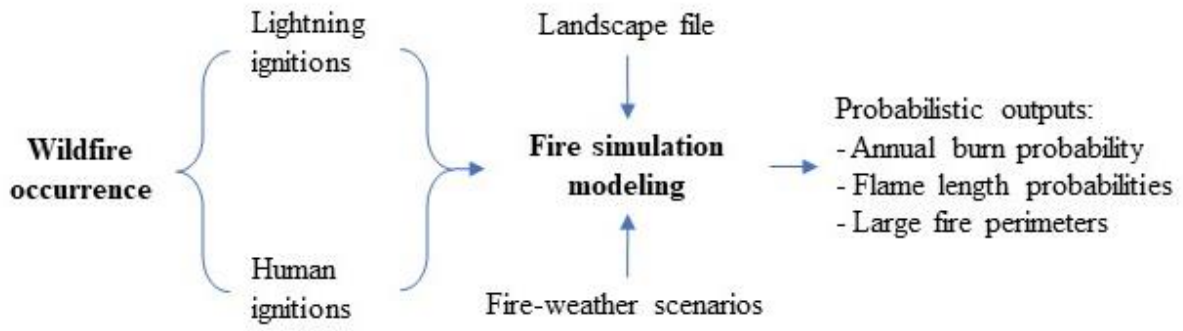

Figure 1: General flowchart of the modeling system.

2.2. Pyrome delineation

We used clustering techniques to delineate the pyromes within the EU ecoregions based on historic wildfire activity (i.e., annual burned area) and large fire weather typologies (Rodrigues et al., 2020). The ecoregions describe the areas with similar ecosystems resulting from edaphoclimatic conditions and dominant vegetation types. The burned area was calculated for a 100-km^2 grid using remote sensing global products. The pyromes were 2,500 to 5,000 km^2 cross-boundary blocks nested within the ecoregion map.

2.3. Pilot site selection

The pilot sites were selected from the NUTS-2 level EU administrative division considering the annually burned area. The burned areas were calculated using remote sensing data and available wildfire records from the last 25 years. We selected four administrative units from different fire-prone Mediterranean countries (Portugal, Spain, Italy, and Greece).

2.4. Input data

2.4.1. Wildfire occurrence

We generated different wildfire occurrence models to predict human and lightning ignition locations. The models were built with machine learning techniques using European-level geospatial data extracted from ignition point locations (Rodrigues and De la Riva, 2014). The number of available years varied between countries but were sufficient to enable us to extract a large data sample to build the models. The fire modeling input data were presented as 100 m resolution ignition probability grids for lightning and human ignitions.

2.4.2. Landscape file

The landscape (LCP) spatial data grids include terrain (aspect, elevation, slope), surface fuels, and canopy metrics. First, we associated a standard fuel model to each land cover class from the 2018 Corine land cover grid to generate the fuel model map (EEA, 2018; Scott and Burgan, 2005). Next, the canopy metrics were **Fire-weather scenarios**

We characterized the most frequent fire-weather scenarios for each pyrome. The winds (speed, direction, and probability) were derived from atmospheric circulation patterns (Rodrigues et al., 2019b), and the fuel moisture content was calculated at 500 m resolution for different percentile values (e.g., 50, 85, 90 and 97th percentiles) with physical models from global products (Resco de Dios et al., 2021).

2.5. Fire simulation modeling

We used the minimum travel time algorithm (MTT) to model fire spread (Finney, 2002). The MTT has been widely used in fire-prone areas to model fire footprints for thousands of synthetic years (Alcasena et al., 2021; Salis et al., 2021). First, the fire spread model was calibrated to replicate the observed fire size distributions. Then, we modeled 10,000 years or iterations at 100 m resolution. Lightning and human fires were separately modeled considering different fire-weather percentile thresholds and frequencies calculated from observed burned areas.

3. Expected results

The expected dataset of probabilistic fire risk components for the three fire-prone NUTS-2 pilot sites will contain the annual burn probability (number of times a pixel burns divided by the modeled years), flame length probability grids (burn probabilities for 20-bin 0.5 m flame length levels), and fire perimeters polygons.

Abstract

Moisture stored in live and dead vegetation acts as a regulator on fire behaviour and area burned. Climate change is altering the distribution of live and dead fuels in forests through drought and insect-induced mortality and simultaneously making dead fuels more flammable because of decreasing fuel moisture. These system changes, both of which are driven by increasing temperature, have the potential to increase the heat flux from combustion, contributing to an increased risk of fires in affected areas becoming plume-dominated. In the southern Sierra Nevada of California and the Rocky Mountains in Colorado, drought and insect outbreaks have increased tree mortality rates, increasing the proportion of biomass that is in dead versus live fuel pools. We sought to determine the contribution that high rates of mortality could have on potential changes in energy release (energy release component and fire radiant energy) for mixed-conifer forests in the southern Sierra Nevada and lodgepole pine forests in the Colorado Rocky Mountains, the site of two large wildfires during the 2020 fire season. We found substantial increases in dead fuels and substantial decreases in fuel moisture during 2020, which increased the potential fire radiative energy. Our results demonstrate that climate-driven tree mortality and increasing temperatures that lead to lower fuel moisture are increasing the amount of energy stored in biomass that is available for combustion.

1. Introduction and Methods

1.1. Introduction

Fuel moisture content (FMC) helps regulate the amount of fuel available for combustion during wildfire (Brown and Davis 1973, Rothermel 1972). Climate warming is increasing atmospheric water demand and early season temperature increases are causing forest fuel FMC to decrease earlier in the fire season (Abatzoglou and Williams 2016, Westerling 2016). Ecosystem drying from increased warming is also increasing rates of tree mortality globally, which has the potential to increase the proportion of biomass within a forest that is more responsive to temperature effects on FMC (Allen et al. 2015, Goodwin et al. 2021).

Drought and insect-induced mortality events increase the total biomass in the dead fuel pool (Goodwin et al. 2020). The primary fuel for wildfire ignition and spread, fine fuels (litter, 1-, 10-, 100-hour), are available to burn for the duration of fire season in dry conifer forests (Rothermel 1972). While fire season length has increased with increasing temperature, it has not influenced the proportion of these quick drying fuels that are available to burn. However, large fuels (1000-hour +) dry out over longer time scales and are typically unavailable to burn during a sizable fraction of the fire season. Climate change may be increasing the availability of these larger fuels because of the increasing aridity that results from increasing temperature (Abatzoglou and Williams 2016).

Two large fire events during the 2020 fire season, the Creek Fire in the southern Sierra Nevada and the Cameron Peak Fire in the Colorado Rocky Mountains, burned through forests that had been heavily impacted by drought and insect-mortality (Meddens and Hicke 2014, Pile et al. 2019). The 153,738 ha Creek Fire began September 4, 2020 and burned through an area where severe drought from 2012-2016 had caused as much as 90% overstory tree mortality. The 84,443 ha Cameron Peak Fire began August 13, 2020 and burned through an area that had extensive mortality from a bark beetle outbreak that peaked from 2007-2009. Here we use forest inventory data

from these two fire footprints to estimate the potential increase in fire radiative energy (FRE) as a function of mortality, temperature, and fuel moisture.

1.2. Methods

We used US Forest Service Forest Inventory and Analysis (FIA) plot data to estimate increases in dead tree basal area before and after drought/insect mortality in the forest types in which these fires burned. Our selection procedure for plots that were measured both before and after disturbance and included the target tree species resulted in a sample size of 118 plots in the Sierra Nevada and 173 plots in the Rocky Mountains. We used changes in dead biomass following drought/insect mortality to calculate changes in fuel availability and FRE.

To quantify changes in 1000-hour FMC and ERC over the past three decades, we used daily maximum temperature, 1000-hour fuel moisture, and ERC data from GRIDMET (Abatzoglou 2013). We also used 1000-hour fuel moisture data for the southern Sierra Nevada from the Wildland Fire Assessment System (WFAS) and temperature data from the Remote Automatic Weather Station (RAWS) Climate Archive to develop monthly fuel moisture and temperature averages for 1998-2002, 2012-2016, and 2020. For the Colorado Rocky Mountains, we used 1000-hr and lodgepole pine (*Pinus contorta v. contorta)* fuel moisture data from WFAS and corresponding RAWS temperature data for 2006-2010 and 2016-2020. We converted FMC to water content to calculate FRE and biomass consumed using the equations outlined in Smith et al. (2013).

2. Results and Discussion

2.1. Results

Drought and insect mortality within these forest types caused a substantial increase in dead basal area when we compared pre/post-drought inventory data (Figure 1). Hotter temperatures during the 2020 fire season decreased 1000-hour fuel moisture and increased energy release component (ERC) over previous seasonal averages (Figure 2). In both the Creek Fire and Cameron Peak Fire footprints, the proportion of 1000-hour fuels available to burn because they fell below the 30% moisture threshold increased during the 2020 fire season, with approximately greater than 80% of the fuel available by the start of the Creek Fire in July in the Sierra Nevada. Similarly, data from the Cameron Peak Fire in the Colorado Rocky Mountains indicate that a 5% reduction in fuel moisture increases dead fuel availability by 7%.

2.2. Discussion

Our results indicate that as climate change interacts with agents of tree mortality such as insects and drought, the amount of dead tree biomass will substantially increase and hotter temperatures can make that biomass more available to burn. Globally, tree mortality is increasing, and this suggests that as ecosystems come into alignment with changing climatic conditions, we can expect an increase in the amount of dead fuel, which is more responsive to changes in temperature and precipitation (Allen et al. 2015, Goodwin et al. 2020). Understanding how this additional stored energy will influence fire behaviour and ecosystem effects are important areas of investigation that requires further investment.

Fuel depth; tree species; fuel bed; boreal; fuel load; BEHAVE

Abstract

The highly managed forests of Fennoscandia are dominated by coniferous (Scots pine and Norway spruce) stands with occasional inclusion of deciduous trees (Betula spp, Populus tremula, Quercus robur). Without active pre-commercial thinning, broadleaved deciduous trees would be more common and it is often assumed this would reduce flammability. Generally, there is little information on surface fuel structure in Fennoscandia and its relation to the dominant tree species. We therefore evaluated fuel characteristics in 153 plots from 82 mature, closed-canopy forest stands dominated by Pinus sylvestris (23), Picea abies (20), Quercus robur (20), Betula pendula (14), Populus tremula (5).

Stand properties (tree species and basal area) were measured on site and fuel bed composition was determined by destructive sampling of two 0.25 m2 plots per stand (species, fuel bed depth, weight, %-coverage). Dry weight per fuel category was measured in the laboratory. The measured parameters were used as input to the BEHAVE wildfire model, to assess relative fire behaviour for these different fuel assemblies.

The results show that the moss/litter layer (sometimes including lichens) was thicker and had a larger dry weight under pure pine stands compared to that under spruce stands. BEHAVE modelling suggested both fireline intensity and rate-of-spread to be substantially higher for pine stands. As for the broadleaved deciduous tree species, even a small inclusion in the coniferous stands severely affected the moss/litter layer. Leaf litter formed horizontal, multi-layered packs that replaced the porous structure and high surface-to-volume ratio of the moss/litter with a more compacted pure litter layer, resulting in reduced flammability.

The BEHAVE models presented here are available at https://www.ri.se/sites/default/files/2021-12/SwedishForestFuels_0.zip.

1. Introduction

Of the three main driving factors for wildfire spread and intensity – weather, terrain, and fuel – it is only the fuel that can be modified to reduce risk (Skowronski & Gallagher 2018). For tactical fire suppression it is also essential to characterize various biotopes from a fuel quality perspective, e.g. in the form of standardized fuel maps (Fernandes, 2009).

As for boreal regions it is often assumed that the fuel situation is relatively uniform, with a conifer canopy above moss/litter surface fuels. There are, however, surprisingly few quantitative analyses to illustrate this (but see Brown, 1974; McRae, 1979). The Fennoscandian boreal region, comprising Sweden, Finland and part of Norway is dominated by two conifer tree species, *Pinus sylvestris* and *Picea abies*, but there is also a high potential for broadleaved deciduous trees, primarily *Betula* spp and *Populus tremula*, which often outcompete the conifers unless culled by pre-commercial thinning (Andersson, 1993).

Experimental burns (Granström & Schimmel, 1998; Tanskanen, 2005) as well as empirical evidence from large fires (Nilsson et al., 2014; Granström, 2020) suggest that fires in Fennoscandia most often burn as surface fires, consuming mainly the moss/litter layer including lichens on the forest floor. Crown fires are rare and when they occur usually cover only minor parts of the burnt area.

Although the tree canopy seldom becomes involved in the fire directly (i.e. crowning), the stand type and structure will have an indirect effect through the litter composition and quantity, as well as by affecting both the vascular and non-vascular flora on the forest floor. For instance, leaf size affects both the litter characteristics and the extent of shadowing by the sub-canopy layer (Kauf et al., 2018; Dickinson et al., 2013). These stand-type to surface fuel relationships are not yet well established in Fennoscandia. Here we aim to relate stand properties to the surface fuel characteristics for five homogenous stand types and to provide indications of how deciduous tree inclusion in coniferous stands alter the surface fuel structure.

Wildfire modelling has several important uses, for instance as an operational tool during large incidents, and in preventive planning, to identify areas with an elevated hazard. In models such as BEHAVE, the fuel composition is accounted for using so called "fuel models". There are 53 predefined fuel models for the BEHAVE software, based on extensive field sampling of biotopes in the U.S. (Burgan & Rothemel, 1984; Scott & Burgan, 2005), which also form the basis for their national fuel map. None of these models apply *a priori* to boreal forests with moss/litter as the main fuel component. Thus, a secondary aim of this study was to build fuel models for wildfire modelling based on the quantitative fuel distributions we obtained.

2. Methods

2.1. Selected sites

Fuel characteristics were recorded for 153 sample plots under 82 mature stands of *Pinus sylvestris* (pine) (23), *Picea abies* (spruce) (20), *Betula pendula* (birch) (14), *Populus tremulus* (aspen) (5) and *Quercus robur* (oak) (20). Stands were sampled from the 55th to the 64th parallel for most species (Fig 1). Homogeneous oak stands, however, occur predominantly in the south-eastern Sweden and thus, geographically restricted the sampling.

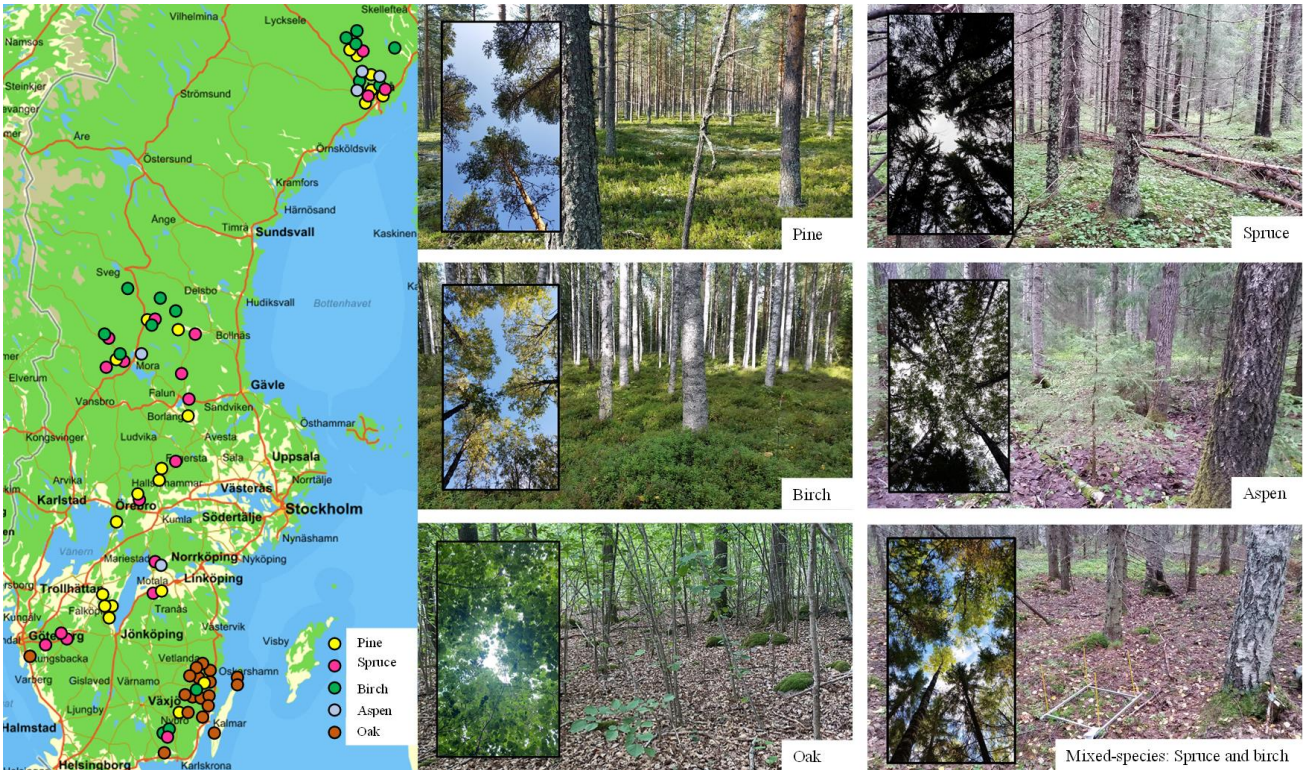

Figure 1. Geographical locations of stands and examples of selected stand types.

The study was delimited by selecting stands that were on dry or mesic soils according to the SLU site index estimation (Hägglund & Lundmark 1977), lacked large stone blocks, had a closed canopy with homogenous stand properties (except mixed stands) and were not in the first cycle of forest on abandoned farmland. Most Swedish forests are production forests where occasional thinning takes place. Thinning will add branch litter and impact surface fuels. We therefore omitted any stand with thinning operations less than 10 year before sampling.

2.2. Field data collection

Stand height and basal area of all tree species in each stand was determined using a relascope and hypsometer. Surface fuel was destructively sampled on two representative 0.25 m^2 plots in each stand (Fig 2). Cover of field layer species (mostly ericaceous shrubs e.g. *Vaccinium* spp or *Calluna vulgaris*) was visually assessed and their respective height measured. They were then cut at the top of the moss layer and brought to lab for obtaining dry weight after drying at 95℃. Similarly, the surface cover of moss/litter layer was assessed per species and litter type (leaves, needles etc.).

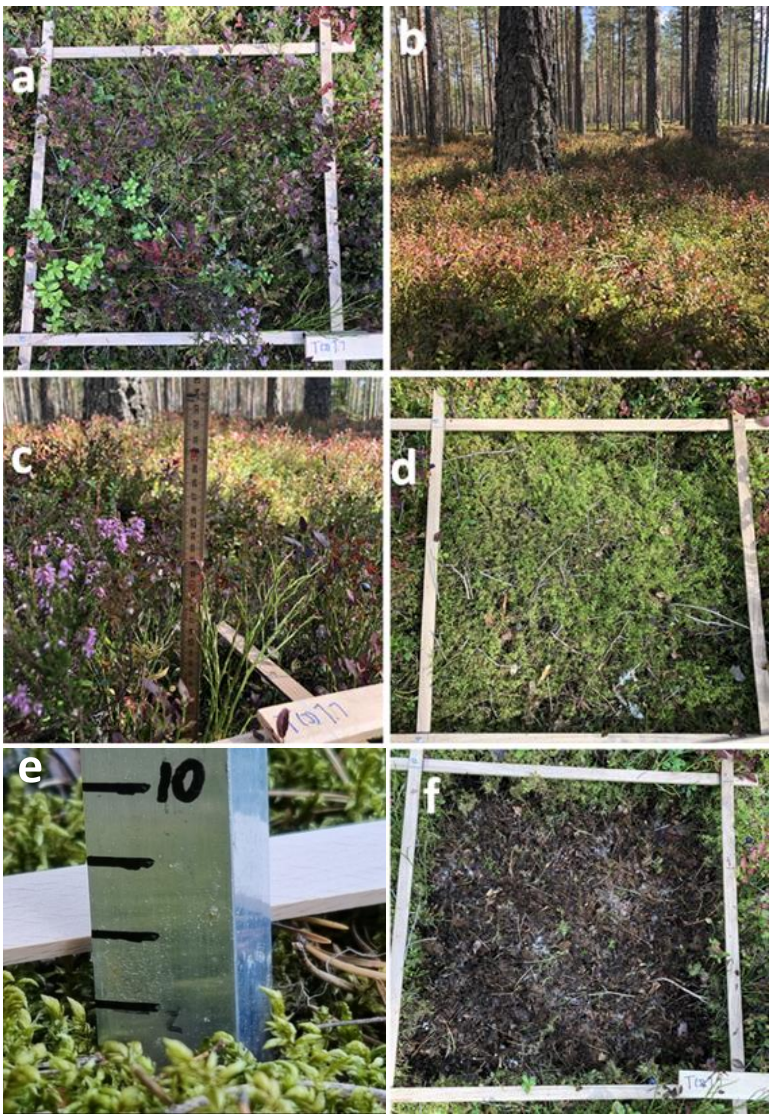

Figure 2. Progressive steps for quantifying the fuel structure: (a) Estimating surface cover of different shrub species; (b) Photographing stand characteristics and performing relascope measurements; (c) Defining shrub height and harvesting for dry weight determination; (d) Estimating surface cover of litter and moss species; (e) Defining depth of moss litter layer by several pressure probe measurements; (f) Harvesting moss/litter layer for dry weight specification and determining humus depth.

Surface fuel depth was determined using the penetration depth of a 2 cm sided L-shaped aluminium probe with a 15 N downward force. This is related to previous observations of what is typically consumed by flaming fire and defines the depth of the moss/litter-layer, a very loosely packed fuelbed of moss/lichen intermixed with tree litter (leaves, needles and other small litter) (Fig 2). The moss/litter layer was thereafter collected to the depth defined by the probe and brought to lab where easily defined litter (dead tree-branches, bark flakes and cones) were separated from the litter/moss-layer, sorted in different size classes (1-h, 10-h and 100-h) (Fosberg, 1971) and dry weight determined. The remaining *Vaccinium/Calluna* stems penetrating the moss layer were also

collected separately. Finally, the humus layer was cut through with a knife and its thickness measured with a ruler, down to the underlying mineral soil.

2.3. Modelling

Results from the field work were used to create five 'custom fuel models' for each fuel type in BEHAVE. BEHAVE divides fuels into different size classes, as well as into a 'live' or 'dead' class. Three modelling parameters; the dead fuel moisture of extinction (25%), the surface area to volume ratio (SA/V) of moss, and other 1-, 10- and 100-h fuels as well as their heat content were extracted from literature (Schimmel & Granström, 1997), Table 1. Finally, all input parameters were weighted based on their average fraction of the dry weight of the fuel package within each size class, Table 2.

Table 1. Fuel parameters taken from Schimmel and Granström (1997)

Modelling parameter	**SA/V** (cm^{-1})	**Heat content** (kJ/kg)
1-h (moss)	115	18700
1-h (needles, bark, dwarf shrub litter etc)	45	18700
10-h	3	18700
Ericaceous shrub	80	21000
Grass and herbs	115	18700

Table 2. Modelling parameters based on the field work

Modelling parameter	**Pine**	**Spruce**	**Birch**	**Aspen**	**Oak**
1-h fuel load (g/m^2)	963	643	396	342	406
10-h fuel load (g/m^2)	40	11	47	47	124
100-h fuel load (g/m^2)	0	3.3	1.3	0	15
Live herbaceous fuel load (g/m^2)	6	6	28	6	8
Live woody fuel load (g/m^2)	192	39	101	63	3
1-h fuel SA/V (cm^{-1})	108.2	107.4	93.8	97.8	97.4
Fuel bed depth (cm)	9.1	5.6	5.5	4.5	2.8
Live fuel heat content (kJ/kg)	20929	20693	20501	19327	19327

These fuel models were run in two different weather situations, (1) a "mild" weather/fuel moisture scenario: 11% m.c. of the dead fine fuel, 170% m.c. of live herbaceous fuel and 100% m.c. of the live woody fuel, and (2) a "severe" weather/fuel moisture scenario (8%, 120% and 90% m.c. respectively). For both scenarios we employed midflame wind speeds ranging between 0-3 m/s and no slope.

Rate of spread (RoS) (m/min), flame length (m) and fireline intensity (kW/m) were obtained for the different type of tree stands as an indication of relative fire hazard.

3. Results and discussion

3.1. Fuel characteristics

The conifer stands, together with birch, had the most developed field-layer (Fig 3). Lingonberry was far more common under pine stands compared to other tree-species. The forest floor in coniferous stands was almost completely covered with moss/lichen while under the deciduous trees the mosses were much reduced, apparently smothered by the leaf-litter. Live herbaceous plants on the other hand, were more abundant under the deciduous stands (Fig 3).

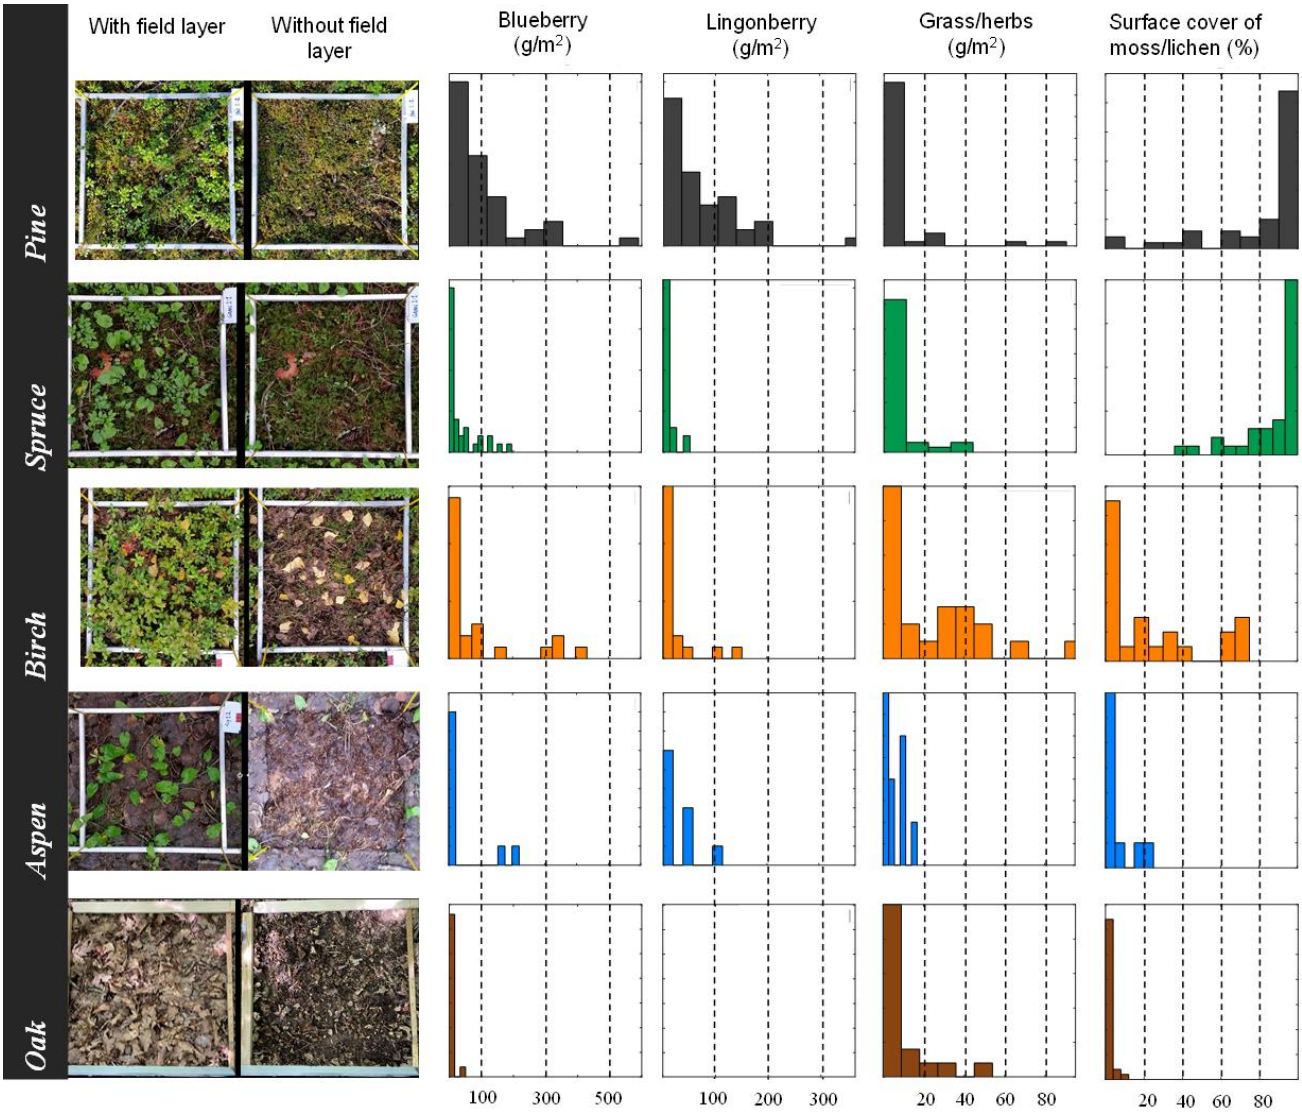

Figure 3. Distributions of measured field-layer fuel parameters and the estimated moss/litter layer surface cover for the five stand types. Photos exemplify the field layer for each stand type before and after removal of the field layer (pine, spruce, birch) and before and after removal of herbaceous species and the litter layer (aspen, oak).

Histograms for the moss/litter layer fuel bed depth and dry-weight show that most coniferous stands had deeper and more massive litter/moss-layers (mean values of 7.6 and 5.2 cm for pine and spruce stands respectively, as opposed to 2-3 cm for deciduous species) (Fig 4). The occurrence of other 1-h fuels and larger-sized litter varied less between stand types except that 10-h fuels were less common in spruce stands and more common in oak stands (Fig 4).

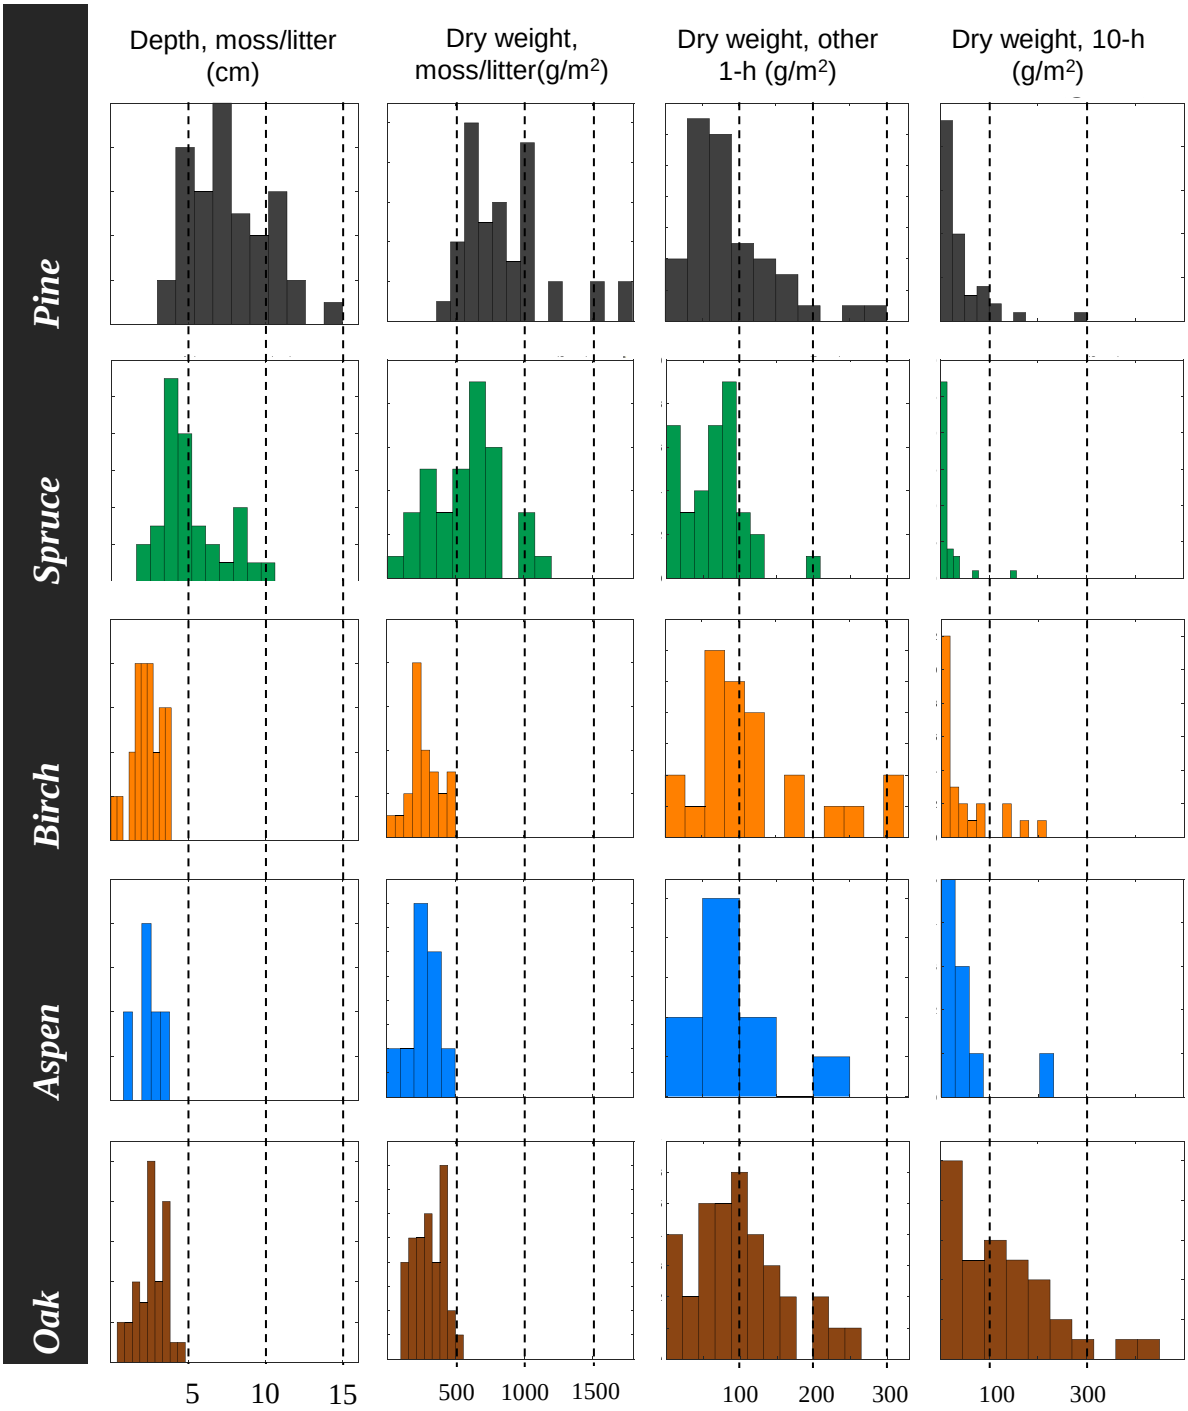

Figure 4. Distributions of measured moss/litter layer fuel parameters for the five stand types. Other 1-h fuels include e.g. easily separated dead tree-branches, twigs and bark flakes.

3.2. Mixed species stands

Sampling of mixed-species stands indicate that even a minor inclusion of broad-leaved trees affected the fuel bed substantially (Fig 5a). The surface cover of moss/lichens was also reduced monotonically with increasing deciduous component (Fig 5b). Moreover, the dry weight of the moss/litter layer decreased with the inclusion of just a few deciduous trees, from 750(±140) g/m^2 for pure conifer stands to an average of around 200 g/m^2 for stands with basal area of birch/aspen trees ≥4 m^2/ha (Fig 5c). No clear effect on the amount of Ericaceous shrubs was found (Fig 5d).

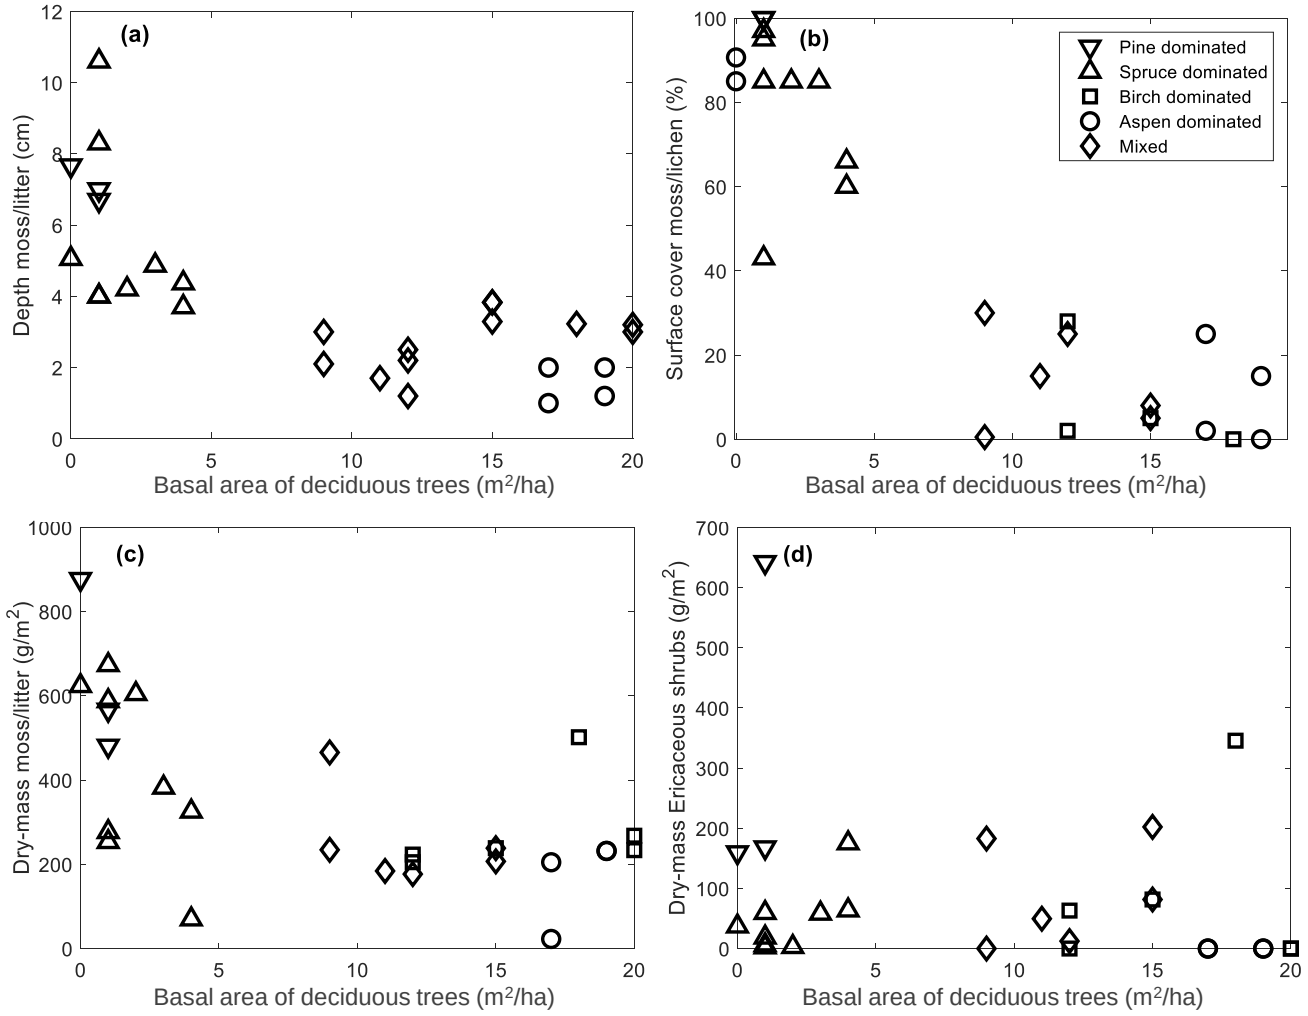

Figure 5. Effect of basal area of deciduous trees (i.e. number of trees in the relascope measurement) on (a) moss/litter depth; moss/lichen surface cover (b); moss/litter weight (c); Ericaceous shrubs weight (d).

3.3. Relative fire behaviour in BEHAVE

For both weather scenarios, pine generated the most severe fire behaviour, followed by spruce, birch, aspen and oak (Fig 6). This relationship holds regardless of wind speed and moisture content and can therefore be normalized to obtain relative behaviour (Fig 7). One can expect the RoS to increase by 50% and 200% when a surface fire enters a pine stand from a spruce or deciduous stand, respectively.

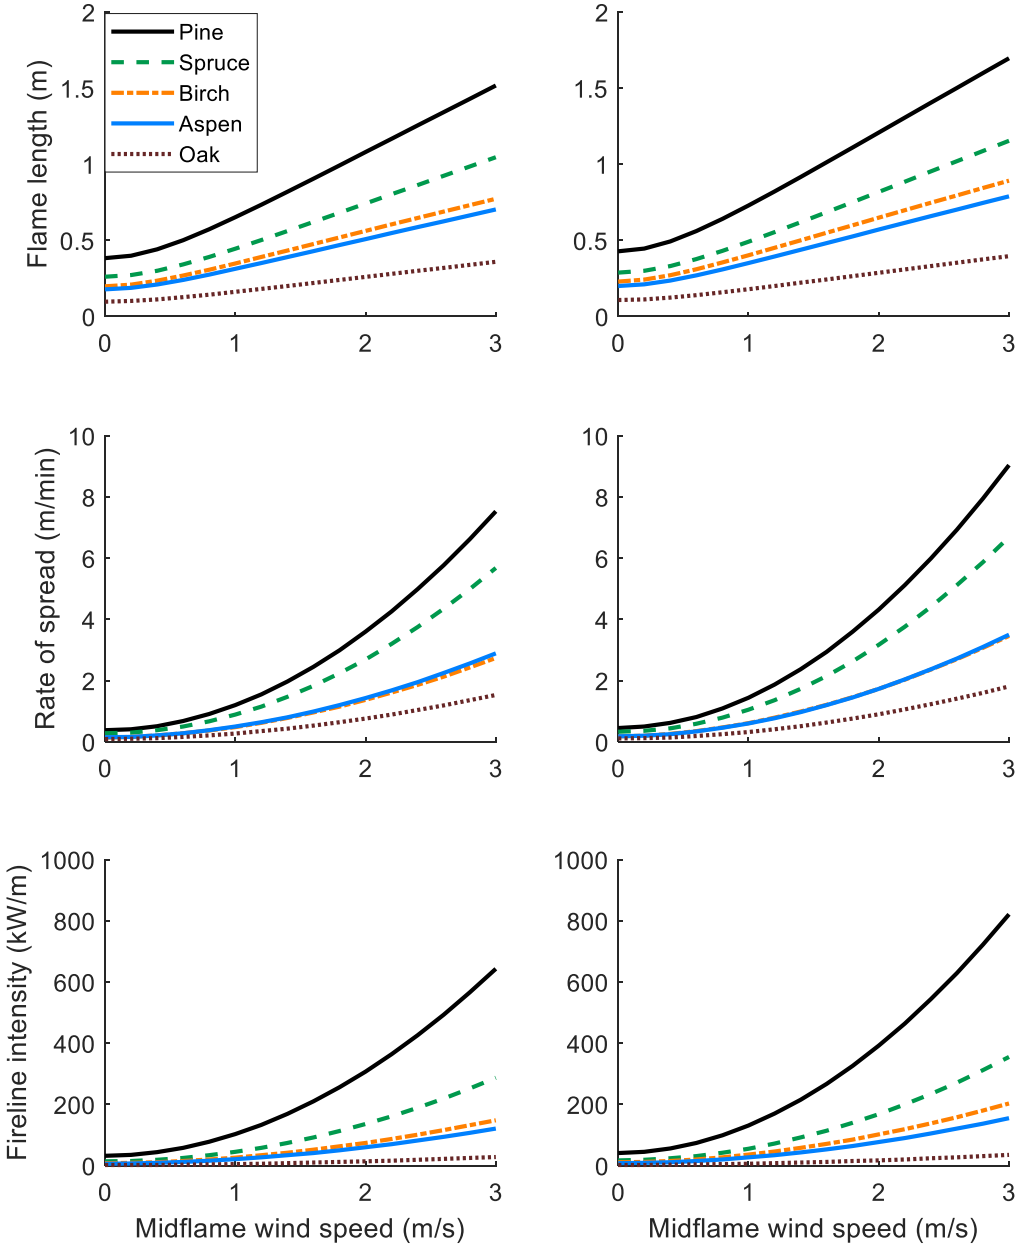

Figure 6. Modelling results for the two weather scenarios: Flame length, rate of spread and fireline intensity

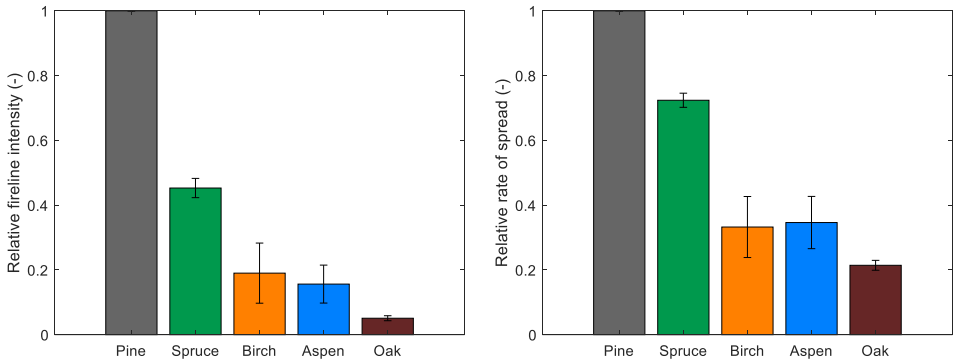

Figure 7. Relative fire behaviour between the different stand types

4. Discussion and conclusions

This study describes the surface fuel characteristics under typical north European closed-canopy stands of five different tree species. It shows that the flat leaves from birch and aspen can smother moss growth and thereby decrease the surface-layer depth and dry weight by more 50%. The porous structure and high surface-to-volume ratio of the moss/lichen under coniferous stands are transformed to a more compact layer of horizontally arranged leaf litter, which likely has a negative effect for both fire rate-of-spread and intensity.

Even a small portion of deciduous trees in a conifer stand has a significant effect on the forest floor fuel structure and as little as 20 % of deciduous trees in a coniferous stand makes the surface fuel structure essentially "leaf-dominated".

In the BEHAVE simulations we found a significant difference in intensity and rate-of-spread between pure pine and spruce stands, mainly due to differences in the depth of the moss/litter-layer. This is possibly related to the higher light availability in pine stands, but also due to structural differences in needles between the two conifers, pine having paired longer needles that add to the loose structure of the moss. According to the BEHAVE modelling this effect results in a 50% and 25% reduction of the fireline intensity and rate-of-spread, respectively, for both normal and extreme summer drought conditions. Relative to pine, broadleaved stands have the potential to reduce both fireline intensity and RoS in a progressing fire front by a factor of 1/5 and 1/3, respectively.

Models are available at https://www.ri.se/sites/default/files/2021-12/SwedishForestFuels_0.zip

Abstract

Response time is an important indicator in fire operations. A continuous assessment of the response time is crucial for monitoring the firefighter's performance level. An initial assessment of fire response time was conducted on selected category A–D fire stations throughout Malaysia from 2018 until 2020. In this study, the mean response time and distance travelled for the selected fire stations were calculated. To measure the fire station's performance, a 10-min standard response time was used as a benchmark. A one-way ANOVA is also applied to determine statistically any significant differences between the mean response time and mean distance travelled. Category C and D fire stations recorded high mean distances travelled and mean response times within the four categories. Most of the fire stations in this category travelled approximately 14 km with a mean response time of 18 mins. A new risk profiling for minimising fire risk stemming from constant development in these areas might be necessary for future improvement

1. Introduction

Fire departments are constantly working with numerous measurements to improve their performance and effectiveness. An essential indicator in the management of any emergency call is the response time. A prompt response by the fire department to the fire scene is crucial for minimising the damage a fire can cause to a structure and public safety. Suppressing a fire before the flashover will reduce the ability of the fire to grow and spread to adjacent areas. A large amount of heat and smoke is generated during flashover, reducing the chances of saving occupants.

The total response time calculation is the period calculated from the receipt of the alarm until the arrival of the first responder team at the scene to initiate action or control the incident. Nonetheless, response times are frequently determined with different measures by firefighters and reported to the public using different approaches (NFPA 1710,2010).

Claridge and Spearpoint (2013) studied the New Zealand Fire Service response time. The response time analysis was established based on topographic conditions and divided into urban and rural area approaches. The response time for the permanent fire station was 90% achievement at 7 min 30 sec while that for volunteer-based fire stations was 90% at 10 min. The United Kingdom regulations for fire are divided into four risk categories (A, B, C, and D), with response times of 5, 8, 10, and 20 min, respectively (Institution, 2019).

Several studies have investigated the response time for monitoring the service performance and capability of fire organisations. Nonetheless, the response requirements vary greatly between countries. The standard response time of the Fire and Rescue Department of Malaysia (FRDM) is 10 min without any classification of demand zone. There have been limited studies on FRDM response times in recent years, but only focused on specific districts or states (Sardi & Razak, 2019; Subramaniam et al., 2012; Tamat et al., 2014). This study

conducted an initial assessment of the response time across different fire station categories and states in Malaysia. In addition, the distribution of Malaysian fire station categories was identified and the mean response times compared using analysis of variance (ANOVA).

2. Methodology

2.1. Data Collection

The fire response time data from 2018 to 2020 were obtained from FRDM. The data were based on fire stations under four categories in five states (Johor, Kedah, Pahang, Selangor and Sarawak). Each state represents a specific Malaysian geographical region, namely East Coast, Northern, Southern, and West Coast Peninsular Malaysia, and East Malaysia. Each state represents a specific Malaysian geographical region. The initial data comprised of fire and rescue incidents, including special tasks assigned such as support to other government agencies on natural disaster relief and handling wildlife. For this study, only fire incidents data recorded from 2018 to 2020 are selected for further analysis.

The State Operations Management Centre or fire station control room involved in the fire incident logs the response time data in the Malaysian Emergency Response Services (MERS) 999 system. The control room duty officer records the interval directly in the MERS 999 system.

The FDRM emergency response time was calculated as follows:

Response time = time of arrival at the scene – time of the alarm is acknowledged at fire station control room

2.2. One-way Analysis of Variance (ANOVA)

Several organisations publish a considerable quantity of statistical data on fires via annual reports on fires and fire departments. Unfortunately, the actual firefighter performance or the relationship between firefighting operations are not included in most statistics (Sardqvist & Holmstedt, 2000).

This study used one-way ANOVA to determine statistically significant differences between the mean response time and mean distance travelled. The first stage of the ANOVA involved constructing a hypothesis statement set consisting of a null hypothesis (H0, all means are equal) and an alternative hypothesis (at least one mean is not equal).

3. Results and Discussion

3.1. Data Description

Currently, there are 324 fire stations in Malaysia and are categorised under A, B, C, D, and E. Nationwide, 52.8% (n = 171) of fire stations fall under category C, indicating moderate-fire risk locations, 25.3% (n = 82) of fire stations are category B, indicating high-risk locations, followed by 11.7% (38) under category A for very high-risk areas. Category E fire stations were excluded from this study as the category encompassed very few fire stations. Figure 1 illustrates the distribution of fire stations in Malaysia according to category.

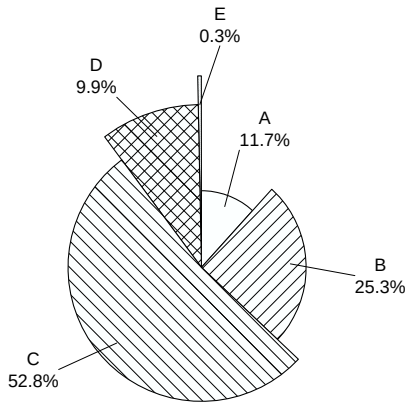

Figure 1. Fire station category in Malaysia

3.2. Fire Incidents of the Selected Stations

Total of 20 fire stations included in this study as listed in Table 1 with 10 233 fire incidents were recorded. Some of the recorded data yielded a negative value due to system error and were excluded from the analysis.

State	Fire Stations			
Johor	Larkin	Kota Tinggi	Pekan Nenas	Yong Peng
Kedah	Alor Setar	Kulim	Pokok Sena	Sungai Petani
Pahang	Bukit Angin	Kuantan	Ringlet	Taman Tas
Sarawak	Kanowit	Limbang	Petra Jaya	Tanjung Manis
Kuala Lumpur	Seputeh	Jalan Hang Tuah	Setapak	Sungai Besi

Table 1. The fire stations included in this study

Figure 2 illustrates the mean fire incidents for 2018–2020 according to category. The mean fire incidents were highest in category A locations, which recorded 50% more fire incidents compared to the other categories. In 2020, there were 15 393 reported fire incidents nationwide from March 18 to August 31. During the same period in 2018 and 2019, 19 165 and 23 094 fire incidents were reported, respectively (Mohammad, 2020). Similar trends were observed for the data from the selected fire stations, where reported cases decreased in 2020. This finding could be related to the issuance of the first Movement Control Order (MCO) beginning 18 March 2020 in response to the COVID-19 pandemic in the country. Over the three consecutive years, the fire incidents reported for all categories was highest for 2019. In the next section, fire station comparisons within a similar category yielded an excellent basis for assessing the response time.

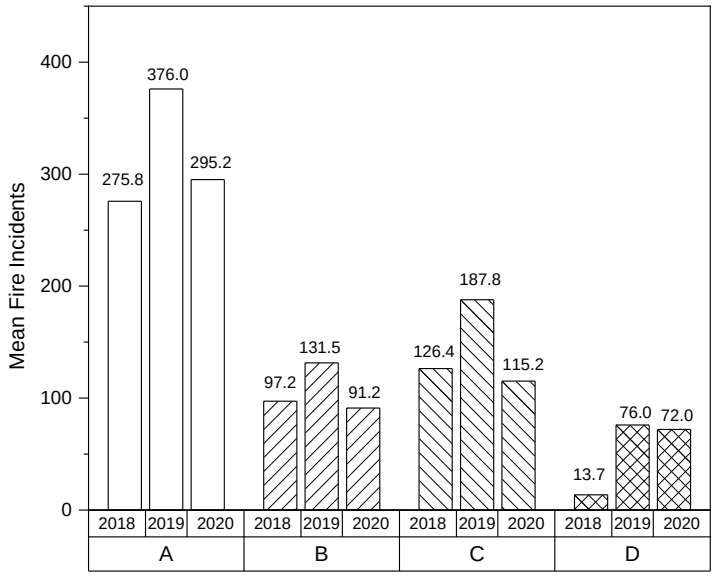

Figure 2. Mean fire incidents reported from 2018 to 2020 for selected fire station for all category

3.3. Mean Response Time from 2018 to 2020

Figure 3 demonstrates that most of the selected fire stations recorded a mean response time of > 10 min between 2018 and 2020. It is worth noting that the mean response time for category A, C, and D fire stations improved, while category B fire stations maintained the same mean response time of 14 min. In 2020, category A and D fire stations met the 10-min standard response time with mean response times of 7.96 and 8.90 min, respectively. The MCO had reduced traffic density significantly, which aided the reduction of the rescue team's delay in arriving at fire incidents as compared to that in 2019, as supported by Chen et al. (2021).

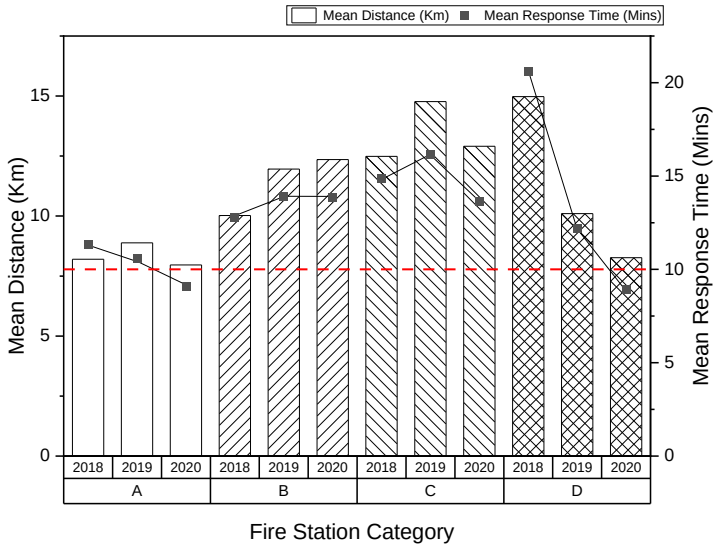

Figure 3. Mean distances travelled against mean response times by fire stations category

The shorter mean distance travelled for category D fire stations could be an important factor for the significant reduction in response time in 2020. Yung (2008), Tómasson et al. (2008), and Claridge and Spearpoint (2013) reported that one of the main factors influencing the response time was the distance travelled, where the city centre recorded average speeds of approximately 20 km/h for a short distance compared to 70 km/h on state highways for longer distances.

This main factor was proven with Pearson's correlation value between response time and distance travelled based on fire station category.

Table 2. Summary of Pearson's correlation analysis

Station category	**A**	**B**	**C**	**D**
Pearson correlation	0.39	0.89	0.76	0.86

Table 2 demonstrates exhibits a strong positive correlation between response time and distance travelled for category B, C, and D fire stations where the values lies between 0.5 and 1. The highest Pearson correlation value was for category B with 0.899, followed by 0.859 and 0.764 for category D and C. This positive value indicates that the response time may increase with distance. Category A fire stations recorded a medium positive correlation (0.387), as the value was < 0.5.

Figure 4 depicts the mean distances travelled and mean response times of the category A fire stations. The highest mean distance travelled and mean response time was recorded for the fire station in Kuantan, a city on the Peninsular Malaysia east coast. East Coast cities are moderately less dense than cities in west or south Peninsular Malaysia. In 2019, Kuantan firefighters travelled a mean 11.76 km to fire incident locations. Meanwhile, from 2018 to 2020, the Kuantan fire station recorded a mean distance travelled of 10.72 km with a mean response time of 13.9 min. The Larkin fire station recorded improved mean response times each year, with a response time of 7.45 min in 2020. The clearer traffic in 2020 could be one of the primary factors for the better response time by the category A fire stations.

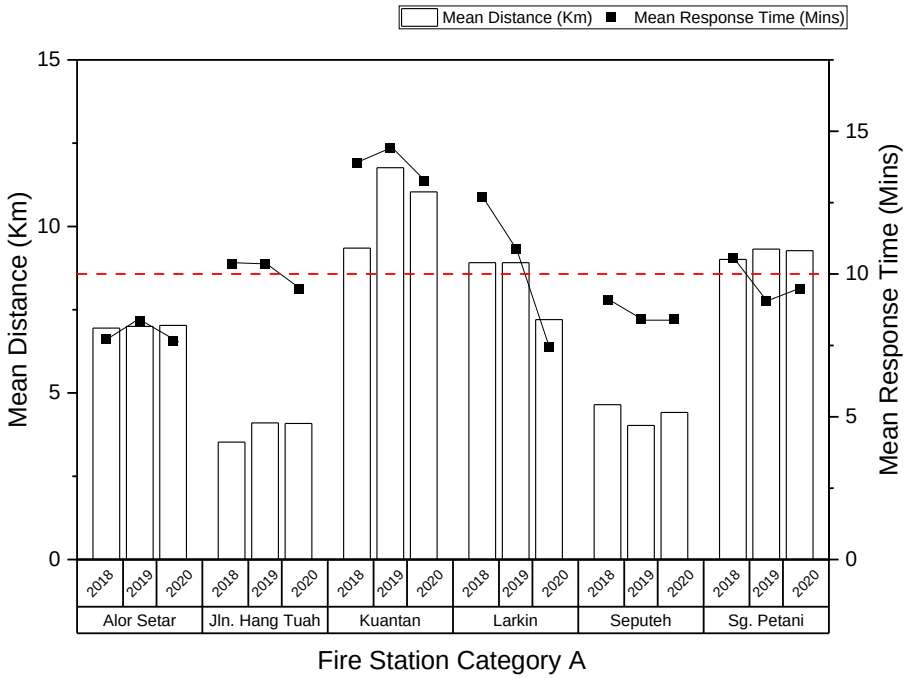

Figure 4. The mean distance and mean response time for category A fire stations

The high response time of the Kuantan fire station might be due to its bigger coverage, as the overall mean distance travelled was 10.88 km. The population and industry distribution in this area are quite distant from each other. A New York study reported that travel time increased linearly with the square root of the distance travelled for short distances and proportionally with the distance travelled for long distances (Kolesar & Walker, 1974).

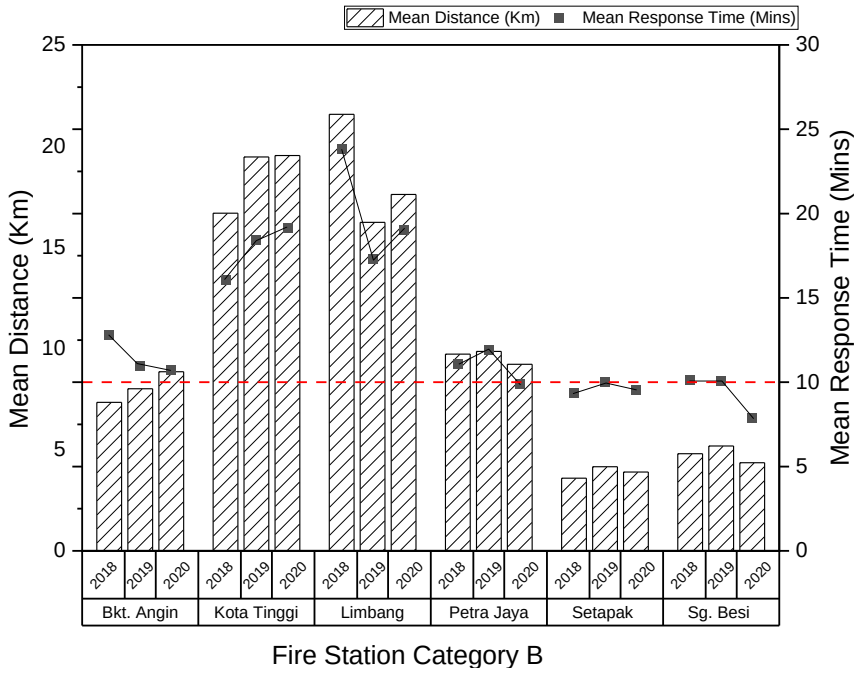

Figure 5. Mean distances travelled and mean response times recorded by category B fire stations

Figure 5 demonstrates that under category B, the Kota Tinggi and Limbang fire stations recorded the highest mean distances travelled and mean response times from 2018 to 2020. The mean distance travelled and mean response times of the Kota Tinggi and Limbang fire stations were 18.6 km and 17.9 mins and 18.5 km and 20.0 mins, respectively. The two fire stations also recorded a slight increment in mean response times for 2019 and

2020. The Setapak and Sungai Besi fire stations recorded consistent mean response times. These two stations experience slower traffic movement during peak hours (to and from the office).

Category C is the largest category of Malaysian fire stations. Figure 6 demonstrates that all fire station except for Kulim fire station did not meet the standard response times in 2019 and 2020. Kulim is a district in Kedah, a northern Peninsular Malaysian state known for its growing industrial area. Kulim firefighters travelled a mean distance of only 8.6 km for three years compared to the 20.1 km by Kanowit firefighters. Kanowit is a Sarawak district with a less dense population and development than other fire stations. This could contribute to larger coverage of Kanowit fire station compare to other areas. The Taman Tas, Yong Peng, and Pekan Nenas fire stations recorded mean distances travelled of < 17 km and decreased mean response times in 2020. The lower traffic density during the MCO could be the main reason for the reduced response times.

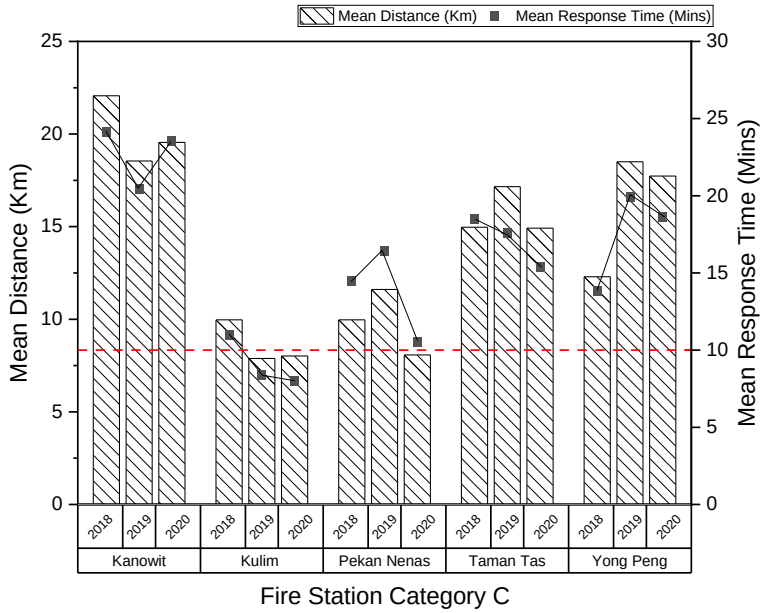

Figure 6. Mean distances travelled and mean response times recorded by category C fire stations

The areas in which category D fire stations are located are considered semi-rural. The low density of these areas results in the fire stations servicing a greater coverage area, as illustrated in Figure 7 for the Ringlet and Tanjung Manis fire stations. Both fire stations recorded a mean distance travelled of approximately 14 km and a mean response time of 18 min.

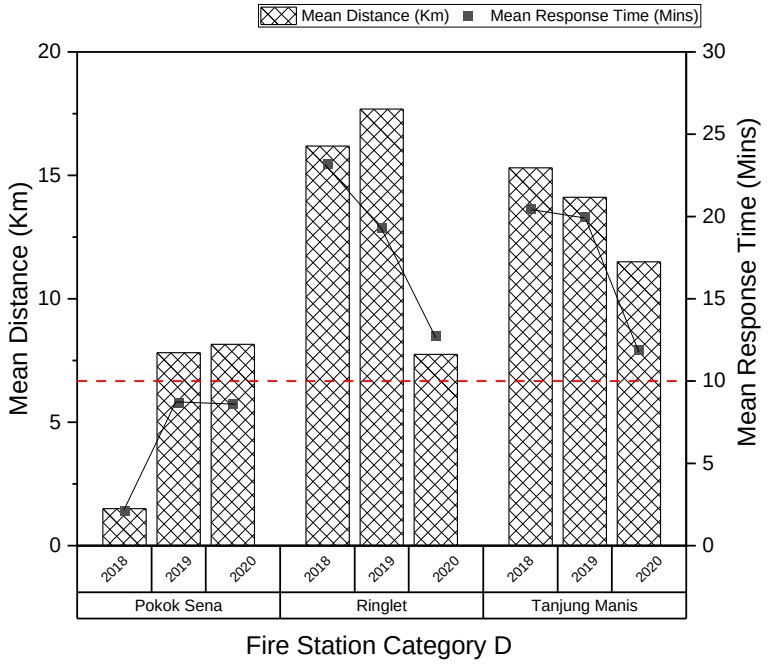

Figure 7. Mean distances travelled and mean response times recorded by category D fire stations

Based on the study conducted by (Tharima, 2010), most fire incidents that happened in semi-rural or rural areas are mainly on houses made of wood. This flammable building material is possible to create a flashover of less than 10 mins. As reported by Zikmund (2001), the flashover can occur from three to eight minutes while Wrack (2010) claims that flashover incidents happen from four to six minutes.

4. Conclusion

The initial assessment demonstrated that, regardless of category, most of the fire station response times recorded an improvement trend from 2018 to 2020. Besides, more than half of the category C and D fire stations recorded shorter mean response times in 2019, whereas fire stations in the other categories demonstrated no significant changes.

The distance travelled demonstrated a directly proportional relationship with the response time, as illustrated by the graphs that supported the Pearson correlations of > 0.7 for category B, C, and D. The findings indicated that new fire station developments are inevitable for reducing the fire incident response time in Malaysia. Developing new fire stations in strategic locations based on the risk profiling schedule and analysing urban planning, particularly in semi-urban areas, would ensure a fast response from firefighters.

Keywords

Global fire model, LPJ-GUESS-SPITFIRE, DGVM, vegetation-fire interactions

Abstract

Fire-enabled dynamic global vegetation models (DGVMs) provide modelling frameworks for integrating many drivers of fire regimes and simulating feedbacks between fire and vegetation. They can then be used to investigate fire-vegetation dynamics and project fire activity into future or past scenarios. Here we present the fire-enabled DGVM LPJ-GUESS-SPITFIRE which combines the widely used LPJ-GUESS DGVM with the SPITFIRE global fire model. We also evaluate the model simulation against burnt area and fire speed Earth observation datasets. We find that the model reproduces the global burnt area patterns with reasonable skill and improves on a previous model version. However there are some regions where model performance is lacking, and through the comparison with fire speed we diagnose some possible causes and suggest potential ways to improve model performance. Despite this, we conclude that overall model performance is sufficient for global scale studies.

1. Introduction

Fire activity is determined by both meteorological conditions and fuel availability and flammability (Bradstock, 2010). Thus, to project future fire regimes under global change, methods must capture not only how fire behaviour responds to changing meteorological conditions (direct effects of climate change), but also how they respond to changing fuel properties. These arise from vegetation responses to climate change, which can include alterations to vegetation structure, species composition and overall biomass productivity, and have consequences for fuel availability, flammability and continuity (both horizontally and vertically). Further to this, human-driven factors, both direct (such as changing ignitions patterns and suppression efforts) and indirect (such as land use change and landscape fragmentation), will also affect future fire regimes (Bowman et al., 2011).

One possible means to integrate all these factors is to combine a dynamic global vegetation model (DGVM) with a global fire model. These models are designed to be applied to the full gamut of global vegetation (and so feature rather generalised representations of fire processes) and operate over gridded domains at comparatively coarse scales (typically 50km or larger). In such model frameworks, the DGVM dynamically simulates the ecosystem state using mechanistic representations of many ecosystem and plant physiological processes such as: photosynthesis; autotrophic respiration; biomass allocation; competition for resources; biomass turnover (i.e. litter production); heterotrophic respiration; and nutrient and water cycling (Prentice et al., 2007). DGVMs may also simulate human land use, such as pasture, cropland and managed forest areas. The simulated ecosystem state is used to derive the fuel properties which are used by the global fire model to simulate fire occurrence and behaviour. The fire activity simulated by the fire model then induces biomass combustion and post-fire mortality in the DGVM's vegetation state, thus representing the bidirectional effects and feedbacks between vegetation and fire.

Global fire models vary widely in their complexity, both in terms of the processes represented and calculated fire properties (Hantson et al., 2016; Rabin et al., 2017). The earliest and simplest models only derived burnt area and applied fixed mortality rates and combustion fractions based on vegetation type (e.g. GlobFIRM,

Thonicke et al., 2001). However global fire models have become increasingly complex over the last two decades and now include representations of fire properties such as number of successful ignitions, rate of spread, intensity, combustion completeness and size-dependent mortality. Here we present the coupled global fire-vegetation LPJ-GUESS-SPITFIRE, which comprises the LPJ-GUESS DGVM (Smith et al., 2001, 2014) and the SPITFIRE global fire model (Thonicke et al., 2010).

2. Materials and Methods

2.1. The LPJ-GUESS DGVM

LPJ-GUESS builds on the biogeography and biogeochemical cycling of the LPJ DGVM (Sitch et al., 2003) by including a forest gap model of vegetation dynamics through the General Ecosystem Simulator (GUESS) (Smith et al., 2001). In this model, vegetation dynamics are represented through competing cohorts of identical woody individuals over a layer of herbaceous vegetation. In the global version used here, 10 different plant functional types (PFTs) are used to represent the global diversity of tree types (for example "boreal needle-leaved evergreen tree"). For the herbaceous layer two grass types are distinguished, a temperate/boreal type which uses C_3 photosynthesis and tropical grass type which uses C_4 photosynthesis. The dynamics of the woody cohorts are driven by establishment and mortality processes and by generic patch destroying disturbance events, here occurring with a mean return interval of 100 years. These processes are implemented stochastically and so a number of replicate "patches" (typically 15-100, in this study 20) are simulated and averaged to smooth out the resultant stochastic variability.

The version of the model used here (v4.1) also includes nitrogen cycling and limitation on photosynthesis (Smith et al., 2014); representation of human land use through croplands, pasture (Lindeskog et al., 2013; Olin et al., 2015) and forest management (Lindeskog et al., 2021); methane emissions from arctic wetlands and permafrost dynamics (Miller & Smith, 2012); emissions of biogenic volatile organic compounds (Arneth, Miller, et al., 2007; Arneth, Niinemets, et al., 2007)**.**

2.2. The SPITFIRE global fire model

SPITFIRE is one of the more complex global fire models. For a full description of the initial implementation see Thonicke et al., 2010, and for details of an earlier version of LPJ-GUESS-SPITFIRE see Rabin et al., 2017. We briefly summarise the main SPITFIRE model structure and logic here. Individual fires are resolved by calculating successful fire starts from potential ignitions from humans and lightning flashes as modified by a flammability index based on fuel moisture. This fuel moisture is based on the Nesterov fire danger index (Nesterov, 1949) and an exponential decay function with smaller coefficients (hence slower fuel drying) for the larger fuel classes. Fire size is modelled as an ellipse with the major axis dependent on rate of spread (which is calculated using the equations of Rothermel 1972) and fire duration (dependent on flammability index with a maximum of 4 hours in the initial formulation). The length-to-breadth ratio of the ellipse is determined by wind speed, and the number of daily fire starts multiplied by the size of each fire gives the daily burned area. Slope is not currently considered in the model as it acts on a landscape scale which is much finer than the coarse continental-to-global spatial scale for which LPJ-GUESS-SPITFIRE is designed.

Combustion completeness, derived from fuel moisture, is used to determine biomass burnt, and trace gas emissions are calculated from biomass burnt using PFT-specific emission factors. Post-fire mortality occurs by two mechanisms, crown scorch and cambial kill. Crown scorch mortality considers the fraction of an individual's crown which is affected by flame height (which is derived from Byram's fire intensity), and a PFT-specific parameter to account for species specific fire resistance. Cambial kill depends on calculated fire residence time (Peterson and Ryan) and bark thickness, with thicker bark providing increased survivorship. Bark thickness is determined based on PFT-specific allometric relationships between bark thickness and diameter at breast height.

Further to this initial implementation described above, the version of SPITFIRE presented here includes a number of modifications. Whilst the original model did not consider burning in agricultural lands, this implementation burns pastures (with the same formulation as natural area) but not croplands. Further, cropland fraction is used to reduce fire size in *adjacent* areas of natural and pasture lands (i.e. in the same gridcell) to represent the effects of landscape fragmentation on fire size. Fire duration has been modified from a maximum of 4 hours to a maximum of 12 hours, but with an additional reduction factor based on human population density

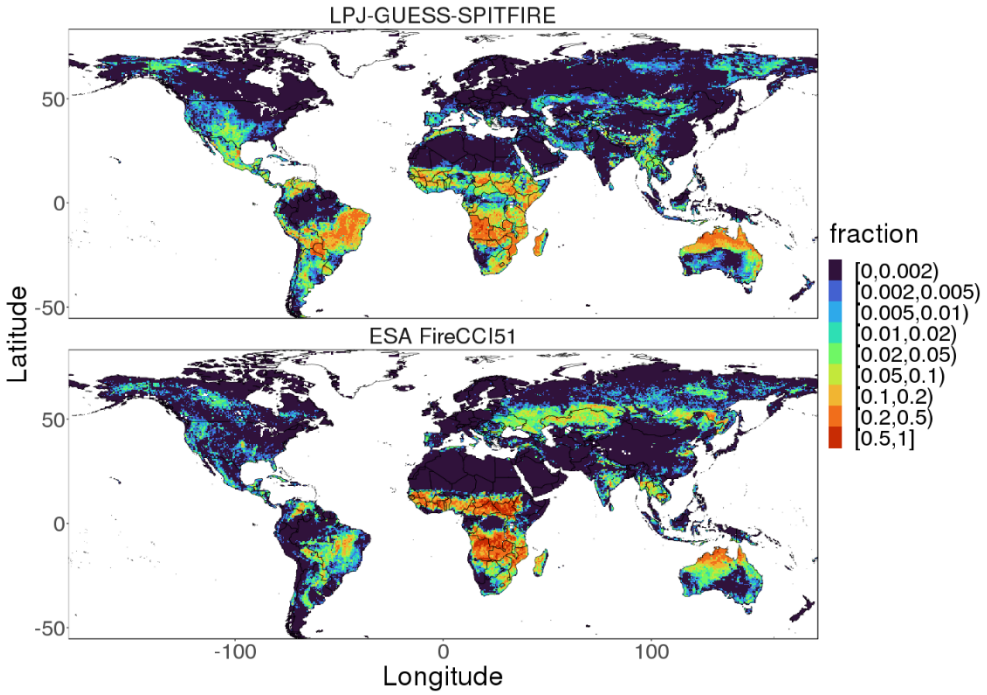
to represent human suppression following Hantson et al. (2015). To integrate SPITFIRE into LPJ-GUESS's replicate patches approach, fire behaviour is calculated separately for each patch and, for the application of post-fire mortality and combustion, burnt area is interpreted probabilistically (ie. each day the patch may burn with probability equal to the daily burnt area) and, if it burns, the combustion effects are applied to the entire patch.

2.3. Simulation set up

For the simulations used here we applied the standard LPJ-GUESS global settings and parameters (Smith et al., 2014). The input datasets required for LPJ-GUESS (climate, atmospheric CO2 concentration, nitrogen deposition and land use data) followed the TRENDY 2019 protocol (Friedlingstein et al., 2019). The TRENDY project coordinates an ensemble of DGVMs for estimation of the land carbon fluxes used in the Global Carbon Budget[30] on an annual basis and so the TRENDY protocol specifies state-of-the-art DGVM input datasets. To provide SPITFIRE with the additional information required for ignitions, the WGLC (Kaplan & Lau, 2019) lightning flash density and HYDE3.2 population density (Klein Goldewijk et al., 2017) datasets were used. The simulations followed the standard LPJ-GUESS spinup procedure whereby the first 30 years of the climate dataset (1901-1930) are detrended and repeated for 500 years to allow the vegetation and soil carbon pools to reach equilibrium. Following this, the full transient climate time series (1901-2018) was used.

2.4. Comparison data sets

To assess overall model performance, simulated burnt area was compared to the observed ESA FireCCI51 burnt area data set (Lizundia-Loiola et al., 2020). Both the observations and model output were summed to annual totals which were then averaged across the years 2001 to 2018. We also compare the daily simulated fire speed to mean fire speed from the Global Fire Atlas (GFA, Andela et al., 2019). SPITFIRE does not explicitly simulate mean daily fire speed, but it can be derived by dividing the length of the major ellipse in the fire size calculation by the duration of the observation period (in this case one day, matching the GFA units of fire speed and observation interval). This "macroscopic" fire speed depends on rate of spread and fire duration (in this case the duration of fire propagation within one day), and so comparing this to observations allows a first-order check of the combined effects of these two simulated properties. In order to examine fire behaviour at the peak of the fire season where the bulk of burning occurs, we compared the maximum of the mean monthly fire speeds.



[30] https://www.globalcarbonproject.org/

Figure 1- Annual fractional burnt area from the LPJ-GUESS-SPITFIRE simulation and the ESA FireCCI51 dataset (mean 2001-2018).

3. Results

LPJ-GUESS-SPITFIRE reproduced the global patterns of burnt area reasonably well (Fig. 1), with the largest burnt area simulated in the tropical savanna and dry forest regions. It also correctly simulated little or no burning in areas which are too arid (ie too dry to allow sufficient accumulation of fuel), humid or cold to burn and a modest amount of burning in the temperate and boreal zones. There were, however, some sizable regional discrepancies and, in some cases, opposite tendencies can be observed in the same climate zones but different continents. In the dry tropics fire activity was overestimated in South America but underestimated in Africa. Burnt area was overestimated in the continental interior of the US, but underestimated in the interior of Eurasia. The model simulated well the extent of burning in the warm temperate coastal and mediterranean regions (e.g. the Pacific coast and South East in the US, southern Australia, around the Mediterranean and across the Cape region in South Africa) with some small regional mismatches. In the boreal zone a reasonable amount of fire was simulated, but there were significant spatial mismatches between the modelled burnt area and the observed data.

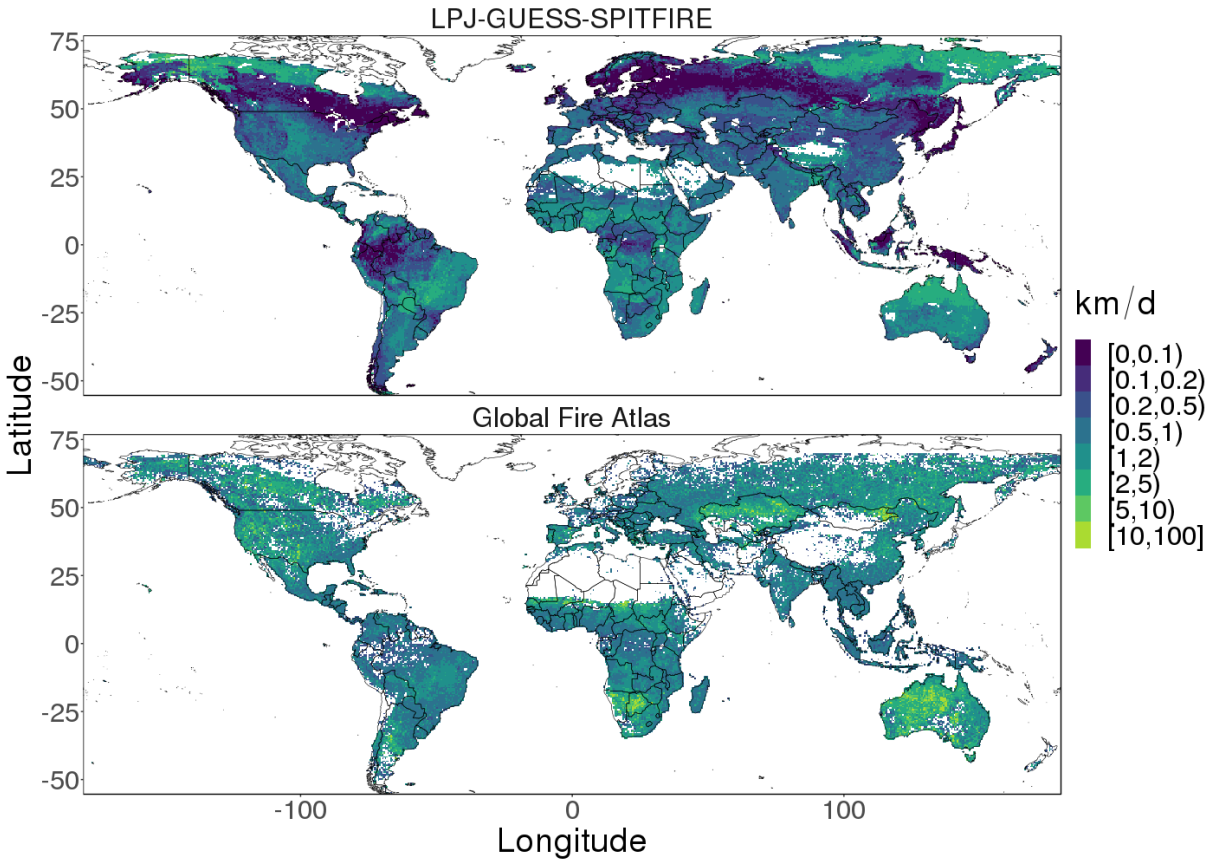


Figure 2 - Maximum of mean monthly fire speed from the LPJ-GUESS-SPITFIRE simulation and Global Fire Atlas dataset (mean 2001-2015).

The comparison of the maximum of mean monthly fire speeds (Fig. 2) gives some indication of what may be driving some of the discrepancies in burnt area. Whilst there was fairly good correspondence in the tropics and much of the temperate zone, there were considerable mismatches elsewhere. In central Eurasia, peak fire speed was underestimated and this corresponds with the region of underestimated burnt area (Fig. 1). Across the boreal forest fire speed was extremely low in LPJ-GUESS-SPITFIRE compared to the GFA observations and at very high latitudes (beyond the simulated tree line) it was very large, even in areas where no fires are observed.

4. Discussion

Compared to a simulation performed by a previous version of LPJ-GUESS-SPITFIRE used in the Fire Model Intercomparison Project (FireMIP, Rabin et al., 2017; Hantson et al., 2020), the simulation presented here showed a tangible improvement, as evidenced by a reduction of normalised mean error (NME, Kelley et al., 2013) from 0.96 (Hantson et al., 2020) to 0.77 (this study). This is similar to the other models from the FireMIP ensemble. However, given the importance of understanding and forecasting fire activity, it is a clear and present priority for the community to reduce this error and improve the skill of global fire models. In the

case of LPJ-GUESS-SPITFIRE, we can identify the boreal and arctic zones as areas for improvement. Our investigation of fire speed indicates that in the arctic region fire speed is too high which can only be a consequence of an over-simulation of fuel load and flammability. A cursory consideration of LPJ-GUESS's global PFTs reveals that there are no tundra shrubs included in the global setup. Instead, the C_3 grass PFT is the only viable vegetation type beyond the tree line, thus an overproduction of highly flammable fuel is simulated.

The underestimation of burnt area in the boreal forest is harder to diagnose. However, corresponding underestimation of fire speed indicates the simulated fuel characteristics are at least partly the issue, giving a definite direction for model improvement.

5. Conclusions

Here we have presented LPJ-GUESS-SPITFIRE, a coupled global fire-vegetation model, and some basic model evaluation. The model shows some regional discrepancies in spatial burnt area patterns, particularly at the higher latitudes, and we suggest some ways forward. However, the model does capture the global distribution of burnt area reasonably well and demonstrates similar model skill to other models in a recent model intercomparison project. We therefore consider it suitable for examining fire and vegetation interactions at global scope.

Drought, Temperature, Forest Fires, Clustering, NUT III

Abstract

The objective of the present work is to find a joint relation of drought and temperature regimes as factors contributing to the occurrence and severity of forest fires in the period 1981-2018 in mainland Portugal. To meet this goal PDSI drought data in NUT III regions from automatic weather stations were matched with temperature regimes obtained from a 3 km downscaling using WRF model and ERA5 reanalysis as forcing data. Clustering analysis was used to aggregate seasons from June to October, according to the weather-climate conditions provided together by drought and temperature regimes. The proposed scheme may be used to compare a seasonal forecast with this database and find a better match in order to support seasonal forestry and forest fire management policies. An additional analysis, also with SPI3 and SPI6 drought indices, was carried out to evaluate the influence of pre-season drought/wet conditions on the forest fire season.

1. Introduction

To better understand Extreme Fire Event conditions at a regional level in Portugal in the scope of the FIRESTORM project a preliminary independent analysis on drought conditions and on forest fires was performed in NUT III administrative organization in the period 1980-2019 (Cardoso *et al*, 2022). This analysis supports a more comprehensive study on the regional level on the relation between weather-climate conditions (drought, temperature, wind) and forest fires (occurrences, burned areas). In the current work the weather-climate conditions are focused on drought and temperature.

2. Data

To classify drought, two indexes were considered – PDSI (Palmer Drought Severity Index) and SPI (Standardized Precipitation Index), the last one for 3 and 6 months configurations (see e.g. Pires *et al.*, 2010, Silva *et al.*, 2014 and Pires *et al.*, 2019). The computation was based on weather station observations in mainland Portugal, with aggregation in 23 NUT III regions on a monthly basis. To classify the temperature regime a 3 km downscaling using the Weather Research and Forecasting (WRF) model and the fifth generation of European ReAnalysis (ERA5) as forcing data were used. Namely, monthly means of maximum temperature were considered over mainland Portugal grid points, that is, a mask was used to exclude grid points over the ocean and Spain. Drought and temperature data were analysed in the period 1981-2018. For the analysis of forest fires, data on occurrences and burned areas, both on a daily and monthly basis, were compiled from the Portuguese records of fire occurrence for the same period (ICNF, 2020).

3. Joint relation scheme of drought and temperature – a seasonal approach

A first step to see how the years could be clustered regarding drought and temperature was to set the most critical months for forest fires in Portugal. These months were set to be the ones between June and October, considering the number of occurrences per month in the dataset (see Figure 1). In this work, these 5 months together are considered a season. For this purpose, each month between June and October in mainland Portugal was reclassified regarding drought index into 4 classes: i) very dry, ii) dry, iii) normal, iv) wet or very wet - depending on the number of NUT III regions and their drought PDSI classification (extreme drought, severe drought, moderate drought, mild drought, near normal, slightly wet, moderately wet, very wet, extremely wet). The reclassification is described in Table 1. A season classification (also with 4 classes) is consequently computed from monthly drought reclassifications, using the percentiles 40, 60 and 90, as described in Table 2.

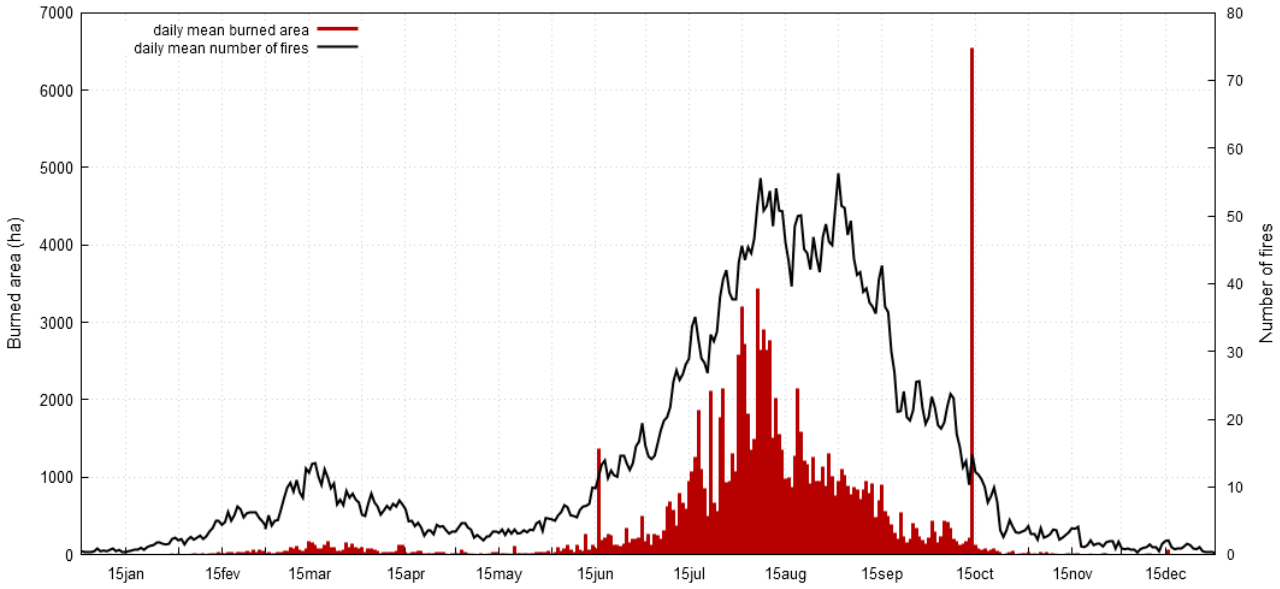

Figure 1- Daily mean values of burned area and number of fires (>1 ha), between 1980 and 2018, retrieved from the Portuguese records of fire occurrence (ICNF, 2020).

Table 1 – Reclassification of drought for a particular month between June and October in mainland Portugal according to the NUT III PDSI drought classification.

Monthly reclassification		Criteria	
1	Very Wet	At least 12 NUT III very or extremely wet PDSI (> 50 %)	At least 18 NUT III in any PDSI wet class (> 75 %)
	Wet	At least 12 NUT III moderately or slightly wet PDSI (> 50 %)	At least 18 NUT III in any PDSI wet class (> 75 %)
2	Normal	If the criteria are not met for very dry, dry, wet or very wet	
3	Dry	At least 12 NUT III in moderate or mild drought PDSI (> 50 %)	At least 18 NUT III in any PDSI drought class (> 75 %)
4	Very dry	At least 12 NUT III in extreme or severe drought PDSI (> 50 %)	At least 18 NUT III in any PDSI drought class (> 75 %)

Table 2 – Season (June to October) classification for drought in mainland Portugal based on monthly reclassifications as described in Table 1.

Season classification (June to October)	Sum of monthly drought reclassification (1 to 4) between June and October from Table 1	Corresponding percentile
Wet	< 10	< 40
Normal	≥ 10 and < 11	≥ 40 and < 60
Dry	≥ 11 and < 16	≥ 60 and < 90
Very Dry	≥ 16	≥ 90

On the other hand, each month between June and October in mainland Portugal was also classified regarding temperature in 4 classes – cold, normal, hot and very hot – depending on the maximum temperature monthly mean percentile over the whole territory in that period of the year. This classification is described in Table 3. Like for drought, a season temperature classification in 4 classes is consequently computed from monthly temperature classifications using the percentiles 40, 60 and 90, as described in Table 4.

Table 3 – Classification of Temperature of a particular month between June and October in mainland Portugal according to maximum temperature monthly mean percentile over the whole territory (also in the period from June to October).

		Maximum temperature monthly mean percentile in period June to October
1	Cold	< 40
2	Normal	≥ 40 and < 60
3	Hot	≥ 60 and < 90
4	Very Hot	≥ 90

Table 4 – Season (June to October) classification for temperature in mainland Portugal based on monthly classifications as described in Table 3.

Season classification (June to October)	Sum of monthly temperature classification (1 to 4) between June and October from Table 3	Corresponding percentile
Cold	< 9	< 40
Normal	≥ 9 and < 11	≥ 40 and < 60
Hot	≥ 11 and < 14	≥ 60 and < 90
Very Hot	≥ 14	≥ 90

4. Results on joint drought - temperature conditions

A joint season classification of drought and temperature was therefore set for the seasons between 1981 and 2018, with a clustering analysis being applied using both K-Means and Generalized EM (Expectation Maximization) with similar results. The results for Generalized EM are plotted in Figure 2 confirming the adequacy of season categorization for drought and temperature. Cluster 1 represents wet to normal and cold to normal seasons, corresponding to seasons that are less likely to originate extreme forest fire occurrences. On the other side of the spectrum lies cluster 2, with hot or very hot and dry or very dry seasons, with a clear signal for 2005 and 2017 on the top right corner of the diagram. Clusters 3 and 4 represent a mix of conditions pulling

in opposite directions in terms of conditions favouring forest fire occurrences. Therefore, cluster 3 aggregates dry or very dry seasons that are somehow compensated by cold to normal temperature regimes. On the other hand, cluster 4 aggregates hot to very hot seasons that are somehow compensated by wet to normal drought contexts.

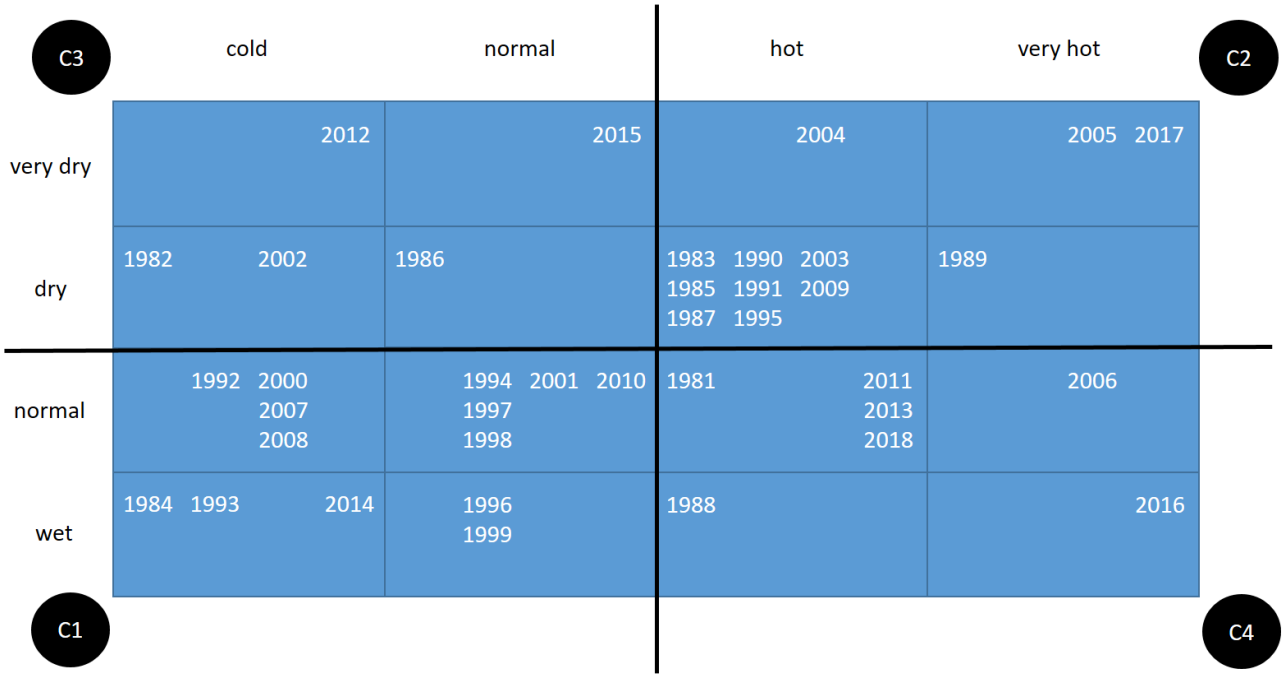

Figure 2 – June to October season clusters (1 to 4) in the period 1981-2018 for a joint drought-temperature classification according to the scheme proposed by Tables 1 to 4 for mainland Portugal.

5. Forest fire severity and pre-season drought conditions – a monthly approach

Despite the benefits of a seasonal analysis for drought and temperature for characterizing the fire season, it was found that seasonal forest fire indicators (occurrences and burned areas) were poorly correlated with pre-season drought indices (PDSI, SPI3 and SPI6) monthly values. Therefore, an additional lagged correlation analysis for NUT III was computed, but considering monthly forest fire indicators between June and October. For each NUT III, these monthly indicators were correlated with the monthly drought indices back to January, considering the 38 years of the dataset (1981-2018). A zero-lag correlation was also computed for determining the baseline.

6. Results on the relation between forest fire severity and drought

Figure 3 shows the baseline zero-lag correlation coefficient between monthly forest fire occurrences and monthly SPI3, PDSI and SPI6 drought indices from June to October at a NUT III level. Note that as drought is defined as negative in the drought indices, drought influence on forest fires will be defined as a negative correlation. The maps in Figure 3 show that, although drought conditions are important to characterize forest fire occurrences and burned areas, clearly other factors have to be taken into account. For example, even for SPI3 - the index that shows better zero-lag correlation results, along with higher statistical significance - the strongest negative correlation index was -0.739 (significant at 99% level) for *Beira Baixa* in June, which means that 54.7% (approximately half) of the variance in the number of occurrences in June is explained by the SPI3 drought index in June. For the majority of NUT III areas, the number of occurrences is generally more negatively correlated with drought indices in June, followed by October and then July. The stronger negative correlations (between -0.4 and -0.6, significant at least at 95% level) are essentially found in NUT III in the North and Centre of Portugal, showing that for these cases only 15 to 35% of the variance on the number of occurrences is explained by drought. Weaker negative (or even positive) correlations happen for August and September, meaning that the number of occurrences in those months shall be accounted for, in a larger proportion, by other

factors. Similar patterns occur if burned areas are considered, but generally with lower and less significant correlations, nevertheless with PDSI and SPI3 indices performing better.

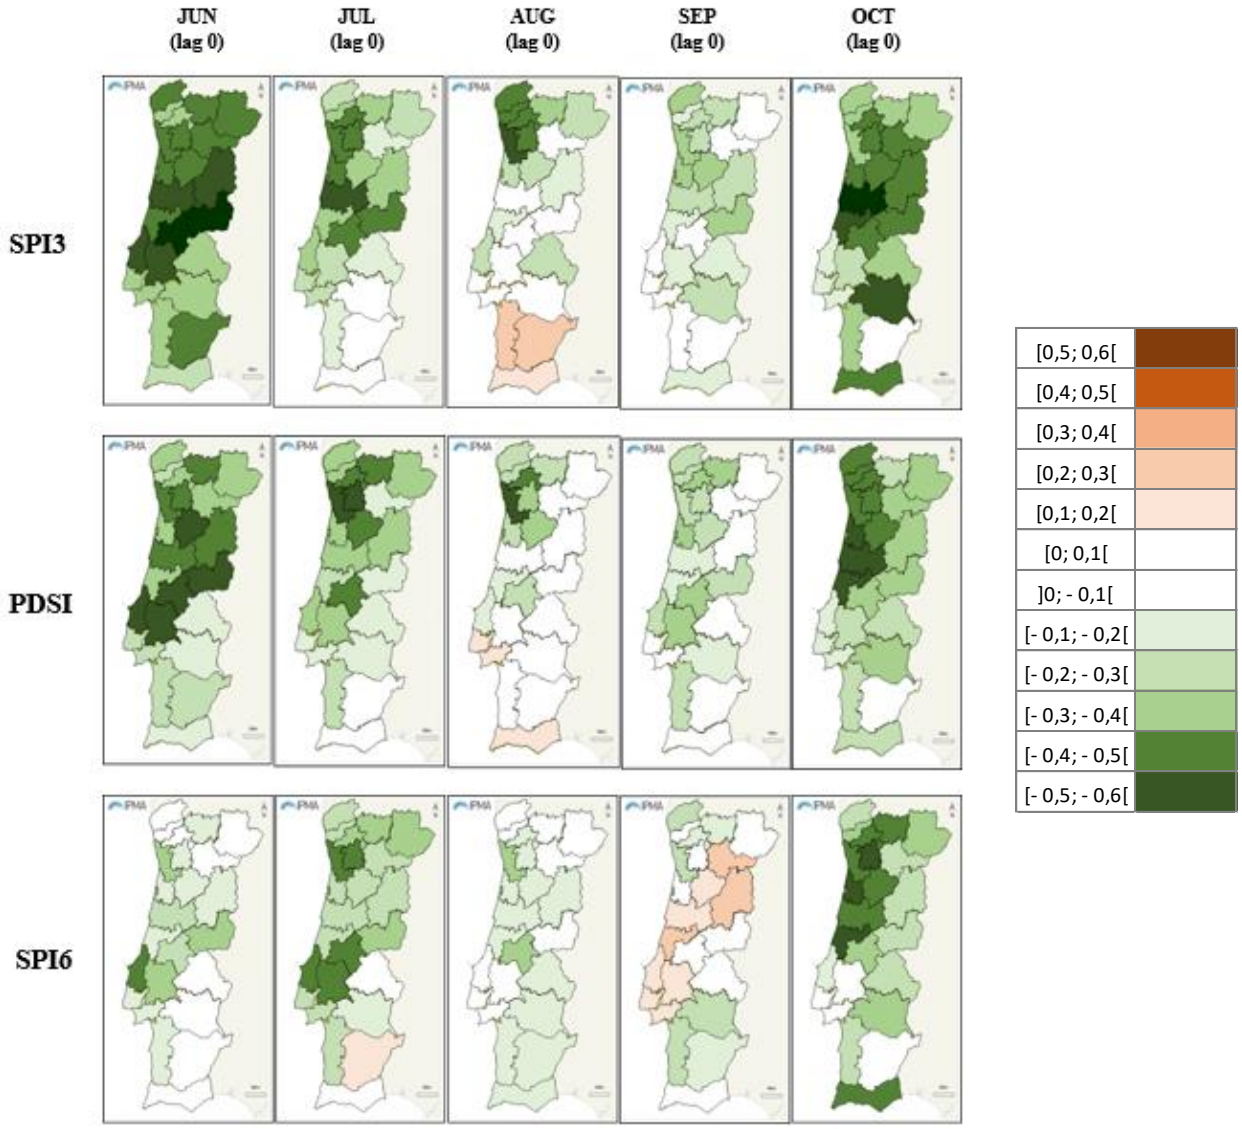

Figure 3 - Correlation coefficient between monthly forest fire occurrences and monthly SPI3 (upper row), PDSI (middle row) and SPI6 (lower row) drought indices from June (on the left) to October (on the right) at a NUT III level. Negative correlation in greenish shades and positive correlation in brownish shades.

It is clear that the negative correlation rapidly gets weaker with lags of 1, 2 or 3 months, even for the cases with stronger negative zero-lag correlation of drought with occurrences and burned areas (see Figure 4 for the case of July). Generally, correlations are not even significant at a 90% level with lags of 2 months or more. For lagged correlation SPI3 now seems to retain a weaker lagged correlation than PDSI (unlike zero-lag correlation). On the other hand, SPI3 seems to retain a higher lagged correlation than SPI6 for forest fire indicators in October, while the opposite happens for July, August and September.

Figure 4 shows that occurrences (also burned areas, not shown) in July for NUT III in the North and Centre of Portugal keep negative correlations of -0.3 to -0.5 (significant at least at a 90 % level) with the 3 drought indices in June and May, the signal being stronger for PDSI and SPI6. Even the strongest negative correlation with SPI6 in April (3 months' lag) for *Oeste* is only of -0.44 (20% of explained variance).

Figure 4 – Lagged correlation coefficient between forest fire occurrences in July and monthly SPI3 (upper row), PDSI (middle row) and SPI6 (lower row) drought indices from January (lag -6, on the left) to July (lag 0, on the right) at a NUT III level. Negative correlation in greenish shades and positive correlation in brownish shades.

Another relevant aspect is the relation between forest fires and wet pre-season regimes (positive values in drought indices) for some areas in the south of Portugal. Forest fire occurrences in *Alto Alentejo*, *Alentejo Central* or *Baixo Alentejo* in June and July (and also burned areas in June) are reasonably correlated with PDSI precipitation regimes in March, with correlation coefficients varying between +0.3 and +0.5 (10 to 25% of explained variance), significant at 90 or 95% level. For SPI3 and SPI6 correlations are lower and less significant, as partly showed in Figure 4 for July. In October, and also in *Alentejo Litoral*, occurrences and burned areas have correlation coefficients, statistically significant at 90 or 95%, between +0.27 and +0.45 (that is, at most 20% of explained variance), with wet regimes in months from January to July (not shown).

7. Final Remarks

Drought-Temperature data for mainland Portugal were jointly analysed in the period 1981-2018, both in a NUT III administrative aggregation and on grid point means. Results show seasons from June to October can be clustered in 4 groups according to monthly drought and temperature regimes. The proposed scheme may be used to compare a seasonal forecast with this database and find a better match in order to support seasonal forestry and forest fire management policies. The current study shows also that, regarding the relation between drought and the forest fire season, occurrences correlate better with drought than burned areas do. Zero-lag correlations are stronger (coefficient correlations of -0.4 to -0.6) in June and October, and in the North and Centre of Portugal, suggesting that other factors (such as the temperature/wind regime or human activity) have to be considered in the other months, namely August and September, and for the south of Portugal. Even for the cases of stronger correlation, pre-season drought conditions do not seem so preponderant, as monthly forest fire activity already has a lower correlation with drought conditions in the previous month, with no statistically significant correlation for more than the 2 previous months, at the most. On the other hand, for the south of Portugal wet regimes in March do explain up to 25% of the variance in forest fire occurrences in June and July (that is, 3 to 4 months ahead), while wet regimes between January and July also seem to explain up to 20% of the variance on forest fire occurrences in October. Finally, it should be noted that this study is based on a NUT

III administrative aggregation, which is in line with the 5 regional administrative domains currently considered in mainland Portugal for managing forest fire prevention and combat.

Circulation Weather Types (WT), Critical Days, Critical Weather Type, Large Fires, NUT III

Abstract

Large fires in Portugal, with a daily burned area equal to or greater than 3000 ha for the entire territory, tend to occur under specific circulation patterns. The severity of the meteorological conditions, expressed by the magnitude of the meteorological parameters anomaly and fire danger indices, associated with these patterns, could be an important tool to enable earlier forecast of fire weather conditions, being a useful support for decision making. However, there are some regional differences that we intend to analyze at NUT III level, contributing to a forecast with greater detail and oriented to support the fight and prevention of forest fires in Portugal. At NUT III level, we considered as Large Fires the 97th percentile of mean burned area of all NUT III, corresponding more or less to 300 ha of daily burned area. To link the synoptic circulation patterns with Large Fires, ten groups or clusters of NUT III were considered and four classes of normalized daily burned area in each NUT III or cluster of NUT III were considered. The six critical Weather Types (WTs) identified (North-easterly, Easterly, Anticyclonic Easterly Quadrant, Cyclonic Easterly, Quadrant, Northerly and Anticyclonic) exhibit distinctive circulation characteristics and mean values and anomalies of the meteorological parameters. The spatial distribution of Large Fires showed preferred regions for some of these WTs. The mean value of the Fire Weather Index (FWI) was computed for each WTs and for Critical Days (days with burned area equal or greater than 300 ha in each NUT III), using the WRF (Weather Research and Forecasting) mesoscale model. The mean value of FWI for each NUT III or cluster of NUT III, showed a few differences according to the WT and region. These values, can thus be taken as historical indicators at regional level of the likelihood of a large fire occurring.

1. Introduction

Large fires are responsible for very significant percentages of burned area every year. In Portugal 92% of the annual burned area is on average consumed during the period June to October, especially in July to September (82%) (Carmo *et al*, 2021). However, even during the fire season, most of the burned area occurs within a few days, these days designated as spread-event days (Lagerquist *et al* (2017), Flanning *et al* (2000), Flanning *et al* 2013). Several studies have pointed out the occurrence of these days associated to specific circulation patterns and associated to weather conditions (Crimmins (2006), Skinner *et al* (2002), Pereira et al (2005), Calheiros *et al* (2020), Duane *et al* (2018), (Dimitrakopoulos *et al* 2011). In the framework of the FireStorm project, a methodology based on circulation weather patterns (Trigo *et al*., 2000) was applied to provide a detailed description of the meteorological conditions during these events in Portugal. This methodology has already been applied to the entire Portuguese territory (Carmo *et al*, 2021). However, some differences amongst the regions of mainland Portugal are expected which can be more significant in certain synoptic patterns and regions. In the present study our goal is to use this methodology to obtain a finer analysis at the regional level of the administrative regions known as NUT III or aggregations of NUT III. Although circulation patterns describe synoptic-scale meteorological phenomena, they imply differences at smaller scales which are associated with fire spread and fire behaviour. The goal of this work is to relate the large fires at the regional level, with the synoptic circulation patterns and search for regional thresholds on the anomalies of the most relevant meteorological parameters and on the values of the Fire Weather index (FWI) and corresponding sub-indices

of the Canadian System. Those thresholds could be good tools to establish a warning system that enable an earlier forecast of fire weather.

2. Large Fires in Portugal and Circulation patterns

2.1. Methodology and Data

To determine the relationship between synoptic circulation patterns and large fires, four classes of daily burned area were established, with the burned area being normalized by each NUT III area, whose distribution in each class was based on the daily time series of burned areas above 1 ha, in Portugal mainland from 1980 to 2018 (Table 1). The cases of fires in the class of burned area equal to or greater than 300 ha were considered as LF. These cases correspond to the 99th percentile if the normalized area is considered or the 97th percentile if the average of the burned area in all NUTS III is considered**.** The days with burned area equal to or greater than 300 ha in each NUT III are critical days and each event is associated with a circulation synoptic pattern.

These cases have been associated to mean values and anomalies, of the meteorological parameters, computed using ERA 5 (fifth generation ECMWF Reanalysis) or with the numerical weather prediction model, WRF (Weather Research and Forecasting). The Fire data was obtained from ICNF (2020) and adapted by (Carmo *et al* 2021).

Table 1 – Daily classification according to burned area.

Class ID	Burned area class (ha)	Number of Cases	Number of Cases (%)
1	< 100	45278	95.5
2	[100, 300 [	1434	3.0
3	[300, 1000 [	524	1.1
4	> 1000	194	0.4

2.2. Weather Types and daily burned area classes

The Weather Types (WTs) were built using the methodology of Circulation Weather Pattern (Trigo *et al*, 2000) which is based on computation of a set of indices of the direction and vorticity of geostrophic flow, either pure or hybrid. Here we used a version with 18 weather types: i) 8 directional ii) 2 pure rotational (anticyclonic and cyclonic) and iii) 8 hybrid (4 anticyclonic and 4 Cyclonic). The distribution of the 18 WT shows high frequency of directional WT (56.6%), with NE being the most frequent (20%). The anticyclonic weather types have 32.2%, with the pure anticyclonic WT A the most frequent (17.7%). The cyclonic weather types have a frequency of 11.2%.

2.3. Critical Days and Critical Weather Types

In the fire data series under study (1980-2018), 409 critical days were found throughout the territory, with a much higher frequency (43%) associated with the WT NE, which is one of the most frequent during summer in Portugal. To find out the statistical significance of the predominance of a given WT on critical days, the Chi-square test between observed and expected days within each WT was computed. Three WTs with more significance (p-value< 0.001) and with more cases observed than expected at national level were confirmed: CQE, E, NE (Table 2).

Table 2 – Chi square tests between observed and expected critical days for 9 weather types. In bold p-values (<0.001) and underlined WTs with more critical days than would be expected by chance alone.

Weather Types	**NE**	**E**	**CQE**	**A**	**N**
Summer days **(Critical days)**	1191 **(176)**	247 **(48)**	103 **(19)**	1057 **(31)**	960 **(46)**
χ^2	**< 0.001**	**< 0.001**	**< 0.001**	**< 0.001**	**< 0.001**
	AQE	**AQN**	**CQN**	**C**	
Summer days **(Critical days)**	114 **(11)**	544 **(22)**	96 **(4)**	385 **(24)**	
χ^2	0.25	0.009	0.3	0.6	

This methodology was applied to the Portuguese administrative regions at NUT III level. In order to obtain groups of NUTs III with similar large fire regime, cluster analysis was used for the daily classes of burned area.

The K-means cluster analysis was used, but considering a subjective adjustment to ensure geographic consistency. Ten clusters of NUT III were taken (Table 3*)*.

Table 3 - NUT III Clusters.

	Cluster 1	**Cluster 2**	**Cluster 3**	**Cluster 4**	**Cluster 5**

	Cluster 6	**Cluster 7**	**Cluster 8**	**Cluster 9**	**Cluster 10**
NUT III	S. Estrela (16J) Beira Baixa (16H)	Coimbra (16E) Leiria (16F) Médio Tejo (16I)	Oeste (16B) A.M. Lisboa (170)	Lezíria Tejo (185) Alto Alentejo (186) Alentejo Centr (187)	Alentejo Lit.(181) Bx. Alentejo (184) Algarve (150)

2.4. Description of the Critical Weather Types

In Figure 1 the most relevant synoptic patterns related with large fires in Portugal are presented. Figure 1and Table 4, highlight the main meteorological characteristics associated with the aforementioned synoptic circulation patterns. These patterns jointly with Iberian thermal low (TL) and the adjustment to local and regional factors, create the weather conditions that can lead to the occurrence of large fires.

The North-easterly flow WT (NE): it is identified by a high pressure system over Atlantic, located at northwest of Coruña (The North Atlantic Block, Kautz *et al*, 2021), extending in ridge to the western Mediterranean, and the TL centered in southwestern Iberia, defining a northeast flow with a warm and dry air mass over mainland Portugal.

The Easterly flow WT (E): this WT results from a block settled over Western Europe with the Azores high located north of Iberia. In low level, the Morocco´s TL, extending to north over southwestern Iberia defining an east flow with a warm and very dry air mass over the Portuguese territory. This WT, together with AQE (Anticyclonic Easterly Quadrant flow), have the highest, warmest and driest air mass in low and middle troposphere, followed by NE (Table 4).

The Northerly flow WT (N): it is identified by the Azores high located over Azores Islands and the TL located in central part of Spain. In this WT the influence of the sea breeze is well marked. This WT has the coldest and wet air mass, among these six WT, followed by CQE (Table 4).

The Cyclonic Easterly Quadrant flow WT (CQE): it is identified by a high north of Azores and a low system located southeast, breaking the zonal flow (cut-off). At low levels, a low is centered south/southwest of Algarve, defining an east quadrant flow with a warm and slightly wetter air mass over Portugal (Table 4).

The Anticyclonic Easterly Quadrant flow WT (AQE): It is very similar to E, but with the high located a little further south (over western Bay Biscay) resulting in a greater pressure gradient over Portugal.

The Anticyclonic WT (A), "The Sub- tropical Ridge"**:** it is identified by a high over the Azores - Madeira region, extending to northwestern Iberia and a low system over Greenland and UK, defining a zonal flow to the north of Iberia. This pattern, combined with TL, defines a northwest flow over Portugal. This WT exhibits average properties close to the normal Portuguese summer (Table 4).

The southerly or southeasterly patterns with intrusion of Saharan air over Iberia, are very adverse patterns for wildfires, but they are very rare (about 2%) in the Portuguese summer.

Table 4 – Meteorological parameters of critical weather types: ERA 5 mean values at 12 UTC of geopotential height at 500 hPa (Z500), temperature and relative humidity at 850 hPa (T850 and HR850). WRF data, mean monthly anomalies (June to October), 2 m minimum temperature (Tm), 2m maximum temperature (Tx), and 2 m minimum relative humidity (HRm).

Data	Parameter	Critical weather types					
		NE	E	CQE	AQE	N	A
Mean Values (ERA5)	Z500 (m)	5849	5886	5844	5887	5808	5854
	T850 (°C)	17	18	17	17	14	14
	HR 850 (%)	45	39	48	39	54	49
Anomalies (WRF)	Tm (°C)	0.9	2.1	2.1	1.1	-0.9	-0.9
	Tx (°C)	2.4	4.4	3.5	3.3	-1.5	-0.6
	HRm (%)	-9.0	-15.0	-8.0	-13.0	3.0	0.0

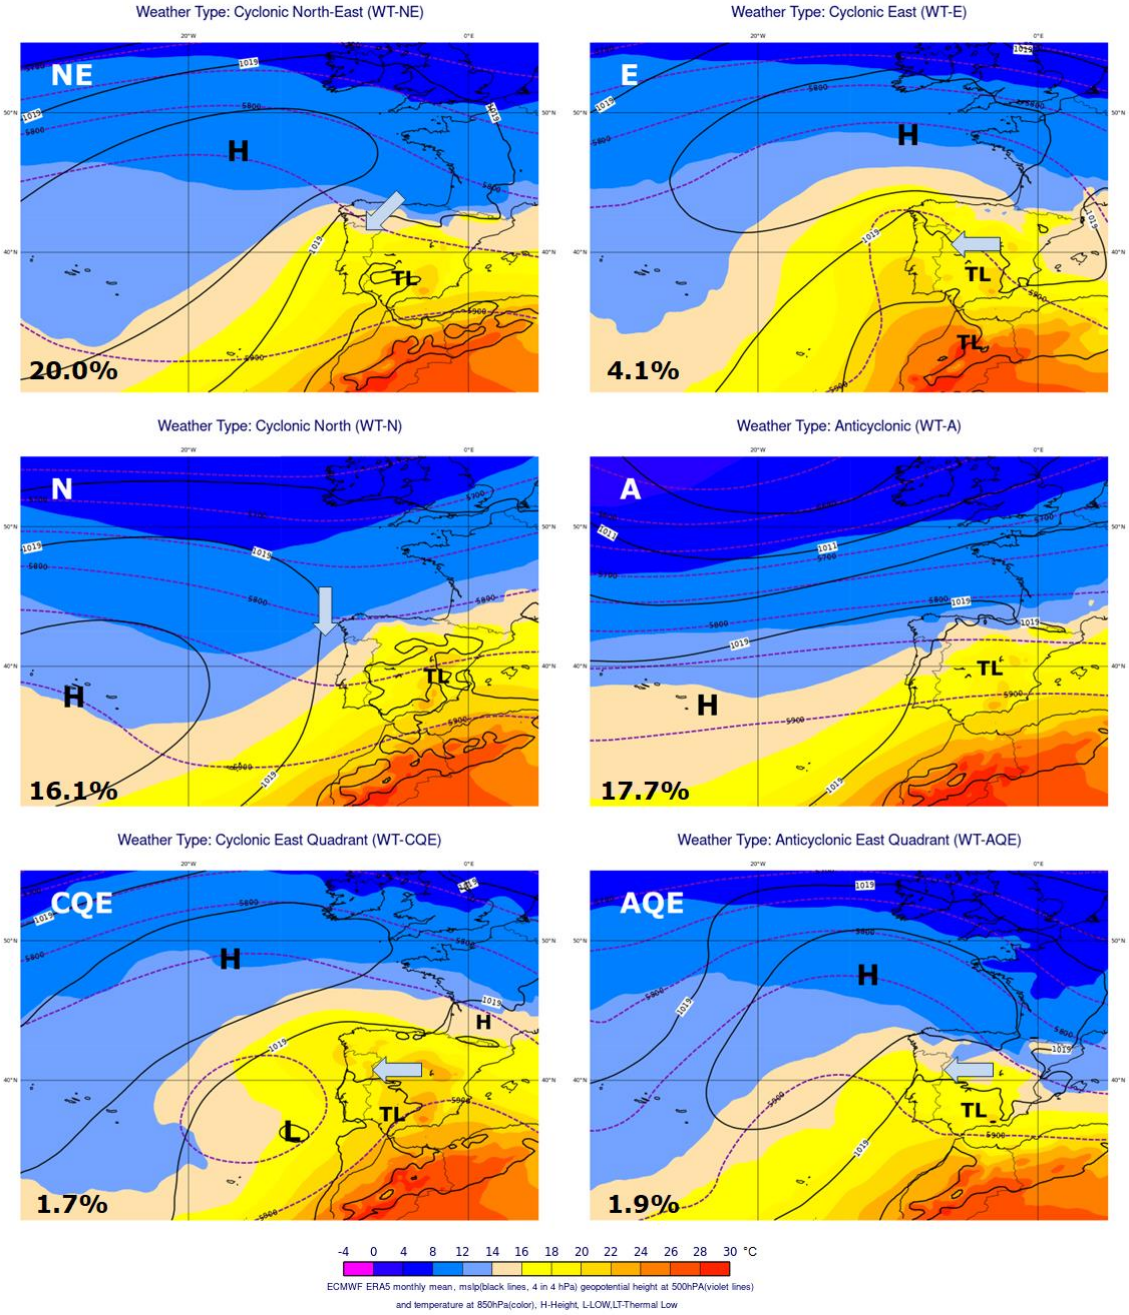

Figure 1- Monthly mean summer (June to October) weather types circulation pattern, from ECMWF ERA5 at 12 UTC in period 1981-2010 and its frequency. NE (Top left), E (top right), N (in middle left), A (in middle right), CQE (bottom, left AQE (bottom right). Mean sea level pressure (mslp, black lines, 4 in 4 hPa), geopotential height at 500

hPa (Z500, lines in violet, 50 in 50 m), temperature at 850 hPa (T850, colour, °C). H – Height, L - Low, TL - Thermal Low, blue arrow - flow direction. WT frequencies (%), June to October, in the bottom left corner.

3. Spatial Fire distribution and Weather Types Frequency

The Figures 2, 3 and 4 shows for each of the ten clusters of NUT III defined in Table 3, the spatial fire distribution for each burned area class in period of 1980-2018, by the six WTs mentioned in chapter 2.2 and 2.3 and three more - AQN, CQN, C - that presented some incidence in large fires in some NUT III. In tables 5, 6 and 7, the frequency of LF in each WT and the respective mean value of Fire Weather Index (FWI) in each of the ten clusters of NUT III is shown.

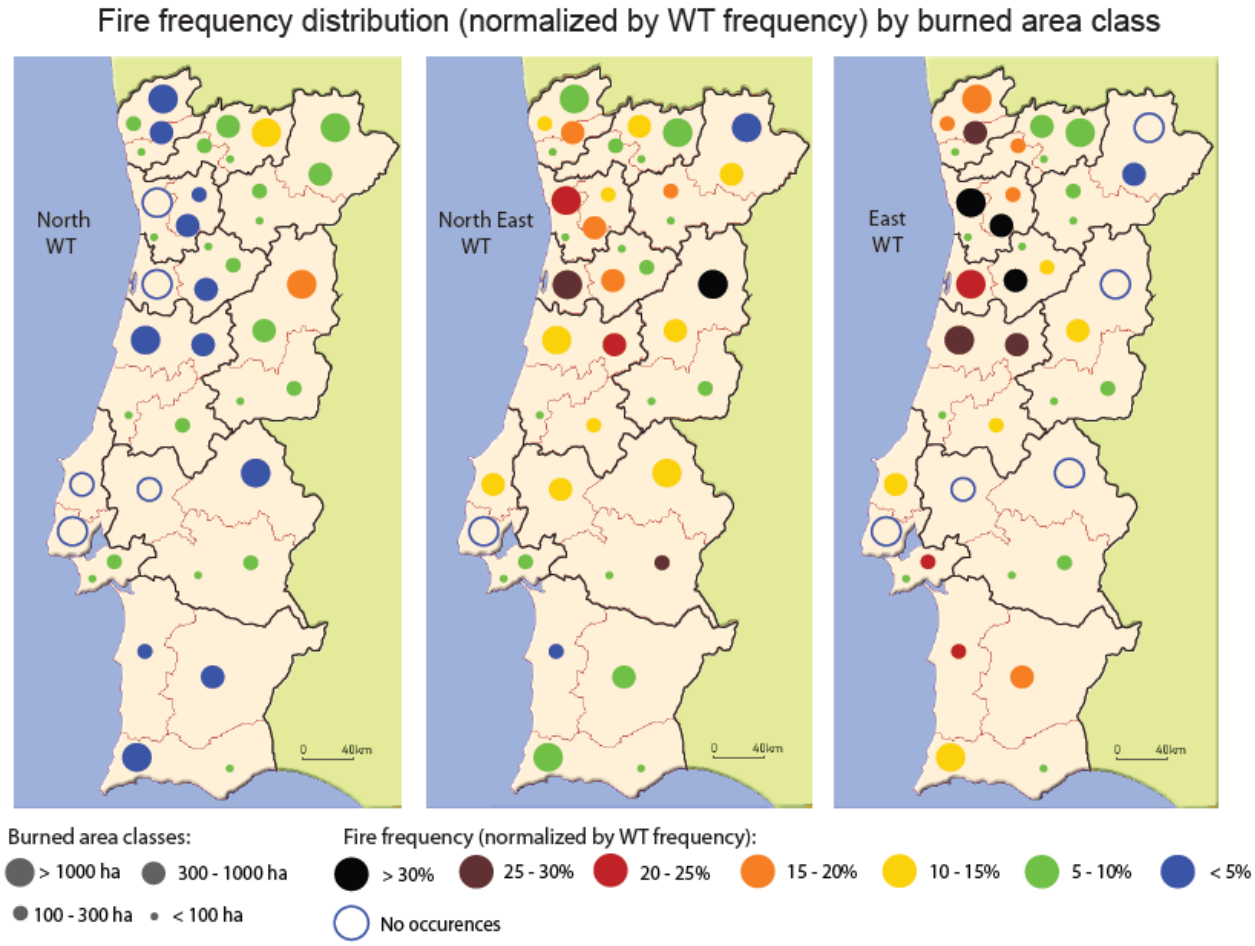

Figure 2 - Spatial Fire Distribution and frequency for each Weather Type in ten clusters of NUT III in Portugal, 1980-2018: N (Left), NE (middle) and E (right).

Table 5 - Fires distribution (%) for the ten clusters of NUT III and for the Weather Types N, NE and E. FWI mean value in NUT III cluster for critical WT and critical days. In bold: Frequency > 25% and FWI > 70.

WT and Burned Area class (normalized daily BA)		**Cl1**	**Cl2**	**Cl3**	**Cl4**	**Cl5**	**Cl6**	**Cl7**	**Cl8**	**Cl9**	**Cl10**

A detailed analysis of fires distribution based on Figures 2, 3, 4 and on tables 5, 6 and 7, is presented below:

- Fires in the two lowest daily burned area classes occur with high frequency (about 70%), mean value for all NUT III, in these critical weather types (NE, E, CQE, AQE, A, N), distributed throughout the territory, especially in the north and centre of the territory, with a higher frequency (60'%) in NE WT and for WTs with an eastern component
- Fires in the two highest daily burned area classes showed a high frequency (about 70%), mean value for all NUT III in NE, E, AQE, CQE and C WTs, being about 90% in NUT III near the coast (clusters l, 3, 5, 7 and 8). Considering only the E WT, there is a high concentration of LF (about 30%) in clusters

l, 3, 5 and 7. On the contrary, in clusters 4 and 9 the E WT has low frequency (< 5%). These cases are associated to high values of mean FWI in each cluster of NUT III, in the order of 60 and 75;

- **N WT** shows some LF distributed throughout the territory, with high frequency (5-10%) in clusters 2, 4 and 6 (far north and eastern territory). The mean value of FWI shows moderate values, in the order of 35 and 45, and above 50 in southern;
- **A WT** shows some LF (< 2%) fires distributed throughout the territory, especially in the North and Central regions and no LF occurrences in NUTIII near the coast. The mean value of FWI shows low values, in the order of 20-30, being below 15 in clusters 1, 2 and 3 and above 50 in the south of Portugal;
- **AQE WT** shows the highest concentration (>35%) of LF in the clusters 8 and 9 and in clusters 10. In the cluster 8, most LF (79%) occurred with this WT. The mean value of FWI shows the highest value of 80 in cluster 10 and values above 60 in all clusters, except in cluster 1, that is 59;
- **C and CQE WTs**, these WTs, especially the C, show LF with higher frequency of about 15% in cluster 4 and 6 (the most eastern part of territory), being more frequent (> 15%) the CQE WT, near the coast and in south (Clusters 1, 2, 3, 5 and 10). These WTs, during summer season, are associated to atmospheric instability under warm and wet air conditions. The mean value of FWI shows high values between 50 and 70.
- **AQN and CQN WTs** show a few cases of LF (< 5%) they are concentrated in most eastern part of territory, especially in cluster 6 (*Serra da Estrela and Beira Baixa*) where these WTs showed a frequency of about 20%. The FWI shows the lowest mean values, in the order of 10 to 25 in most of the territory, being below 10 in most northwestern territory. These WTs are associated to cold air mass and for the CQN precipitation is likely.

4. Final remarks:

This study confirmed that large fires (LF) in Portugal are associated with certain synoptic patterns of circulation. The patterns with flow from the east quadrant are the ones with the highest frequency (> 70%), corresponding to most cases of LF in the NUT III, located in the most western part of territory. In this study, the set of critical Weather Types (WTs) are well identified, as well as the differences in the regional distribution of the LF according to these WTS.

The mean value of FWI in each NUT III or cluster of NUT III, showed large differences, according to the WT and region. The highest mean FWI reaches the maximum value of 80 for AQE WT in cluster 10. Nevertheless, the mean values of FWI for A WT are moderate or low (<25) in most NUT III and the north component hybrid WTs (AQN and CQN) exhibit the lowest FWI, below 20 in most NUT III and below 10 in cluster 1 and 2. These values can thus be taken as historical indicators at regional level of the likelihood of a large fire occurring.

The high frequency of directional or hybrid WTs show the importance of wind-driven fires in LF in Portugal. Additionally, orographic effects have to be considered as they can intensify the large-scale flow characteristics. Ultimately, it will be this combined effect that will support a better relation between the synoptic pattern, described by the Weather Types, and the Large Fires regime.

Abstract

Anticipating future fire activity at global and regional scales is critical in a changing climate. Indeed, fire seasons are expected to lengthen and fire prone areas are expected to expand, but the magnitude, location and timing of such increases remain uncertain. Moreover, an intensification is expected during the core of the fire season of already fire-prone regions. However, quantifying seasonal and spatial impacts of climate change on fire activity is challenging. Here, we projected future fire activities in Southern France using the Firelihood model. This Bayesian probabilistic model operates on a daily basis in 8-km pixels, allowing to analyze both seasonal and spatial distributions of fire activities in a framework integrating stochasticity. Projections were computed for 13 GCM-RCM couples under two RCP scenarios (4.5 and 8.5), assuming that the only factor of change in future fire activity was the daily fire weather. The fire season was defined as the period with fire-activity level higher than the level of the 15th of July of the present period. The fire-prone region corresponded to locations with fire-activity levels higher than the 2nd level of a 5-level fire-activity scale derived from numbers of fires larger than 1ha, 100ha (N1ha and N100ha) and burnt areas (BA).

Simulations under RCP8.5 show that large increases in fire activity should be expected from the mid-century and that the rate of increase should then accelerate, leading to more than three-fold increases for number of fires larger than 100ha by the end of the century. In particular, all metrics except N1ha increased faster than the mean FWI and even the mean DSR. Such increases were partly caused by a massive seasonal lengthening from 42-43 days to up to 100 days, almost equally distributed between spring and autumn. However, the intensification during the present fire season was found to contribute slightly more to the overall increase than the lengthening itself. For example, for N100ha, the intensification would represent a 200 % increase in fire activity with respect to the present seasonal reference, whereas the lengthening outside of the present season would represent +190%. The fire prone area would increase by 140%, shifting from 28 to 67% of the regional total area. However, the intensification inside the already fire-prone region was found to contribute more to the increase than to the spatial expansion. For example, for N100ha, the intensification would represent a 183% increase with respect to the present fire-prone regional reference, whereas the expansion outside of this area would represent +101%.

These drastic increases provide a good indication of the potential lengthening of the fire season, spatial expansion and intensification of future fire activities under RCP 8.5, all three being importantly concerned, but dominated by intensification. Expanding and lengthening suppression policies may allow to mitigate projected increases, but the intensification of fire activity during the core of the fire season overwhelm current fire suppression capacities.

1. Introduction

Anticipating future fire activity at global and regional scales is critical in a changing climate. Indeed, burnt areas have already increased across parts of the globe over the last decades and are expected to keep growing over the century (Abatzoglou and Williams 2016; Amatulli et al. 2013), as the potential for large fires (Barbero et al. 2015; Ruffault et al. 2020). Fire seasons are expected to lengthen and fire prone areas are expected to expand (Flannigan et al. 2013), but the magnitude, location and timing of such increases remain uncertain, especially in the Mediterranean area. Moreover, an intensification is expected during the core of the fire season of already

fire-prone regions, which should become more severe (Dong et al. 2022; Senande-Rivera et al. 2022). Quantifying those changes remain challenging at the regional scale, because of the complex interactions between climate, meteorology, vegetation, humans, and fires. In particular, disentangling seasonal lengthening and spatial expansion from intensification has been seldom addressed.

Here, we estimated future fire activities in Southern France with climatic projections of simulations of the *Firelihood* model. This region has already showed an increase in fire danger mostly attributed to anthropogenic climate change, resulting in drastic increase in the frequency of heat waves, as observed in 2003 (Barbero et al. 2020). The Bayesian probabilistic model allowed to analyze both future seasonal and spatial distributions of fire activities in a framework accounting for stochasticity. Thanks to 300 replications of potential future activities, fire activity metrics were used to compute the expansion, the lengthening and the intensification of future fire activities under two RCP scenarios (4.5 and 8.5).

2. Methods

Fire activity were simulated with *Firelihood*, a probabilistic Bayesian framework designed and validated for stochastic modeling of summer fire activity (number and size) in southeastern France (Pimont et al. 2021). The occurrence of escaped fires (i.e. number of fires larger than 1ha) is modelled through a space-time Poisson process simulating the number of fires occurring in each 8km-pixel and day of year. For each fire, its burnt area (fire size in ha) is assigned by sampling from the estimated distribution of burnt area in each pixel and day. Explanatory variables are the FWI, which summarizes the influence of fire weather on daily fire danger, and the Forest area as a landscape factor representing exposition to wildfire danger. Here, the fire size model was slightly improved, thanks to the inclusion of spatial effects operating at NUTS3 level, to improve the accuracy of spatial predictions.

Present and future FWI were estimated from weather data derived from 13 climate models of the EURO-CORDEX initiative for RCPs 4.5 and 8.5, which were developed for IPCC Assessment Reports and representative of the currently most-likely radiative forcing trajectories. For each of the 26 FWI simulations, Firelihood was used repeatedly by sampling from the posterior distribution of the Bayesian model to provide 300 replications of fire activity, which represent both the distributional uncertainty associated with stochastic processes and the statistical uncertainty from the estimation of model parameters. Such replications allow to compute fire occurrences and sizes in each pixel × day through different fire metrics of numbers of fire larger than certain thresholds (N1ha, N10ha, N100ha, N1000ha) and burnt areas (BA).

To analyse seasonal variations, fire metrics were aggregated by day of year and the fire season was computed for the whole area for three periods (2000-2019, 2040-2059 and 2080-2099). We selected the 15th of July (day of year 196) as the reference date of the present period (2000-2019), as it corresponds to the beginning of the fire season in agreement with considerations of operational services. This reference date was used to identify a reference level for each fire activity metric, which was subsequently used for determining the end of the fire season of the present period, as well as future fire-prone periods. Intensification and lengthening were quantified as the percentages of additional future fire activities with respect to those of the present fire season, occurring respectively inside and outside of the present season.

To analyse spatial variations, fire metrics were aggregated by pixels to determine the fire distributions for three periods (2000-2019, 2040-2059 and 2080-2099) on a yearly basis. In order to facilitate interpretation, fire activity metrics (N1ha, N100ha and BA) were classified according to three different levels corresponding to low, moderate, high, very high and extreme fire activities, by means of "k-means" clustering. We defined the present extent of the present fire-prone region as regions where the fire activity level is at least moderate, so that the expansion corresponds to pixels that would shift from low to moderate levels. The intensification and expansion were quantified as the percentages of additional future fire activities with respect to those of the already fire-prone region, occurring respectively inside and outside of this region.

3. Results and discussion

Firelihood allowed to distinguish the effects of projected climate on several fire metrics, as represented in Figure 1. For RCP 4.5, the increase factor remained limited to 1.6 folds, with a saturation after 2040. Similar results

were observed for RCP8.5.5 until 2040, but the increase factor reached between 2.1 and 3.4 folds for respectively 1 ha and 100 ha fires near the end of the century. 1000 ha fires and burnt areas increased slightly slower than 100 ha-fires, which is explained by a steeper response to FWI for 100 ha than for larger fire size, especially in the 20-35 range (Pimont et al. 2021; Fig. 3b). This could reflect that landscape factors, such as fuel continuity or natural barriers (Mediterranean Sea, riparian zones) induce a constraint on the development of very large fires. Another explanation could be some limitations in the FWI for rating consistently the fire danger in Southern France, as already pointed out in Pimont et al. (2021). For all fire activity metrics, the increase was faster than the one of the mean FWI (1.76 folds) and even DSR (2.2), except for 1ha fires which increased slower than the DSR. This is an important result, as the mean DSR -also called SSR- is often used to estimate the difficulty to control fires and seasonal length (Flannigan et al. 2013).

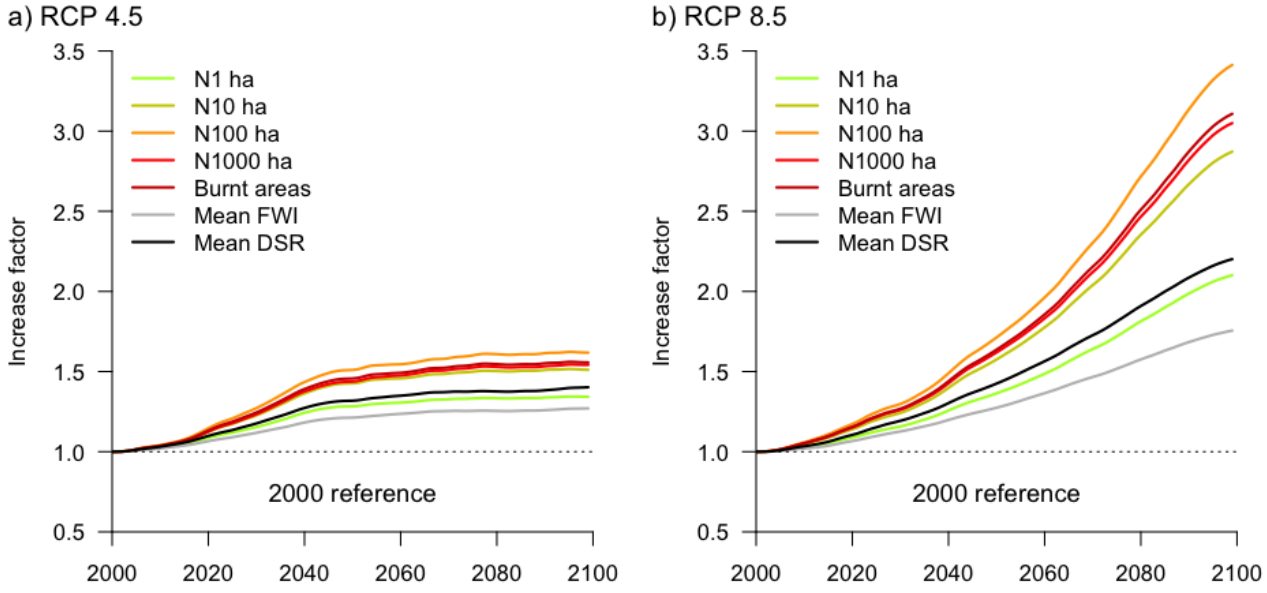

Figure 1- Trends in fire activity metrics under a) RCP 4.5 and b) RCP 8.5

Future expected fire activity increased for all days of the warm season (between day 148 and 309, Fig. 2), with a greater absolute increase in summer than in spring and fall. These increases translate into the lengthening of the fire season, as well as into the intensification of the fire activities during the present fire season. The lengthening was roughly equally distributed between spring and fall, differing by only a few days. Such a symmetric lengthening is expected in other temperate ecoregions, contrary to other regions where the fire season typically ends with the arrival of monsoonal precipitation (Barbero et al. 2015; Dong et al. 2022). The worse increases (RCP8.5 in 2090) were observed for N100ha and BA, showing +56 days by the end of the century. With respect to fire activities occurring during the present fire season, an increase by roughly 180-200% should be expected from intensification for N100ha and BA. With respect to the same reference, an increase by 180-190% is expected for new fire activity occurring during the lengthening period. The intensification in N1ha was slightly smaller than lengthening.

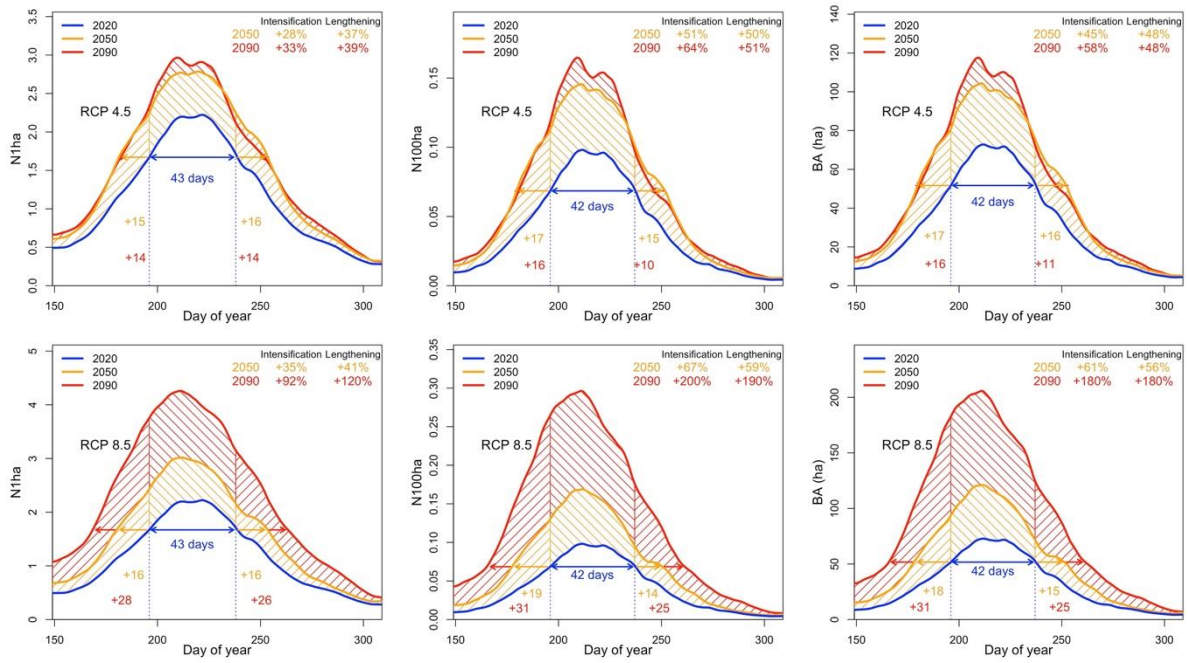

Figure 2- Seasonal lengthening and intensification for 1ha fires (N1ha), 100ha fires (N100ha) and burnt areas (BA) for RCP 4.5 (up) and 8.5 (down). Downward and upward hatches correspond to respectively the intensification and the lengthening of the fire season. There are expressed in percentages of the metric sum with respect to the present fire season.

Fire activity maps derived from the five levels are plotted in Fig. 3 for the three different periods and scenario RCP 4.5 and 8.5. The fire prone region should expand from 28% to 45% and 67% of the region of interest, with a strong expansion in the western part of the region. A potential expansion in Corsica and eastern parts was apparently more limited, probably because of mountainous barriers. As a result, the major part of expected increase was related to intensification in fire prone areas, which was roughly twice as large as the part related to expansion, despite of the large spatial expansion (Table 1). These spatial projections of fire activity were consistent with expected trends in FWI in France, which anticipate a strong heat-induced increase in fire danger in the French already fire-prone region (Fargeon et al. 2020).

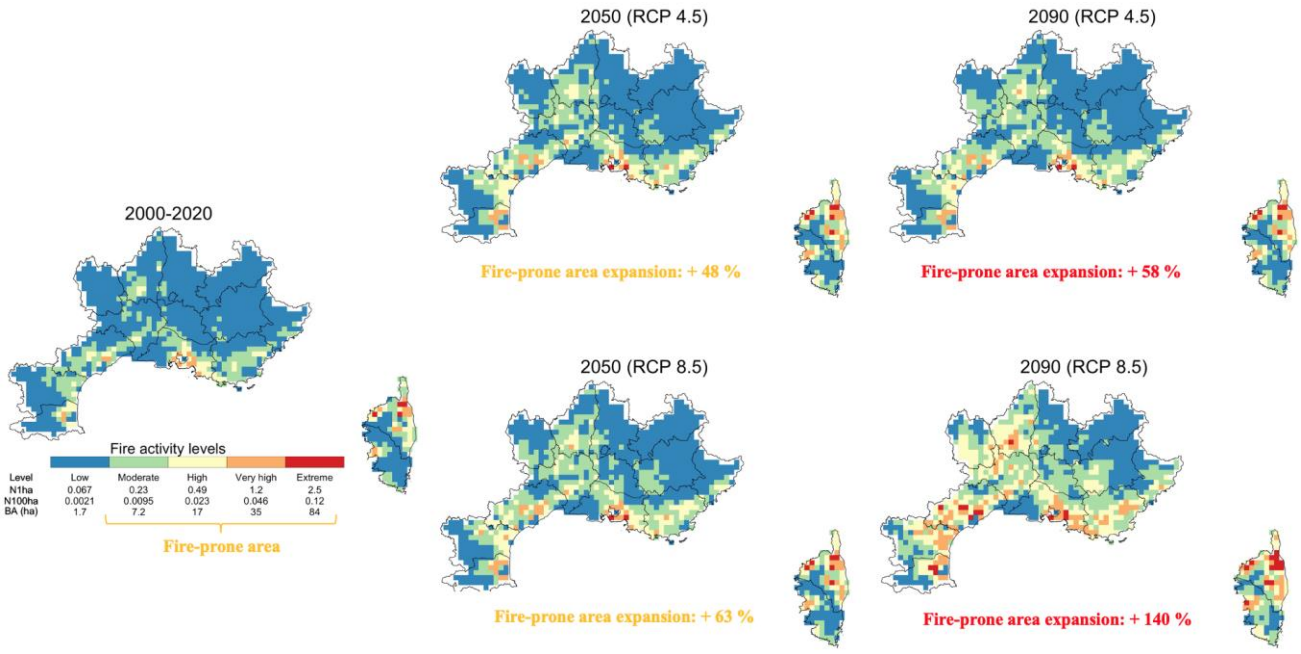

Figure 3- Fire activity level maps (Fire prone area expansion corresponds to pixels that should turn from low to moderate level).

Table 1- Percent fire activity changes due to the intensification and the expansion (Expressed in percentages of the metric sum over the fire-prone area for the present period).

RCP	Period	Fire metric	Intensification	Expansion
4.5	2050	N1	+30%	+14%
		N100	+54%	+21%
		BA	+48%	+20%
	2090	N1	+32%	+17%
		N100	+58%	+26%
		BA	+52%	+25%
8.5	2050	N1	+34%	+18%
		N100	+64%	+29%
		BA	+57%	+27%
	2090	N1	+90%	+52%
		N100	+183%	+101%
		BA	+162%	+93%

This study assumed that everything but climate remained equal, an assumption common to many projection studies, but which becomes questionable facing such large changes and long-term perspective. Land use and land cover could be included in the modelling framework of Firelihood (Castel-Clavera et al. 2022), but projecting future values for these variables remains challenging even if scenarios are becoming available. Moreover, even if fire return intervals remained quite large in 8-km pixels, local reburns can be frequent (Ganteaume and Barbero 2019), so that the increasing impact of fire-activity on fuel structure should be accounted. Finally, the expansion, lengthening and intensification were estimated assuming that suppression and prevention will remain identical. Expanding and lengthening management may allow to mitigate projected increases, at the cost of significant expansion of these policies. The intensification could be even more problematic, as suppression might be more frequently overflowed by simultaneous escaped fires (N1ha) and large fire events (N100ha).

4. Conclusion

These drastic increases provide a good indication of the potential lengthening of the fire season, spatial expansion and intensification of future fire activities under RCP 8.5, all three being importantly concerned, but dominated by the intensification in the case the spatial expansion. Lengthening and expansion might be mitigated by an expansion of the fire prevention and suppression policies, but the intensification might raise most operational concerns.

Erosion; Sediment connectivity; post-fire; index of connectivity; modelling approach

Abstract

Rivers act as a network of channels that carry water, sediment, and energy downstream. On the heterogeneous area of the watershed, some areas might be responsive to disturbance (e.g., wildfires and droughts), while others may be resistant to the change. As a disturbance, fire is usually regarded as a key agent of soil erosion and land degradation. Fires are thought to be responsible for: (i) overland flow and reduction of the capacity of infiltration; (ii) increase of the availability of ash and debris and disruption of the soil nutrient cycle; and (iii) increase of connectivity across the watershed. The potential fire effects on soils and aquatic resources have created a strong demand for a post-fire sediment loss prediction tool. Taking this in mind, this study aims to assess post-fire soil erosion patterns at the decadal scale comparing different approaches. The methodology comprises (i) a process-based model that is able to investigate long-term and large-scale spatial landscape evolution, LAPSUS model; (ii) an index that represents a connectivity assessment based on local landscape information, the Borselli Index of Connectivity (IC); and (iii) and the sediment export that represents the sediment eroded that actually reaches the stream based on local landscape information, combining the IC with the Revised Universal Soil Loss Equation (RUSLE) model. Results include a comparison between the approaches used in the context of specific fire events between 1979 and 2020 for the Agueda watershed in central Portugal. The authors believe that assessing the spatial-temporal evolution of connectivity in the actual landscape with the appropriate tool is extremely important to estimate the probability that a given part of the landscape transfers its sediments downstream.

1. Introduction

Rivers act as a network of channels that carry water, sediment, and energy downstream (1). On the heterogeneous area of the watershed, some areas might be responsive to disturbance events (e.g., wildfires and droughts), while others may be resistant to the change (Khan et al., 2021).

Fire disturbance is usually regarded as a key agent of soil erosion and land degradation (Shakesby, 2011). Fire is pointed as responsible for: (i) overland flow and reduction of the capacity of infiltration (Basso et al., 2021; Fernández et al., 2010); (ii) increase of the availability of ash and debris and disruption of the soil nutrient cycle (Basso et al., 2021); and (iv) increase of connectivity across the watershed (van der Grift, 2021). The potential fire effects on soils and aquatic resources have created a strong demand for a post-fire sediment loss prediction tool (Fernández et al., 2010; Larsen & MacDonald, 2007; Vieira et al., 2014).

It is then important to have a working connectivity definition and usable indices and models to assess its spatial and temporal distribution. In this study, the authors work with the sediment connectivity definition recognized by the scientific community: the capacity of sediment to move through the watershed (Bracken & Croke, 2007; Crema & Cavalli, 2018; Hooke, 2003). To assess sediment connectivity spatial and temporal distribution the authors use three different approaches based on information available in a GIS environment: the Index of Connectivity (IC)(Borselli et al., 2008), the long-term landscape evolution model LAPSUS (Landscape Process Modelling at Multi-Dimensions and Scales) (Baartman et al., 2010; Temme et al., 2011), and the Sediment Export (SE) approach (Sharp et al., 2020).

This study seeks to answer the specific research questions: (i) "What aspect of connectivity do the different indexes and models measure?"; and (ii) "How these approaches are related?".

2. Data and Methods

This study focused on the Águeda watershed located in the central area of mainland Portugal. This watershed is a representative region where different agents contribute to landscape evolution/modification, and where sediment connectivity should consider the contribution of such agents to erosion and transport and their influence on the morphological settings that control sediment conveyance (Cavalli et al., 2013).

To assess sediment connectivity the authors used IC, LAPSUS, and SE for different soil burn severity scenarios for 1979-2020. These approaches need as inputs: (i) fire severity, (ii) land use information, (iii) USLE-C factor values; and (iv) annual soil parameters (P-factor, LS-factor, K-factor, and R-factor). To test independence and find interactions between the three approaches the authors used contingency tables, accuracy metrics and statistical measures of association.

3. Results and discussion

Results include the connectivity description and the comparison between the approaches in the context of specific fire events between 1979 and 2020. The three approaches take different times to be computed, due to the necessity of LAPSUS need to be calibrated. From the 3 approaches, LAPSUS needs more inputs and IC fewer inputs. The relation is better between LAPSUS and SE than between LAPSUS and IC. In addition, this relation between LAPSUS and the other approaches depends on the target year and/or fire characteristics.

4. Conclusion

This study presents 3 different approaches to assess sediment connectivity which lead to the identification of potential sources of ash and post-fire contaminants. The authors believe the results of this study are extremely important to estimate the probability that a given part of the landscape transfers its downstream.

Canadian Forest Fire Weather Index System, Fire Radiative Power, Fire Danger Thresholds, SEVIRI/MSG satellite data, Mediterranean

Abstract

Fire danger rating systems (FDRS) are widely used across the world for many purposes, from planning for the daily deployment of fire suppression resources to the evaluation of fire management strategies. FDRS can also be incorporated into different types of models and regions to assess the short and long-term effects of specific fire regimes and fire management policies. The Canadian Forest Fire Weather Index System (FWIS) is a widely known FDR system, being extensively applied for fire danger early warning in several regions around the world, namely in Europe. The FWIS includes a set of six sub-indices, based on meteorological data, to predict fire weather danger and fire behavior over regions under study. In order to have a reliable assessment of the fire danger based on the FWIS, it is essential to define the most suitable threshold values for each danger class of the FWIS sub-indices over different regions. To establish those limit values for each class of the FWIS sub-indices, historical percentiles were computed for the period understudy, taking into account the occurred fire events (hotspots), despite the lack of information regarding fire events history and its relation to FWIS sub-indices. To accomplish the proposed validation, our approach is based on Fire Radiative Energy (FRE) released by each fire event that occurred in the Mediterranean region, over the study period. The FRE is computed from Fire Radiative Power (FRP) product as obtained from MSG/SEVIRI, generated and disseminated in near real-time by EUMETSAT in the framework of Land Surface Analysis Satellite Applications Facility (LSA SAF). Since FRP estimates the radiative power emitted by a given fire, it can be linked to local fuel burned amounts and be used as a proxy of fire intensity. By integrating FRP measures emitted during the lifetime of the fires that occurred over the regions under study, an estimate of the total FRE released can be easily obtained for each event. To obtain the FRE data for this work, it was considered the period of available FRP/SEVIRI data, from March 2010 to October 2021. Threshold values of each defined danger class for the FWI, FFMC, and ISI indices were calculated considering the total FRE hotspots registered, in agreement with the different fire regimes of the Mediterranean region. Since extreme wildfire patterns in Southern Mediterranean countries have been increasing over the last years, FRP/FRE products are a key tool to monitor and improve fire managing activities, preparedness-including planning for deployment of fire suppression resources, over affected regions.

1. Introduction

To establish fire danger conditions in a given location or region, a fire danger rating system (FDRS) or a model should be able to reproduce short and long-term variations of temperature, relative humidity, precipitation, and wind intensity, in the variation of fuel humidity, that can be used to forecast fire occurrence and it (Di Giuseppe et al., 2016, 2020; Stocks et al., 1989). FDRS are often included or linked to different types of models to assess the long-term effects of fire regimes and specific fire management policies (Dacamara et al., 2014; Durão et al., 2010; Flannigan et al., 2001; Pereira et al., 2011; 7. San-Miguel-Ayanz et a., 2012, 2013; Sousa et al., 2015). FDRS like the Canadian Forest Fire Weather Index System (FWIS) transforms daily meteorological observations into relatively simple indices that can be used to forecast fire weather danger, the dead fuel moisture content and consequentially fire behavior, and impacts; being widely used for a fire danger early warning in several regions around the world, namely in Europe (Stocks et al., 1989; Van Wagner, 1987). To obtain a reliable assessment of the fire danger based on the FWIS it is crucial to determine the limit values for

each fire danger class of the FWIS sub-indices for a given region and day. One of the simplest methods to define the fire danger classes is to compute daily percentiles based on historical data, but this method lacks information regarding wildfire history and its relation to FWIS sub-indices. In order to overcome this lack of information, the Fire Radiative Power products, generated and disseminated in near real-time by EUMETSAT Land Surface Analysis Satellite Applications Facility, were used in this validation work. Since FRP consists of estimates of the radiative power emitted by fires it can be directly linked to the amount of fuel burned and smoke production (Wooster et al., 2005), being used as a proxy of fireline intensity helping to develop and improve suppression and mitigation strategies (Johnston et al., 2017; Smith and Wooster, 2005). Namely, in Mediterranean countries, the use of this type of FRP product is very useful, since extreme fires have been increasing in the last years, presenting an eruptive or erratic behavior pattern, running out the responsiveness and suppression capacities of local authorities (Dacamara et al., 2019; Evin et al., 2018; Fernandes et al., 2016; Pinto et al., 2020; San-Miguel-Ayanz et al., 2018).

2. Materials and Methods

2.1. Study Area

The study area of this work comprises the countries of the Mediterranean basin, accordingly to figure 1.

To be easier to evaluate and compare the local fire danger thresholds, the Mediterranean area was split into small areas of interest: Portugal (PT), Iberian Peninsula (IP), North Africa 1 (NA1), North Africa 2 (NA2), Southern France (SF), Italy (IT), Greece, Turkey and Cyprus (GTC), as can be seen in Fig 1 and Table 1.

2.2. Fire Radiative Energy

The analysis of the fire severity is based on the Fire Radiative Energy (FRE) released by each fire, computed as a daily accumulation of Fire Radiative Power (FRP) delivered by the Land Surface Analysis Satellite Applications Facility (LSA-SAF) from EUMETSAT (Trigo et al., 2011; Wooster et al., 2005). The FRP (Heward et al., 2013), registers data on the position, timing, and fire radiative power (in MWatts) output per pixel of fire events detected every 15 minutes. FRP is disseminated for the full spatio-temporal resolution of SEVIRI (*Spinning Enhanced Visible and Infrared Imager*) imager on board the Meteosat Second Generation (MSG) series of EUMETSAT geostationary satellites (Wooster et al., 2015), provided for the whole MSG disk (up to 72◦ view zenith angle), where each active-fire position is represented at the center of the SEVIRI pixel, with a 3 km spatial sampling distance at sub-satellite point (decreasing away from the West African sub-satellite point). Since FRP estimates the radiative power emitted by fire events, integrating it over the length of a fire event, an estimation of the total Fire Radiative Energy (FRE) emitted by each one can be computed. By definition, the daily FRE is the energy released by a fire at a given pixel, by the integration of the 15-minute FRP records, accordingly to Pinto *et al* (Pinto et al., 2018a, 2018b)' formula:

$$E_{pd} = 0.9 \times \left(\sum_{k=1}^{96} \mathrm{FRP}_{kp}\right)_d,$$

where k is the daily sequence of 15-minutes, FRP_{kp} is the fire radiative power (in megawatts) in a given pixel p of image k, and the 0.9 factor converts the obtained result into gigajoules units (GJ). In addition, the FRE can be defined as the emitted radiant energy released during biomass combustion, being proportional to the total amount of biomass burned during a given fire (Pinto et al., 2018a, 2018b).
The FRE values were computed for all the fire events that occurred over the period under study, as can be seen in Table1.

2.3. Meteorological Fire danger

Briefly, the FWIS consists of six sub-indices that account for the effects of fuel moisture and weather conditions on fire behavior, by providing numeric ratings of relative potential for wildfire occurrence (Stocks et al., 1989; Van Wagner, 1987; Wotton, 2009). The first three indices of FWIS (FFMC, DMC, and DC) are the fuel moisture codes, which are numeric ratings of the moisture content of litter and other fine fuels, and the average moisture content of deep and compact organic layers. The remaining FWIS indices (ISI, BUI, and FWI) are fire behavior indices, which represent the rate of fire spread, the fuel available for combustion, the frontal fire intensity, or the fire weather index. The values of these behavior indices increase as the fire danger increases (Stocks et al.,

1989; Van Wagner, 1987; Wotton, 2009). The previous indices selected to perform this validation are the Fire Weather Index (FWI), the Fine Fuel Moisture Code (FFMC), and the Initial Spread Index (ISI).

FWI is defined as a numerical rating of the potential frontal fire intensity, that indicates fire intensity by combining the rate of fire spread given by the Initial Spread Index (ISI), with the amount of fuel being consumed given by the Build-Up Index (BUI). FFMC is defined as an indicator of the moisture content in litter and other fine fuels less than 1 cm in diameter (needles, mosses, twigs), being representative of the top litter layer less than 1-2 cm deep. FFMC values change rapidly because of a high surface area to volume ratio, and direct exposure to changing environmental conditions (Van Wagner, 1974, 1987; Van Wagner et al., 1985; Wotton, 2009). ISI is defined as the numeric rating of the expected rate of fire spread. It is based on wind speed and FFMC. Like the rest of the FWI system components, ISI does not take fuel type into account. Actual spread rates vary between fuel types at the same ISI.

The indices of the Canadian Forest Fire Weather Index System (FWIS) are computed based on the meteorological parameters (temperature at 2 m, relative humidity, wind speed at 10 m, and accumulated precipitation in 24 h) of the short-term forecasts of the numerical forecast models delivered by the European Center for Medium-Range Weather Forecasts, ECMWF. Then, FWIS data delivered by the ECMWF are interpolated into the MSG grid, generated, and distributed as layers of the Fire Risk Map (FRM) product of the LSA-SAF under the framework of the Land Surface Analysis Satellite Applications Facility (LSA SAF) project.

2.4. Methodology

The proposed calibration is based on two main steps: firstly the Fire Radiative Energy (FRE) emitted by the fires was computed as a daily accumulation of the Fire Radiative Power (FRP) from MSG/SEVIRI, over the period 2010-2021; secondly, the fire weather danger percentiles of the FWI, FFMC, and ISI indices were extracted for the areas of interest, to assess local fire weather conditions and the different fire Mediterranean regimes.

Considering the study period from March 2010 to October 2021, the P_k percentiles were extracted for the FWI, FFMC, and ISI indices, namely percentiles P25, P50, P60, P65, P70, P75, P80, P85, P90, P95, P98, and P99, considering the total number of hotspots occurred over the study areas.

Additionally, since 2000 GJ is the typical daily amount of the energy released by a severe fire and very difficult to suppress (Pinto et al., 2018), this calibration analysis was performed in two steps - without considering any FRE threshold (FRE > 0 GJ) and considering an FRE severity threshold of 1500 GJ (FRE > 1500 GJ). The rationale is to identify the Mediterranean areas with the most severe wildfires.

3. Results and Discussion

The number of the total events registered, without considering any FRE threshold (FRE ≥ 0 GJ), is 246444 over almost 12 years of the study period. The number of events registered considering the threshold of FRE >1500 GJ is 16366, which represents 6.6% of the total events, as can be seen in Table1.

Results show that a major part of the fire events considering FRE ≥ 0 GJ, occurs in Greece, Turkey, and Cyprus (GTC) region with approximately 35% of the total hotspots since this area spans most of the Mediterranean basin. Conversely, considering the 1500 GJ threshold, the Iberian Peninsula (IP) stands out with approximately 51% of the total hotspots, followed by Italy (IT) (18,3%), North Africa 2 (NA2) (18,1%), Greece, Turkey, and Cyprus (GTC) (16%), North Africa 1 (NA1) (3,2%), and finally South France (SF) (2,8%). However, it should be noted that some selected areas are overlaid.

To compare and validate the results, we consider the European thresholds of the European Forest Fire Information System (EFFIS), established by the European Commission for supporting the services in charge of the protection of forests against fires in the EU and neighboring countries (http://effis.jrc.ec.europa.eu).

The EFFIS network adopted, as well, the Canadian Forest Fire Weather Index system with the main goal of providing a harmonized picture of the spatial distribution of fire danger levels throughout Europe, the Middle East, and North Africa (https://effis.jrc.ec.europa.eu/about-effis/technical-background/fire-danger-forecast). Currently, FWI is classified into seven classes [Very Low, Low, Moderate, High, Very High, Extreme, and

Very Extreme] accordingly to the update of the last fire season whereas; FFMC and ISI are still classified in five classes (see Table 2.).

The obtained FWI percentiles (P50, P75, P85, P95, P99), considering FRE >1500 GJ, for the seven areas of interest, are presented in Table 3. It can be seen, that 50% of the fire events that occurred in the Mediterranean basin and all areas, belong to the four last fire danger classes: High, Very High, Extreme, and Very Extreme, accordingly to EFFIS classification (see Table 2).

Histograms for the FWI were computed for the Mediterranean basin and the Portuguese hotspots (Figures 2 and 3, respectively). Regarding both figures, where percentiles P50, P75, P85, P95, and P99 are marked, it is clear the increment of the FWI values, when the more severe fires are considered, namely when FRE>1500GJ. It is also noted the large number of hotspots related to low danger classes, and, therefore, lower fire intensity, concurrently to more severe fires.

Taking a closer look at Portuguese FWI values in Table 3, it can be seen that 50% of the fire events are classified in the last three classes: Very High, Extreme, and Very Extreme. Moreover, this pattern indicates that Portugal itself or considering the Iberian Peninsula, has more fire events, with more severe behavior and intensity than the remaining Mediterranean interest areas under study.

4. Conclusion

Results highlight the robustness of the proposed methodology that will also be applied to FFMC and ISI indices. Therefore, an overall discussion of the fire danger thresholds would be very fruitful and will be done in further work. However, these first results regarding the FWI clearly show already the differences in the fire regimes and fire intensity for the Mediterranean basin countries. They also reveal that all the fire-related activities of local authorities, such as fire danger assessment, monitoring, planning, and mitigation activities should be adopted or taken accordingly to these local patterns.

Abstract

In the European Mediterranean region natural-caused wildfires are a small fraction of total ignitions. Lightning strikes are the most common source of non-human fires, being strongly tied to specific synoptic conditions and patterns associated with atmospheric instability, such as dry thunderstorms. Likewise, lightning-related ignitions often associate with dry fuels and dense vegetation layers. In the case of Iberian Peninsula, the confluence of these factors favors recurrent lightning fires in the eastern Mediterranean mountain ranges, the western region of "El Bierzo" and central Portugal. However, under appropriate conditions lightning fires can start elsewhere, holding the potential to propagate over vast distances.

In this work, we assessed the likelihood of ignition leveraging a large dataset of lightning strikes and historical fires available in Spain. We trained and tested a machine learning model to evaluate the probability of ignition provided that a lightning strikes the ground. Our model was calibrated in the period 2009-2015 using data for mainland Spain plus the Balearic Islands. To build the binary response variable we classified lightning strikes between that triggered a fire event. For each lightning strike we extracted a set of covariates relating fuel moisture conditions, the presence and density of the vegetation layer and the shape of the relief.

The final model was subsequently applied to forecast daily probabilities at 1x1 km resolution for the entire Iberian Peninsula. Although the model was originally calibrated in Spain, we extended the predictions to the entire Iberian Peninsula. By doing so we were able to validate in the future our outputs against the Portuguese dataset of recent natural-caused fires (bigger than 1 ha) from 2001 to 2021. Overall, the model attained a great predictive performance with a median AUC of 0.82. Natural-caused ignitions triggered mainly in low dead (dFMC <8%) and moderate alive (DC > 250) fuel moisture conditions. Lightning strikes with negative polarity seem to trigger fires more frequently when the mean density of discharger was greater than 5. Finally, natural wildfires usually started at higher elevations (above 500 m.a.s.l.).

1. Introduction

In Europe, natural-caused fires represent a small percentage of the total number of fires. In contrast to anthropogenic fires, which are arranged in a spatial pattern close to the human footprint, the spatial location of natural fires is often clustered in specific hot spots of intense lightning occurrence and fuel availability. Recent studies warn of the likely increase in fire frequency and size linked to climate warming and global change. Most climate predictions envisage a decrease in fuel moisture content while fuel accumulation due to land abandonment is creating the perfect conditions for larger and more extreme fires. Although further research is needed, there is already evidence of an increase in the occurrence of natural fires related to the increased frequency of dry storms and heat waves (Li et al. 2020; Coogan et al. 2020). Lightning fires start more frequently in distant and remote regions, which pose an additional layer of difficulty to suppression, potentially growing into large fire events when fuel and relief conditions facilitate fire spread.

The Iberian Peninsula is one of the main hotspots of forest fire activity in Europe and the western Mediterranean basin. Numerous studies have focused on addressing the probability of fires caused by lightning, by man or by

both. Understanding the linkages and feedbacks between environmental and atmospheric conditions that ultimately relate to lightning-caused fires is relevant. Most studies dealing with natural fires are based on historical compilations of natural fires coupled to environmental and climatic variables (Rodríguez-Pérez et al. 2020) or on meteorological data to determine the atmospheric conditions conducive to lightning fires (Soler et al. 2021; Pérez-Invernón et al. 2021; Pineda et al. 2022). Other works, like the one by Couto et al. (2020), investigated the interactions between atmospheric models and the rate of spread of wildfires. However, there is still a lack of homogeneity in the methods, variables, and protocols to predict, and therefore anticipate, the occurrence of natural wildfires. We advocate an approach that decouples the conditions that favor lightning strikes from the environments that favor ignition.

The present work is developed within the framework of the H2020 project FireEUrisk, aimed at understanding, modeling, and predicting fire risk conditions by addressing the main risk components (hazard, exposure, and vulnerability) and mitigation steps (prevention, planning and adaptation) at the European scale. The main objective of this work is to predict the probability of ignition of natural forest fires using lightning records in the period 2009-2015. For this purpose, we analyzed a large lightning strike dataset (more than 17 million) to ascertain the conditions under which a lightning strike will trigger an ignition, i.e., the probability of ignition conditional on the occurrence of the lightning strike itself. The model was initially trained and validated using data covering all peninsular Spain plus the Balearic Islands, subsequently investigating its ability to predict ignitions in Portugal. Several variables related to fuel moisture content and vegetation structure, topography, as well as some factors related to polarity, intensity and density of impacts were used. The methodology is based on Random Forest modeling and other related techniques to assess the accuracy of the probability obtained. In this way, a daily and high-resolution lightning ignition prediction for the whole Iberian Peninsula has been elaborated.

2. Material and methods

The study area encompasses the whole Iberian Peninsula, i.e., mainland Spain and Portugal plus the Balearic Islands, covering a surface circa 588,000 km2 (Figure 1).

Figure 1- Digital elevation model and rivers network of mainland Spain plus Balearic Islands and Portugal.

2.1. Dependent variable: lightning strikes and fire ignitions

The core of our approach leverages a large and comprehensive dataset of cloud-to-ground lightning strikes recorded in the period 2009-2015. The dataset was provided by Meteogrid S.L.. It consists of more than 17 mill records reporting the intensity (and polarity) and density of flashes. Information about fire ignitions (location, date, cause, and size) was retrieved from the Spanish (EGIF) and Portuguese (DECIF) databases. The Spanish dataset was used to identify those lightning strikes that started a fire while the Portuguese records were retained to evaluate the applicability of the model to the specific conditions of Portugal.

The response variable was extracted from ignitions in Spain consisted in 11,000 fires. Approximately 2,500 fires were matched to a lightnings strike (i.e., occurring within 1,000 meters and no more than 3 days holdover

period respect to the ignition date). Upon this information we built a binary response variable combining lightnings that triggered a fire (1 or presence) with lightning not related to a fire (0 or absence). We implemented a stratified sampling procedure to prevent undesired effects from the largely unbalanced response (more 0 than 1) and minimize spatial autocorrelation.

2.2. Independent variables

To predict the probability of fires, we employed 7 factors related to vegetation state, topography and others directly linked to sparks' discharges (Figure 2). Firstly, we retrieved both the daily dead fuel (FM; calculated as described in Resco de Dios et al. (2015) and live fuel moisture content (using the Drought Code -DC- as proxy) at 11 km of spatial resolution. Secondly, elevation (*elev*) and relief curvature (*curvG*) were selected to depict the influence exerted by the terrain in the ignition of natural-cause fires. In turn, we included the vegetation height (hveg) as a proxy of the vegetation structure. The model also accounts for lightning-related features, such as strike intensity (mxi) and density (nse). To perform model predictions the latter two were set as constant figures equal to their average value over the study area (-10 of intensity and 5 discharges, respectively). All variables (aside FM and DC) were retrieved at 30x30 meters of resolution and later resampled at 1x1 km.

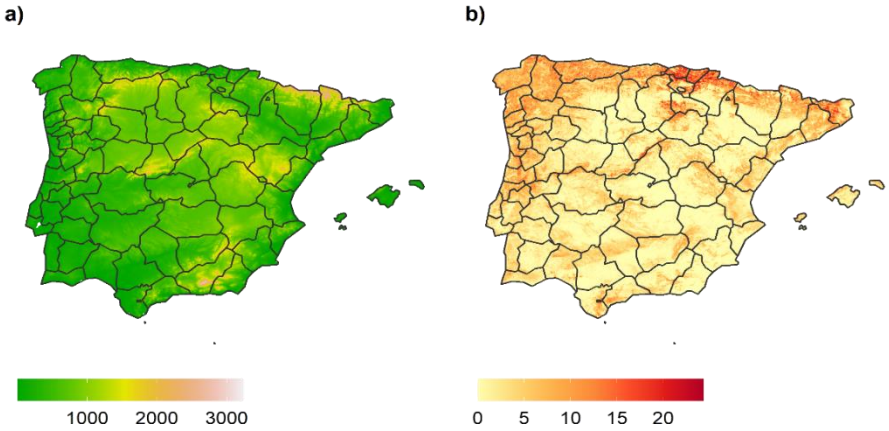

Figure 2- A) Digital elevation model (meters) and, B) height of vegetation (meters) in mainland Spain plus Balearic Islands and Portugal.

2.3. Model calibration with random forest

The model was trained using the random forest algorithm (Breiman 2001). We trained a total of 100 models exploring different realizations of the response variable. For each realization we extracted a balanced sample of 1-presence (flashes igniting a fire) and 0-absence (lightnings non-conducive to fire). The process was stratified using a 100x100 km grid so that at each grid cell we extracted an even sample of 1-presence and 0-absence. In turn, the absence observation pool included the same number of records in days experiencing fires and days not experiencing a fire. It must be noted that we only analyzed the April-to-October period, since natural fires seldom occur outside that season.

Model calibration was conducted using the caret package (Kuhn 2008) in the R environment for statistical computing (R Core Team, 2021). For each model realization we implemented a 5-fold repeated (3 repetitions) cross-validation, optimizing model parameters: number of trees (ntree) and number of variables to use at each split (mtry). We evaluated the importance of each co-variate using the Mean Decrease in the Gini index and the overall performance of each model via AUC. Out of the set of 100 models we selected the one attaining the average prediction performance (AUC=0.828) as candidate model to forecast and map the daily evolution of lightning-related ignition probability. The model was subsequently evaluated calculating the AUC from the Portuguese fire data, which consisted in 105 lightning fires (>1ha) in the period 2009-2015.

3. Results

In general terms, the Random Forest models attained a high AUC value (average AUC=0.828; Figure 3). The most relevant factor was fuel moisture content (DC and FM), followed by elevation, density of strikes, relief curvature, intensity/polarity and vegetation height. The response to fuel moisture content was the most

remarkable linkage found (Figure 4). In the case of DC (i.e., live fuel moisture content), the response curve showed an increase in ignition likelihood peaking around the 300 mark, remaining constant afterwards. In turn, dead fuel moisture content (FM) related to higher ignition likelihood below 10% moisture content. Likewise, probability peaked at above 20 of strikes density up yo 1,500 m.a.s.l. According to the spatial distribution of daily natural-caused probability, the highest values were often in the inner mountain ranges of the Iberian Peninsula, especially in the south-eastern half (see Figure 5). Locally, the likelihood of lightning fires is more common in the forested areas of medium elevations, thus usually excluding the lowest and altitudes but also the agricultural areas.

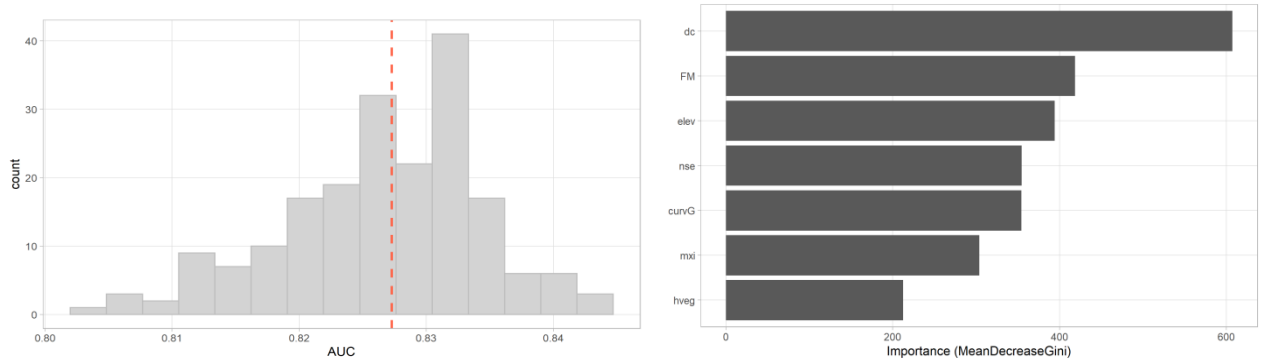

Figure 3- Model accuracy according to Area Under the Curve (left) and Random Forest variable importance (right).

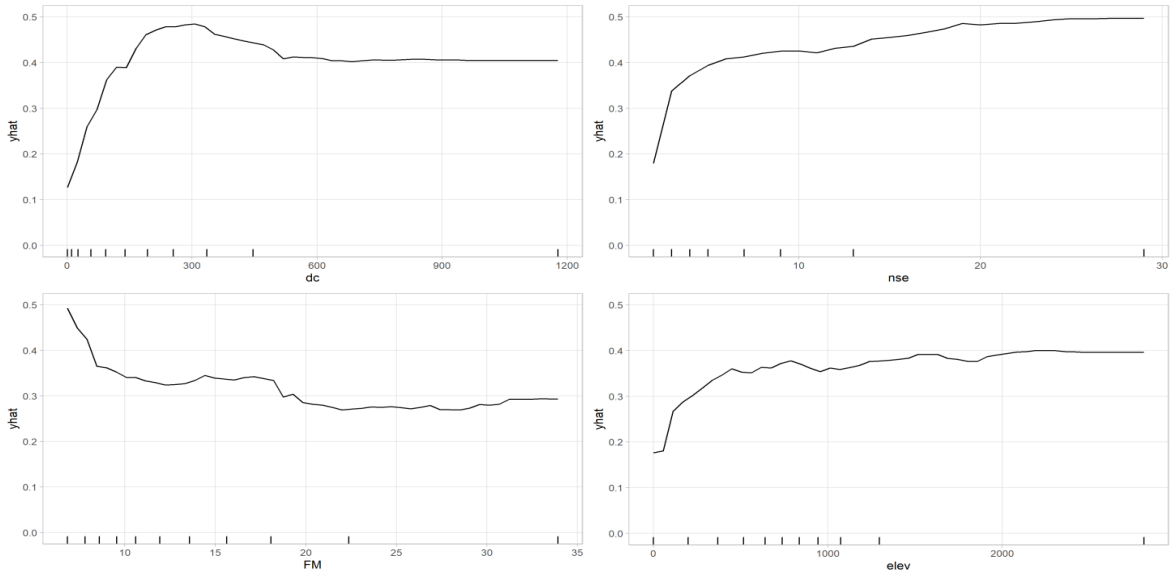

Figure 4- Partial effects plots for the most important variables included in the Random Forest model built to predict the natural-caused probability.

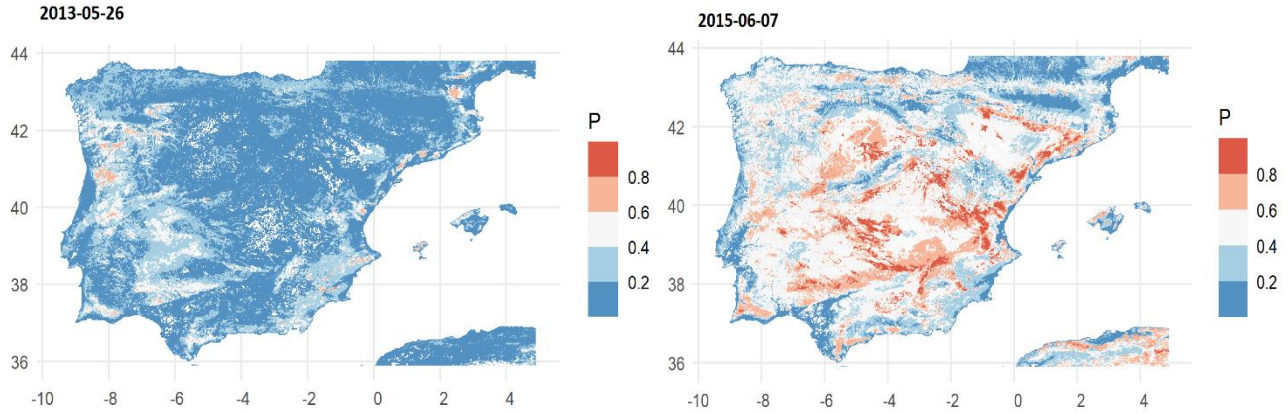

Figure 5- Daily lightning wildfire predictions examples for four specific days in the Iberian Peninsula and Balearic Islands.

4. Discussion

In this work we produced a daily forecast of natural-caused wildfire ignition probability over the whole Iberian Peninsula plus the Balearic Islands. We followed a novel method based mainly on lightning strikes, opposite to fire-based approaches. The model holds a good predictive accuracy (around 0.82 AUC), which is noteworthy given the rare nature of thunderstorm-driven fires (Fernandes et al., 2021). In turn, the future calibration of our fitted model in Portugal shows the feasibility of extending the model to regions like Spain. The observed relationships between ignition drivers and predicted likelihood are in line with the expected behavior, i.e., fuel moisture as the most influential factor modulating ignition followed by topography. The important role of the moisture of the live/dead fuels causing the ignition and propagation of new fire events have been documented in many works previously (Baranovskiy & Kirienko, 2022; Resco de Dios et al., 2021, 2022; Rodrigues et al., 2021). However, our findings were non-conclusive in terms of the role of the characteristics of the fire-prone flash. We did not find a strong signal in terms of intensity nor polarity, though an increased density of strikes did increase the chance of ignition.

In terms of risk assessment, we believe that the strategy of breaking down ignition likelihood and the probability of lightning occurrence offers several advantages. Decoupling both phenomena allow us to better understand their relative importance while enabling embedding different models for lightning or thunderstorm forecast, or even real observations of lightning flashes. That is particularly important for short-term predictions. In turn, long-term modeling would also benefit for such approach. Our ignition forecast requires few weather-related factors (the same necessary for the calculation of the FWI), thus their prediction under climate scenarios (SSP or RCP) is already feasible. In the same line, several models are available to forecast lightning strikes (Woodard et al., 2014), hence, being possible to combine them with the ignition component. Our next steps include extending the temporal span of calibration and, more important, modeling the phenomena in other locations, preferably in northern latitudes. Furthermore, we need to investigate the performance of the model outside the calibration time frame, both forward and backward in time.

5. Conclusions

In this work we produced a daily forecast of the probability of natural wildfires in the Iberian Peninsula and the Balearic Islands. We combined lightning and wildfire data with environmental variables to train and test a binary Random Forest model. Our results revealed the major role played by fuel moisture content, the most sensitive factor to climate warming in the coming decades. This highlights the need for further research and consideration of natural ignitions in hazard mitigation plans, even though their contribution to fire activity is currently moderate.

Abstract

Forest fuel moisture content is an important parameter that determines fire risk and fire behaviour. An accurate prediction of moisture content is therefore of great importance in fire management. In the fire risk period, dead forest fuel moisture content changes mainly by water vapour sorption processes so its knowledge enables the development of predictive fire risk models.

In the present work, the adsorption and desorption processes and equilibrium moisture content of 10-hour dead Pinus pinaster branches (diameter between 0.6 cm and 2.5 cm) were described in order to develop a moisture content prediction model for this type of fuels.

Laboratorial tests were used to determine sorption curves, timelag and equilibrium moisture content for different sets of air temperature (range between 20°C and 40°C) and relative humidity (range between 10% and 90%). The sorption curves and equilibrium moisture were also modelled with forest fuels and agricultural and food products existing models.

Field tests were used to evaluate the sorption and equilibrium moisture content models performance. Dead Pinus pinaster branches were collected in central Portugal through the year 2020 and 2021 on the Portuguese fire risk period (15th May to 15th October) between 12:00h and 13:00h LST. Samples with 0.6 cm to 2.5 cm diameter were collected and transported to laboratory to determine moisture content.

The laboratorial drying and wetting curves of dead Pinus pinaster branches (0.6 cm to 2.5 cm diameter) show that they are not pure exponential functions, but with different timelag values until equilibrium is reached. Additionally, the results suggest no significant relationship of the timelag periods with air relative humidity but a dependence with air temperature, showing an increase in the sorption rates with temperature. In terms of sorption curves, Modified Henderson and Pabis model provide the best fitting.

For this type of fuels, the representation of EMC values as a function of air relative humidity at constant temperature allowed to obtain a typical sigmoid curve. The EMC values obtained were higher for desorption process than for adsorption process, indicated the typical hysteresis effect in these processes. It was found that, besides the models used in forest fires, other EMC models are also suitable to predict fuel moisture content of dead Pinus pinaster branches, as the ones used in agricultural and food analysis.

1. Introduction

Forest fuel moisture content (FFMC) has a considerable influence on many aspects of forest fire behaviour, including rate of fire spread, ignition probability, flame dimensions and fuel consumption (Rothermel 1983; Viegas et al. 1992), however, its accurate prediction is difficult due to its interactions with weather conditions, topography and vegetation (Matthews 2014).

In the absence of rainfall, dead forest fuels respond to changes in meteorological conditions by sorption processes where it dominates water transfer mechanisms below the fiber saturation point. In these conditions, and at constant air temperature and relative humidity, the FFMC changes (increases or decreases) until it reaches a constant value designated equilibrium moisture content (EMC) (e.g. Catchpole et al. 2001; Viney and

Catchpole 1991). These moisture sorption processes are also characterized by a response time or log drying rate or timelag (τ) that is the time required for the fraction of evaporable water remaining in the forest fuel to decrease from 1 to 0.368 (Byram, 1963). Timelag is on the basis of forest fuels classification into four categories (1-hour, 10-hour, 100-hour and 1000-hour fuels) (Bradshaw et al. 1983).

In the present work, the adsorption and desorption processes and EMC of 10-hour dead *Pinus pinaster* branches (diameter between 0.6 cm and 2.5 cm) were determined in order to develop a moisture content prediction model for this type of fuels.

2. Methods

Laboratorial tests were used to determine sorption curves, timelag and EMC of dead *Pinus pinaster* branches (0.6 cm to 2.5 cm diameter) for different sets of air temperature (range between 20°C and 40°C) and relative humidity (range between 10% and 90%). Samples were placed inside a climatic chamber (Aralab Fitoclima 300) equipped with an analytical balance (precision of 0.001g). Continuous weighing was recorded until it reached constant weight, determining dead *Pinus pinaster* branches moisture content evolution and showing the changing rates at which equilibrium approaches.

In terms of mathematical modelling, sorption processes were modelled using the exponential equation described by Byram (1963) (equation 1), Page (1949) (equation 2), Henderson and Pabis (1961) (equation 3), two-term (Henderson 1974) (equation 4) and Modified Henderson and Pabis (Karathanos, 1999) (equation 5).

$$\mathrm{E(t)}_1 = \exp\left(\frac{-\mathrm{t}}{\tau}\right) = \exp(-\mathrm{k}_1\mathrm{t}) \tag{1}$$

$$\mathrm{E(t)}_2 = e^{-k_1 t^n} \tag{2}$$

$$\mathrm{E(t)}_3 = a_1 e^{-k_1 t} \tag{3}$$

$$\mathrm{E(t)}_4 = a_1 e^{(-k_1 t)} + a_2 e^{(-k_2 t)} \tag{4}$$

$$\mathrm{E(t)}_5 = a_1 e^{(-k_1 t)} + a_2 e^{(-k_2 t)} + a_3 e^{(-k_3 t)} \tag{5}$$

where τ is the timelag (h), t is time (h), k_1, k_2 and k_3 are the drying constants (h^{-1}) and n, a_1, a_2 and a_3 are empirical dimensionless constants. The fraction of evaporable water remaining in the fuel at time t, E(t), was calculated using equation 6. Model parameters and constants were obtained from laboratory data

$$\mathrm{E(t)} = \frac{\mathrm{m_{(t)}} - \mathrm{m_e}}{\mathrm{m_0} - \mathrm{m_e}} \tag{6}$$

where m(t) is the fuel average moisture content at time t, m_0 is the value of m at t = 0, m_e is the value of m as t approaches infinite (m_e approaches EMC).

To assess the relationship between EMC of dead *Pinus pinaster* branches and air temperature and relative humidity were used semi-empirical and empirical models such as Van Wagner (Van Wagner, 1987) (equation 7), Modified Halsey (Iglesias and Chirife 1976) (equation 8), Modified Oswin (Chen 1990) (equation 9), Nelson (Nelson, 1984) (equation 10) and Modified Chung-Pfost (Pfost et al. 1976) (equation 11).

$$EMC = \frac{1}{100}\left[a(100RH)^b + ce^{(100RH-100)/d} + e(21.1 - T)(1 - e^{100fRH})\right] \tag{7}$$

$$EMC = \left[\frac{e^{(a-bT)}}{-ln(RH)}\right]^{1/c} \tag{8}$$

$$EMC = (\mathrm{a} - \mathrm{bT})\left[\frac{RH}{(1-RH)}\right]^c \tag{9}$$

$$EMC = \frac{1}{a} ln\left(-\frac{RT_K}{Me^b} ln\left(\frac{RH}{100}\right)\right) \quad (10)$$

$$EMC = -\frac{1}{a} ln\left[-\frac{(T+b)}{c} \ln(RH)\right] \quad (11)$$

where a, b, c, d, e and f are coefficients specific to individual equations, RH is the relative humidity, T (°C) and T_k (K) are the temperatures, R is the universal gas constant (1.987 cal.mol^{-1}K^{-1}) and M is the molecular weight of water (18 gmol^{-1}). Model constants were obtained from laboratory data.

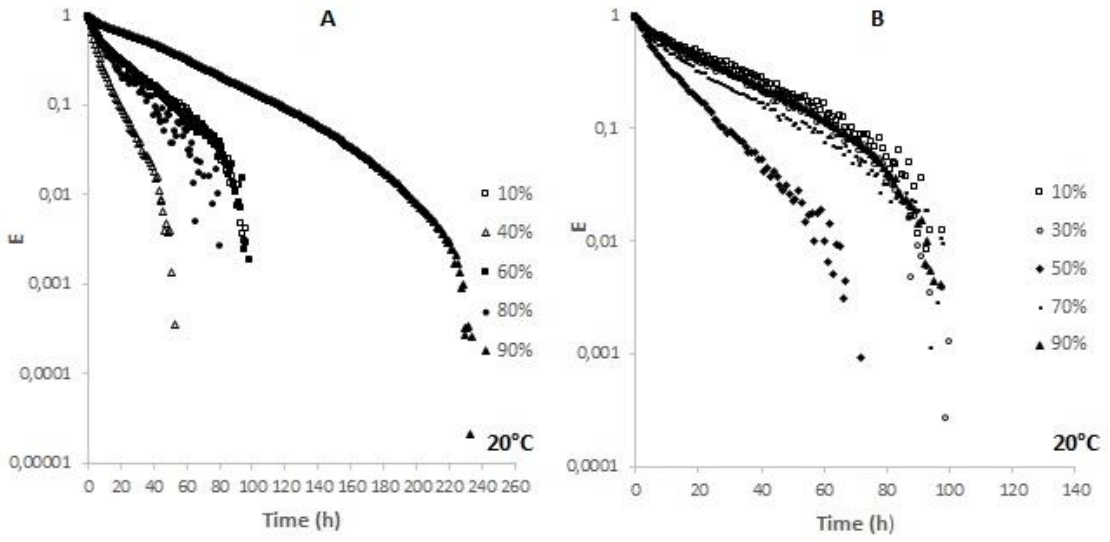
In the field tests, used to evaluate the sorption and EMC models performance, dead *Pinus pinaster* branches were collected from *Pinus pinaster* forest stands in Viseu (40°42'30.02"N, 7°54'8.96"W) in central Portugal through the year 2020 and 2021. Field sampling was performed on the Portuguese fire risk period (15th May to 15th October) between 12:00h and 13:00h LST. Samples with 0.6 cm to 2.5 cm diameter were collected and transported to laboratory in an isothermal bag to avoid moisture changes. Here, samples were weighted and then oven-dried at 105°C for 24 h, until constant weight, to obtain its dry weight and therefore the dry basis moisture content.

Hourly meteorological conditions (air temperature, relative humidity, wind and rainfall) from a weather station located approximately at 10 km south of the sampling site, were used to characterise weather conditions during field tests.

To assess the model fitting quality some statistical parameters were calculated namely the mean absolute error (MAE), the mean absolute percentage error (MAPE), the root mean squared error (RMSE) and the determination coefficient (R^2). RMSE and MAPE show the accuracy of model fitting, MAE measures the bias of the model and the R^2 measure how well observed values are replicated by the model. Usually, higher values of R^2 and lower values of MAE, MAPE and RMSE, associated with randomly distributed residuals indicate a good fit.

3. Results

Figure 1 shows the drying and wetting curves of dead *Pinus pinaster* branches represented by the evaporable water fraction (E), described in equation 6, as function of time for air temperatures of 20°C, 30°C and 40°C in a range of relative humidity between 10% and 90%. The drying and wetting curves show a deviation from pure exponential behaviour, which means that other functions should be considered as well to represent these processes. Additionally, these curves show some fluctuations, particularly in the late stages of the experiment mainly caused by temperature and relative humidity oscillations inside the climatic chamber.



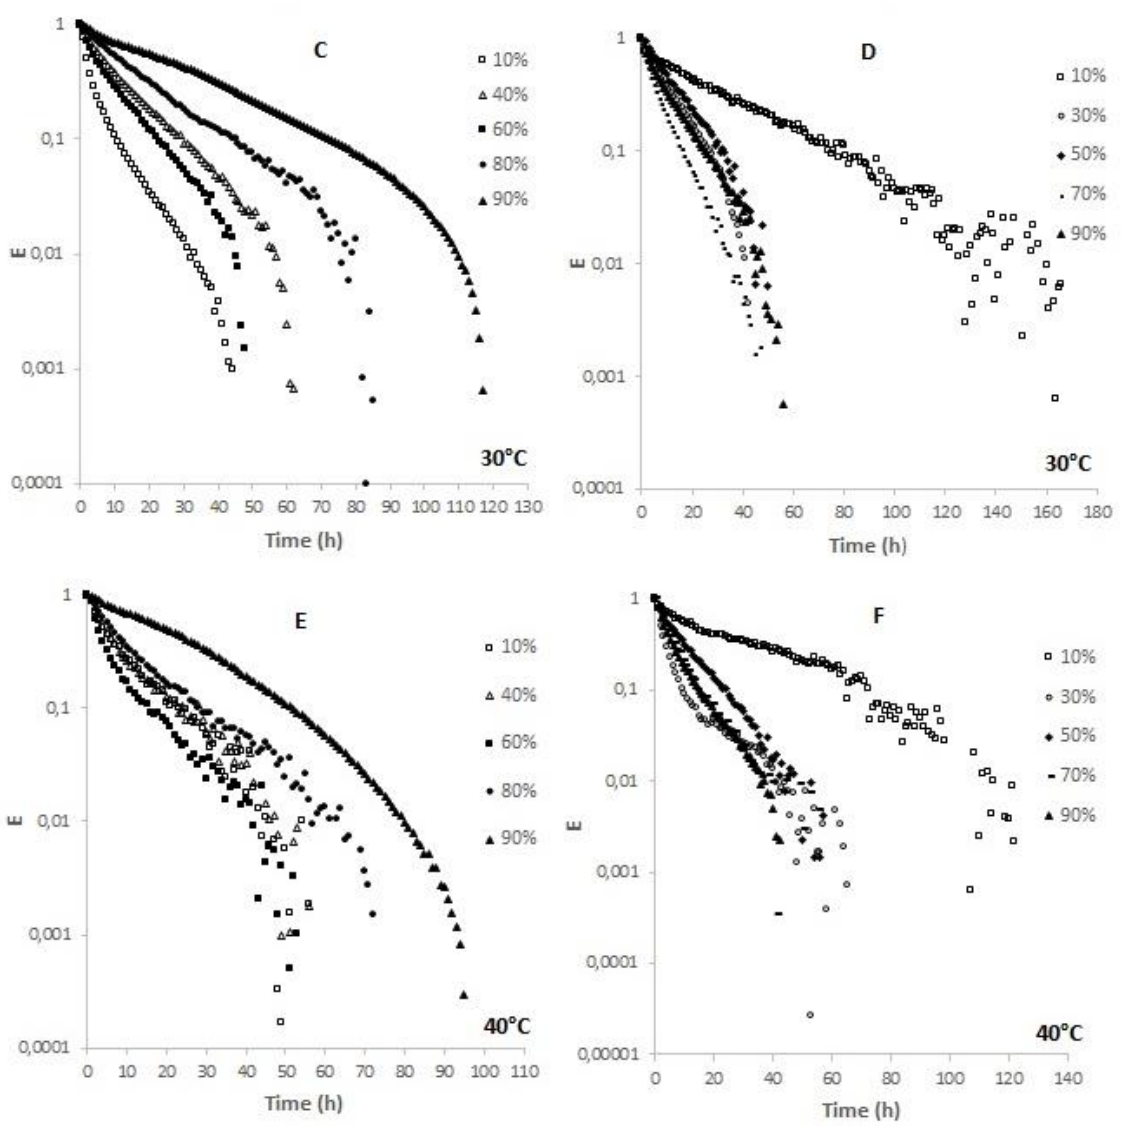


Figure 1- Semi-log graphs of desorption tests (A, C, E) and adsorption tests (B, D, F)

Breaking the drying and wetting curves in four periods and assuming a constant rate as fuel approaches EMC in each step, it was calculated the four timelag values. Table 1 shows the average timelag periods obtained in the laboratorial tests. No significant relationship of the four timelag periods with air relative humidity was found therefore an average value is presented. However, a dependence of the four timelag periods with air temperature was observed.

Table 1- Average timelag periods obtained in order of air temperature

Process	Temperature (°C)	First timelag (h)		Second timelag (h)		Third timelag (h)		Fourth timelag (h)	
		Average	s.d.	Average	s.d.	Average	s.d.	Average	s.d.
Desorption	20	20,99	14,04	26,46	11,38	19,89	11,50	16,76	6,09
	30	8,12	6,46	12,85	5,80	9,65	5,10	7,86	4,49
	40	8,23	6,43	9,96	4,24	9,60	4,02	7,37	2,62
Adsorption	20	19,02	7,60	23,32	8,25	22,38	9,98	13,71	10,48
	30	9,31	5,50	11,65	5,04	9,09	4,19	6,97	5,10
	40	6,29	3,40	12,09	11,29	8,89	4,44	6,65	3,20

Table 2 shows the estimated parameters for sorption processes based on the laboratorial tests for the models described from equation 1 to equation 5. As it can be seen, drying and wetting experimental curves are best

fitted by the Modified Henderson with a R^2 of 0.694 and 0.749 and a RMSE of 0.134 and 0.116 for desorption and adsorption processes, respectively.

Laboratorial EMC values of *Pinus pinaster* branches obtained in both adsorption and desorption tests in a range of relative humidity between 10% and 90% for three air temperatures 20°C, 30°C and 40°C are shown in Table 3 and plotted in Figure 2. These results were fitted to five EMC models and Table 4 shows the EMC model parameter estimation obtained for the desorption and adsorption processes described in equation 7 to equation 11. As an example, the estimation by the Van Wagner model is also shown in Figure 2.

As can be seen, for a wide range of temperature and relative humidity values all sorption models show good fitting ability with the laboratory results however the Van Wagner model presented the best fit for both adsorption and desorption processes. This model gives the higher R^2 of 0.991 and 0.984, the lowest MAE of 0.428 and 0.453 and the lowest RMSE of 0.514 and 0.584 for desorption and adsorption processes, respectively. The residual distribution was also analysed and showed that all adsorption and desorption models presented a random residual distribution indicating good fitting ability and only Halsey model presented a systematic residual distribution.

The EMC values obtained were higher for the desorption process than for the adsorption process, presenting the typical hysteresis effect.

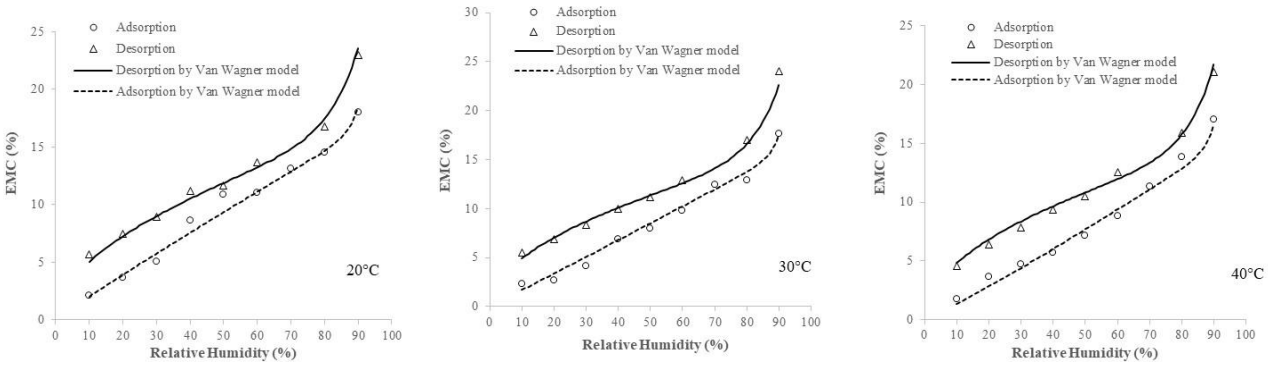

Figure 2- EMC of Pinus pinaster branches in both the adsorption and desorption processes. Estimates obtained by Van Wagner model.

In terms of model validation, Figure 3 shows the comparison between the predicted (line) and the observed (dots) FMC of *Pinus pinaster* branches. Predicted values result from the Modified Henderson and Pabis model for the drying and wetting curves and the Van Wagner model for EMC, both with empirical parameters estimated in the present work. The observed FMC values were obtained in the field tests. FMC values corresponding to rainfall events were excluded from the model validation.

Comparing the predicted and the observed FMC values, in terms of MAE, MAPE and RMSE, the results show a high prediction ability, with a MAE equal to 1.83%, a MAPE equal to 19.34% and a RMSE equal to 2.11.

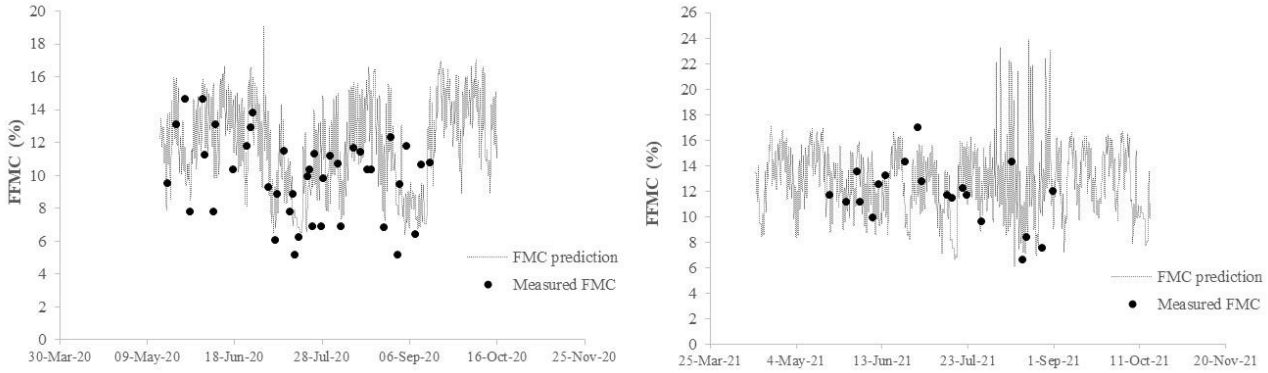

Figure 3- Comparison between the predicted (line) and the observed (dots) FMC of Pinus pinaster branches during 2020 and 2021 (15th May to 15th October). Predicted values result from the Modified Henderson and Pabis model for the drying and wetting curves and the Van Wagner model for EMC.

4. Discussion and Conclusion

The drying and wetting curves of dead *Pinus pinaster* branches (0.6 cm to 2.5 cm diameter) show that they are not pure exponential functions, but with different timelag values until equilibrium is reached. Additionally, the results suggest no significant relationship of the timelag periods with air relative humidity but a dependence with air temperature. An increase in the sorption rates with temperature is observed in this study that is in agreement with the results reported by Byram (1963). However, the pure exponential equation of Byram (1963), that is usually used in forest fire research, does not represent well the drying and wetting curves of dead *Pinus pinaster* branches. Modified Henderson and Pabis model provide the best fitting.

For this type of fuels, the representation of EMC values as a function of air relative humidity at constant temperature allowed to obtain a typical sigmoid curve. The EMC values obtained were higher for desorption process than for adsorption process, indicated the typical hysteresis effect in these processes.

It was found that, besides the models used in forest fires, other EMC models are also suitable to predict fuel moisture content of dead *Pinus pinaster* branches, as the ones used in agricultural and food analysis.

Comparing the predicted and the observed FMC of *Pinus pinaster* branches, the results show a high prediction ability of the best models, with a MAE equal to 1.83%, a MAPE equal to 19.34% and a RMSE equal to 2.11. Lee et al. (2020) and Dios et al. (2015) obtained similar results using other models type with this type of forest fuel (10h-fuels).

Abstract

Identifying the drivers of fire activity's spatio-temporal variability is challenging in densely populated and fire prone landscapes. Human usage and climate affect the local fire regime in contrasting ways. The identification of these drivers is further complicated due to the stochastic nature of fire activity. Fire regimes in Mediterranean France show contrasted spatial patterns and temporal changes at decadal scales. While overall, the number of fires decreased over the last thirty years, certain zones suffered local increases in fire activity. To describe and understand the drivers of those changes and the spatial variability, we introduced several improvements in the *Firelihood* model - a probabilistic framework capable of prediction fire occurrence of >1ha fires, and exceedance probabilities of 10 and 100 ha thresholds - by incorporating Land-Use Land-Cover (LULC) explanatory variables, as well as by enhancing its spatio-temporal components to account for unexplained variability in models. The novel model - fitted on a 2km-pixel grid, but relying on variables aggregated at various spatial aggregations (2, 4, 8 and 16km) - is used to explain the observed spatial patterns of fire activity during the last 27 years, as well as the regional and local changes observed between two decades with contrasted fire activities by running counterfactual scenarios.

LULC variables, including road density, wildland-urban interface, or expert-based fuel type rating explain a significant part (as much as fire-weather) of the variability in fire occurrence (>1ha), thereby reducing the effect of unexplained spatial variability. The selected occurrence model uses only 2km-resolution variables, as local factors have a high influence on fire ignition and initial spread. The occurrence of larger fire (>10 ha or >100 ha) is largely driven by fire-weather, followed by unexplained spatial variability; selected models for larger fires uses a few LULC variables aggregated at 4, 8 and/or 16 km. This indicates the influence of surrounding factors on fire size extension. The spatial effect for fire occurrence presents contrasted hot and cold-spots throughout the area, while it has a clear east to west decreasing trend for fire size.

Regarding temporal changes in fire activity between the two decades, changes in fire weather induced a strong increase in fire probability in many hot spots throughout the region, but this effect was overcompensated by a negative trend associated with unexplained temporal factors (and of larger magnitude than fire weather). LULC variables had negligible effect on the fire regime's temporal trends. Moreover, an east-to-west gradient appears for the spatial trends of the larger fires, and for the temporal trends in all sizes, highlighting the increase in fire activity in the western side of the region. Those results suggest that observed temporal changes in fire activity are the result of a changing socio-economic or policy frame, probably related to reinforced suppression policies following the year 2003, and the increasing agricultural abandonment.

1. Introduction

In south-eastern France, the Mediterranean climate creates fire-prone fuel moisture conditions and regional winds often trigger large fire events (Ruffault et al. 2017). The climatic and land characteristics of the region (Fréjaville and Curt 2015; Barbero et al. 2019) shape the spatial patterns of fire activity: highest burnt area in fire-prone populated areas, with high exposure of human settlements to fire, and in hinterland and inland mountains lower summer fire activity, despite local "hot-spots" (Figure 1A).

Fire-weather largely drives seasonal and interannual variations in fire activity in south-eastern France (Pimont et al. 2021), and it has increased in the last decades, suggesting a rise of potential fire risk (Fréjaville and Curt 2015; Barbero et al. 2020), yet the translation of this potential to realized fire risk remains unknown. Fire records

show a decrease in fire activity in the last 40 years which makes the assessment of the weather effects more difficult. To understand past changes in fire regimes and risk, and anticipate future scenarios, it is necessary to disentangle how climate, landscape and human factors affected spatio-temporal dynamics of fires.

Several studies aimed to explain different aspects of fire activity in south-eastern France and how it varies in time and space (e.g., Ruffault et al. 2017, Pimont et al. 2021). However, there are still many uncertainties about the role of human and biophysical factors in the spatial and temporal trends in this region. Here we improved the *Firelihood* probabilistic fire activity model (Pimont et al. 2021) to quantify how much of the observed changes in fire activities can be attributed to these factors and how these temporal changes are distributed at the regional scale. This second goal is not only important in the context of retrospective analysis of changes in fire activity, but also in the context of anticipation of the near future.

2. Materials and methods

Firelihood (FL) is a Bayesian probabilistic framework accounting for the stochastic nature of fire activities with several statistical components that model daily occurrence and size of wildfires as a marked point process parametrized with several explanatory variables (Pimont et al. 2021). FL models the occurrence of fire larger than 1ha (escaped fires) as a Poisson process and the size of these fires as a combination of exceedance threshold probability and piecewise size distributions. FL includes spatio-temporal effects to account for limitations in explanatory variables. Effects are adjusted with the R-INLA package, which implements the Integrated Nested Laplace Approximation and allows spatial effects with Matérn covariance function represented through the Stochastic Partial Differential Equation (SPDE) approach.

The first developments (in the following FL1) included FWI and Forest Area as explanatory variables and spatio-temporal effects of the occurrence component were seasonal, spatial and annual, with a shift following the 2003 heat wave. The estimation was done in 8-km pixels (Pimont et al. 2021). In FL1, spatio-temporal effects were critical to mitigate the impact of large unexplained effects which can induce confusion between factors and limit the accuracy of estimated effects of explanatory variables. Moreover, they allow a realistic representation of processes involved in fire activities, so that simulations can be used to carry out spatio-temporal analyses, despites of the stochasticity in fire observations.

FL1 was limited for detailed analyses of the evolution of spatio-temporal patterns of fire activity. We develop an extension of FL1, referred as FL2, which includes additional LULC at 2-km resolution and refined spatio-temporal effects. The occurrence component of FL2 includes a yearly effect and a spatial effect for temporal trends (equation 1). Size exceedance models for 10 and 100 ha include a yearly effect and spatial effects for Sylvo-Eco Regions exhibiting similar characteristics (equation 2).

$$\log N_{i,d}^{1ha} \sim \beta_0 + \underbrace{f_{FWI}(FWI_{i,d}) + f_{WEEK}(WEEK_{i,d})}_{FL1} + \beta(WAp_{i,y}) + \sum_{LULC} f_{LULC}(LULC_{i,y}) + f_{X,Y}(X_i, Y_i) + \underbrace{f_{YEAR}(y) + f'_{X,Y}(X_i, Y_i)(y - 1992)}_{Spatio-temporal\ trends} \quad (1)$$

$$log\,\frac{p_{i,d}^{u}}{1-p_{i,d}^{u}} = \beta_0^{p,u} + f_{FWI}^{p,u}(FWI_{i,d}) + \sum_{LULC} f_{LULC}^{p,u}(LULC_{i,y}) + f_{YEAR}^{p,u}(y) + f_{BESAG}^{p,u}(SER) \quad U = [10,100] \quad (2)$$

Simulations with FL2 (Figure 1B) allowed to (i) quantify the relative contributions of the different variables to spatial patterns thanks to a partition of variance; (ii) predict the evolution of fire activities from the 1993-2002 decade, to which would have occurred during the 2009-2018 decade if only climate, LULC or unexplained factors had changed at a time, allowing to attribute observed changes to the different explanatory variables.

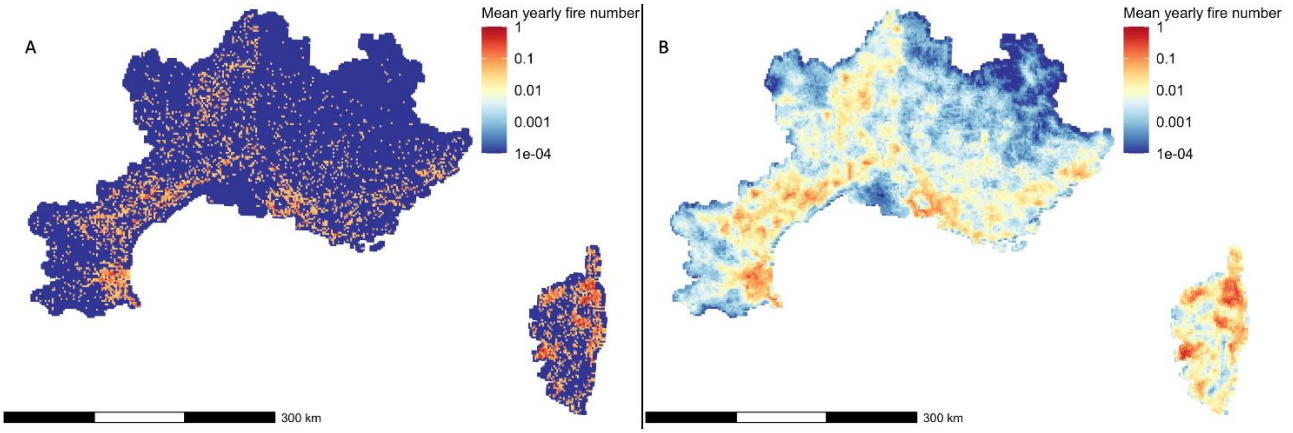

Figure 1. Fire occurrence over the study period expressed as the mean number of fires larger than 1ha per year in each 2km pixel: (A) Observed; (B) Simulated.

3. Results and discussion

3.1. Variable selection and model performance

Variable selection based on DIC and AUC led to FL2, summarized in Table 1. Significant improvements were obtained with the inclusion of LULC. The coarser scales of spatial aggregation (4, 8 and 16km) underperformed to explain occurrence, so that only finer predictors (2km) were retained. This highlights that occurrence patterns were better explained by fine scale landscape factors, contrary to size models for which 4km and even 8 and 16km were sometimes better predictors.

The effects of the occurrence model components were consistent, showing increases associated with FWI (Figure 2B), fuel type rating (Figure 2C), wildland area (Figure 2A), road length and population (not shown). Inverted U-shape responses associated with wildland area, slope, aspect or wildland urban interface were explained by reverse effects of these factors on ignition and initial spread, as already observed for wildland area in Pimont et al. (2021). Road length and population are among the most influential variables, confirming the key role of accessibility to forest areas found in other regions of Europe and the influence of human activities (e.g. Costafreda et al. 2017).

The yearly effect (Figure 2D) confirmed the huge decay in fire activity observed after the 2003 crisis. The negative values of the spatial effect (Figure 3A) corresponds to areas where explanatory factors tend to overestimate the observed activity. The spatial distribution of annual trends (Figure 3B) was contrasted from west to east, with positive trends to the west and negative to the east. In a context where unexplained factors depending on the local conditions are very important, this approach allowed accurate estimations of the effect of explanatory variables and of residual unexplained spatio-temporal random effects.

The partial effects of both size models were similar (100ha in Figure 2), with monotonic responses. Exceedance probabilities increased with FWI (Figure 2F), fuel type rating (Figure 2G), wildland (Figure 2E), shrubland and coniferous areas and slope, and decreased with broadleaved and agricultural areas, and population (not shown). Upper ranges were generally associated with saturations. The yearly effect for the 100ha threshold decreased - except the 2003 peak-, but with a non-significant trend as current trends (blue dashed line) were inside the credible interval of early years (Figure 3H. The spatio-temporal effects here are less sophisticated because the datasets for fires above 100 ha were too small to afford the approach described above for occurrence. The temporal effects allowed potential yearly changes and spatial effects into SylvoEcoRegions and proved to enhance the predictive ability of the model. The spatial effect (Figure 3C) shows a west-east gradient with increased probability in the eastern part and in mountainous regions, possibly explained by operational constraints in suppression policies in remote mountainous regions.

Table 1. Variable selection of the occurrence model (OCCURRENCE) and size models for the 10 ha (SIZE 10) and the 100ha (SIZE100) exceedance thresholds. The distance indicated in parenthesis refers to the spatial aggregation used for a given variable (by default is 2km).

Model	Variables	DIC	AUC (training)	AUC (validation)
OCCURRENCE	Intercept + WAp + Fuel + WA + Aspect + Slp + WUI + Pop + Agri + Roads + SPDE + Sp_temp + Years	50131,24	0,877	0,827
SIZE 10	Intercept + FWI + WA(4km) + Agri (4km) + Con + Brl + Shr + Pop + Slp + Mxf (8km) + Fuel + Besag + Years	5646,03	0,71	0,66
SIZE 100	Intercept + FWI + WA(4km) + Agri (4km) + Con + Brl + Shr (4km) + Pop + Slp (16km) + Fuel + Besag + Years	2002,53	0,79	0,78

Where: : **WAp** – Wildland area presence, **Fuel** – ONF's fuel rating, **WA** – Wildland area, **Aspect –** Aspect of the pixel, **Slp** – Slope, **WUI** – Wildland to Urban interface, **Pop** – Population per pixel, **Agri** – Agricultureal area, **Roads** – Road length, **Con** – Coniferous forest area, **FWI** – Fire Weather Index, **Brl** – Broadleaved forest area, **Shr** – Shrublkand area, **Mxf** – Mixed forest area, **SPDE** – Spatialmodel, **Sp_temp** – spatio-temporal model, **Besag** – Spatial model based on the SER. DIC and AUC are the criterion for the model evaluation," fit" and "pred" Make refference to the training and validation data respectively.

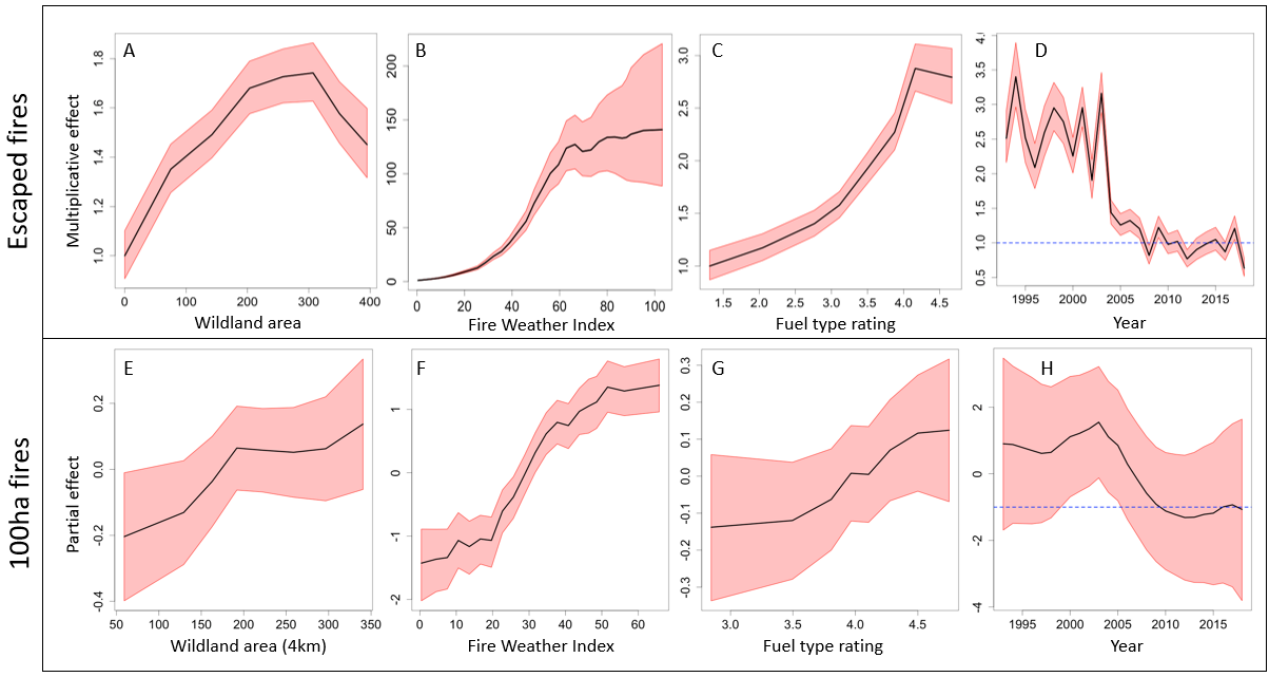

Figure 2. Examples of: (A-D) multiplicative effects for the predictor variables of the occurrence model (escaped fires) with confidence intervals; (E-H) partial effects (E-H) of the predictor variables for the 100ha exceedance probability models.

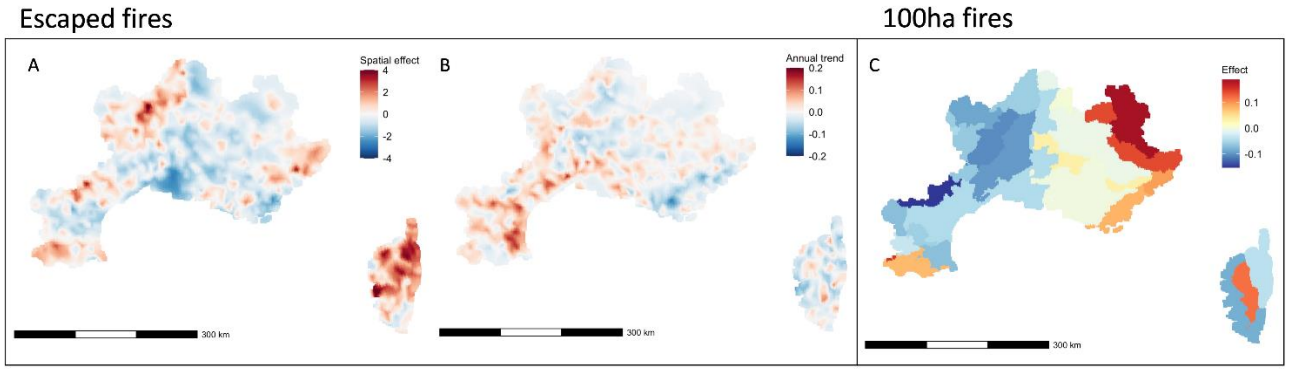

Figure 3. Spatial effect of the occurrence model from SPDE (A); spatial trends of the occurrence model (B); Spatial effect from the "Besag" component of the 100ha exceedance model (C). The effect's magnitude is drawn in a color coding in each pixel, the labels inside each polygon (thin black lines) corresponds to the code of the SylvoEcoRegions.

3.2. Factors explaining spatial distributions and their changes

The partition of fire activity variance allowed to attribute the spatial variability to three types of effects (Fire-weather, LULC and unexplained) over the whole period. The spatial effect had the biggest contribution to 1ha-number simulations (40%), while LULC and fire-weather explained one fourth of the total variance each. The "temporal effect" in spatial patterns - associated with spatial trends- was less important. For larger fire numbers (N10 and N100), the fire weather explained the biggest part of spatial variance (~50%), followed by the spatial effect (~25%), while LULC were around 17-20%. The temporal effect was marginal. Therefore, fire-weather and LULC together explained roughly 50% of spatial distribution of 1ha fires and up to 70% for larger fires (N10 and N100).

The next analysis aimed at determining whether the changes in spatial distribution between 1993-2002 and 2009-2018 could be explained by these variables. The comparison between decades for the actual evolution of variables confirmed a decrease in fire numbers for all sizes, ranging between -50 and -60%. When considering changes in factors one at a time, simulations for the recent decade were more contrasted. The "Fire-weather-change" scenario shows an increase in fire events while the "LULC-change" scenario did not affect the fire number. The "other-temporal-change" scenario showed a decrease in fire number, but with bigger magnitude than the "actual" simulations. The potential increase caused by fire-weather change was overcompensated by temporal changes which were not explained by LULC variables. It is very likely that suppression fire policy strongly reduced the number of escaped fires in part of the region.

We then investigated the spatial distributions of these changes by mapping anomalies between the reference period and recent scenarios (Figure 4). The spatial distributions were similar throughout the three fire sizes. Both the real-present and the other-temporal-changes (Figure 4A,D) scenarios showed a widespread decrease over the eastern regions and sharp local increases in the western regions, revealing that the overall trend was very heterogeneous over the territory. Fire-weather change (Figure 4B) induced scattered increases in a few "hot spots", in locations where the effect on activity should have increased the most, without other changes. Finally, changes in LULC (Figure 4C) produced marginal changes, clearly not explaining any of the recent fire regime change.

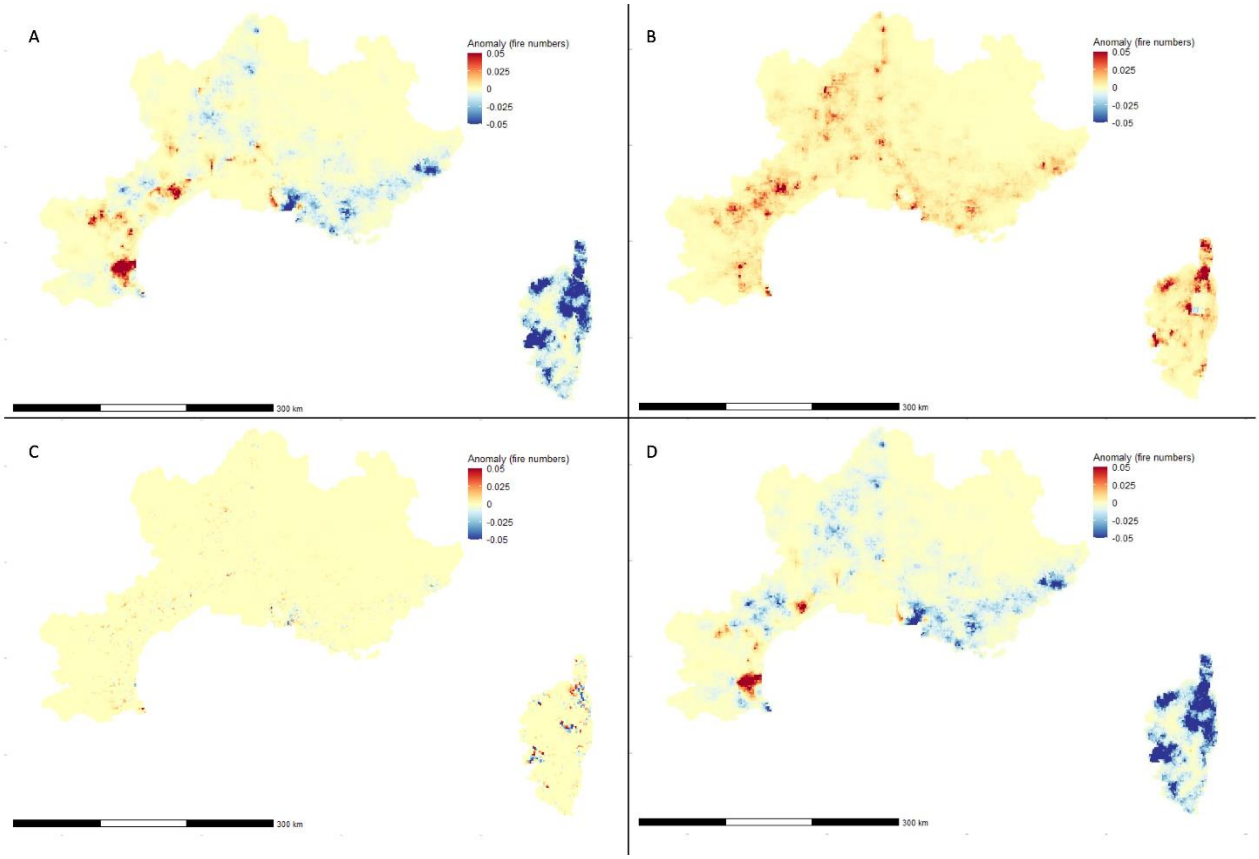

Figure 4. Spatial distribution of anomalies between the 1993-2002 and 2009-2018 decades for 1ha fire numbers. A: Real present. B: Fire-weather. C: LULC. D: Other temporal changes.

4. Conclusion

Analyzing factors of fire activities at regional scales is highly challenging. Our modeling framework and the simulation plan allowed to quantify important changes in fire activity and their drivers. We showed that usual explanatory variables (fire-weather, LULC) failed to explain the main temporal changes observed over recent decades, because of large unexplained factors. Among these unexplained factors, prevention and suppression policies affect the fire regime. Our study reveals that, if very significant reductions occurred after the 2003 heat wave on the number of escaped fires (1ha fires), no significant reduction could be detected over the last decade, neither on the ability of escaped fires to turn into large fires. Finally, spatial patterns of these changes were very contrasted from west to east, suggesting that significant reductions could be reached. Our framework might be extended to future scenarios involving climate, vegetation or human drivers

Keywords

Ecosystem multifunctionality, high severity, Mediterranean ecosystems, post-fire treatments, wildfires

Abstract

Wildfires are a widespread phenomenon in forests across the Mediterranean Basin but have increased in risk and severity in recent decades. Post-fire treatments are measures that help recover burned vegetation and their functionality but to what extent they also help recover soil functionality is currently unknown. The main objective of this study was to assess the effect of post-fire treatments on ecosystem multifunctionality after a large wildfire in the Cabrera mountain range in 2017 (NW Spain) where close to 10000 Ha of forest were burnt. At the end of 2017 and during 2018, the administration applied different post-fire treatments in high fire severity affected areas: i) straw mulching, ii) woody debris and iii) subsoiling and iv) mechanical hole afforestation. In each treatment, we established ten 2 x 2 m plots and ten adjacent untreated burned plots and collected a composite soil sample from each plot four years after the fire (2021). We calculated regulating services as the standardized mean of total soil organic C (climate regulation), soil water repellence (water regulation) and soil aggregation (soil protection). Supporting services were measured as the standardized mean of mineral N-NH4+ and N-NO3- and available P (soil fertility), β-glucosidase, urease and acid phosphatase (nutrient cycling) and microbial biomass (soil quality). Ecosystem multifunctionality was measured as the standardized mean of all functions measured. Application of straw mulch and woody debris increased regulating ecosystem services in relation to burned control plots. Afforestation with holes had no impact but subsoiling decreased regulating ecosystem services in relation to burned control plots. Post-fire treatments did not have any effect on supporting services. Straw mulch, Woody debris and afforestation with holes improved ecosystem multifunctionality when compared with subsoiling methods. These results show that post-fire stabilisation treatments, in particular straw mulching have a significant positive impact on regulating services and are effective measures in restoring the ecosystem multifunctionality, helping develop effective management based-decisions for the recovery of ecosystem services and functioning after large wildfires.

1. Introduction

Wildfires are a very common phenomenon in the Mediterranean Basin and have increased in severity in recent decades, a rise that is likely to continue in the future (Wagenbrenner et al., 2021). This is not only because of increased temperatures and drought with climate change (IPCC 2021) that is exacerbating wildfire conditions, but also because of socio-economic factors such as land use change and urban expansion that are also considered main drivers of increased fire severity and surface (Pausas et al., 2008). Increase fire severity is not only affecting vegetation composition and growth but also lead to the appearance of serious impacts on forest soils such as loss of soil quality, increased runoff, flooding and/or erosion (Fernández-García et al., 2021). All these changes are associated with a loss of important ecosystems functions and services that not only have a negative impact on rural populations but also for society as a whole. These has resulted in both the scientific community and government administrations being increasingly worried in evaluating and implementing measures that help mitigate wildfire impacts. In recent years, effective post-fire measures have been developed focusing on stabilising the burnt area to prevent further additional damage to essential resources such as water supply systems or human infrastructures and critical habitats for protected species (e.g. straw mulching to prevent soil

erosion). These measures need to be implemented as soon as possible after the fire to avoid potential damaging effects of rain events as their effectiveness in preventing soil erosion is high (Fernández and Vega, 2016). In other cases, post-fire treatments are implemented to assist and facilitate the recovery of the damaged ecosystem after the wildfire (e.g. vegetation afforestation). This type of treatments is usually applied in areas degraded by repeated fires that prevent the natural regeneration of vegetation (García-Matallana et al., 2022).

Many studies have evaluated the effectiveness of these practices on individual ecosystem properties in soil (erosion, runoff…) (Gómez-Rey et al., 2013; Prats et al., 2021) and vegetation (species richness, vegetation cover...) (Duniway et al., 2015; García-Matallana et al., 2022) but ecosystems provide multiple functions and services at the same time (ecosystem multifunctionality *sensu* Garland et al., 2020). Ecosystem multifunctionality could be considered as the ability of an ecosystem to supply multiple ecosystem functions and services increasing the benefits that societies can be obtain from an ecosystem (Hölting et al., 2019; Liu et al., 2021). However, the influence of these post-fire treatments on the provision of multiple ecosystem services and the recovery of the ecosystem multifunctionality (EMF) has not, to our knowledge, yet been analyzed (Taboada et al., 2021). As a soil contribute to a range of ecosystem services, in this study we focused on a set of ecosystem indicators that are relevant to a successful recovery and functioning of the ecosystem. Soil plays an important role as a carbon sink helping to favour infiltration and mitigate erosion and contributing to the development to microbial community. Therefore, our main objective was to evaluate the medium-term impact of four post-fire treatments (straw mulching, woody debris, afforestation with mechanical hole and afforestation with subsoiling) on ecosystem services and ecosystem multifunctionality after a large wildfire in Northwest Spain

2. Material and methods

The study area is located in the Cabrera mountain range, León province (NW Spain) where a large wildfire burned close to 10000 Ha of forests and scrub dominated areas in 2017 (Fig. 1). The burnt area was dominated by *Quercus pyrenaica* Willd forests and *Pinus sylvestris* L. afforestations (3480 Ha), different scrub formations dominated by *Genista hystrix* Lange, *Erica australis* L., and *Cytisus scoparius* (L.) Link (5440 Ha) and Mediterranean grasslands (580 Ha). The fire was intentionally set and the adverse weather conditions at the time, with maximum temperatures of 35ºC, a 35% relative humidity in combination with two months of drought prior to the fire increased its virulence and facilitated its spread. The climate in the area is Mediterranean with dry temperate summers with mean annual temperatures of 9ºC and mean annual precipitation of 700-800 mm (Iberian Climate Atlas, 2011) The orography is heterogeneous with altitudes ranging from 836 to 1938 m.a.s.l. Soils are acidic (pH ~5), with slates, sandstones, and quartzites from the Ordovician period as the predominant type of rocks (Huerta et al., 2020).

At the end of 2017 and during 2018, the regional government administration implemented a series of post-fire actions aimed at protecting the soil in the most affected and steeper areas and facilitate the recovery of vegetation. These included: (1) addition of straw mulching and (2) woody debris with the aim to protect soil and, (3) subsoiling and (4) mechanical hole afforestation in the steeper areas (Fig.1). In each treatment, ten 2 x 2 m plots and ten adjacent untreated burned plots were established during 2018. In summer 2021, we collected 4 randomly selected soil samples within the 2 x 2 m plots using an auger (7 cm diameter x 3 cm depth) that were pooled together in a composite sample for each plot. Half of the sample was air dried and sieved (<2 mm) to analyse chemical and physical properties and half frozen (-18ºC) to determine soil $N\text{-}NO^{-3}$ and $N\text{-}NH^{+4}$ and microbial biomass an activity. Total organic carbon (TOC) was determined following the combustion method (Dumas 1831), using a EuroVector EA3000 elemental analyser and available P was measured at 882 nm wavelength after digestion with HClO4 (Olsen et al. 1954). We measured weight diameter (MWD) to determine the average size of stable aggregates (Kemper and Rosenau 1986) and we used the water drop penetration test (WDPT) was used to determine soil water repellency (WR) (Doerr, 1998). Ammonium (N-NH4+) and nitrate (N-NO3-) were extracted with 2M KCl at a 1:10 soil-extractant ratio (Keeney and Nelson 1982) and measured by distillation with an automatic micro-Kjeldhal analyzer (Bremner 1965). β-glucosidase (β-D-glucoside glucohydrolase) and acid phosphatase (phosphate-monoester phosphohydrolase) activities were analysed following Tabatabai (1994) and urease (urea amidohydrolase) activity following Kandeler and Gerber (1988). Microbial biomass C was determined by the fumigation-extraction method (Vance et al., 1987).

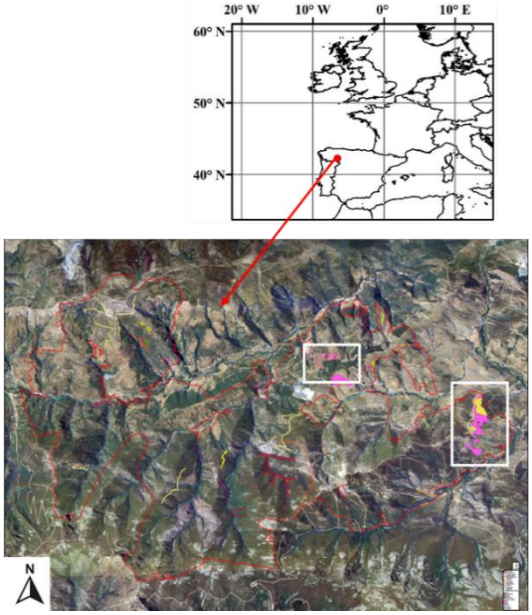

Figure 1- Post-fire treatments (yellow and pink) within the perimeter (red) of Cabrera wildfire which occurred in 2017.

Each of these variables was assigned to a regulating or supporting ecosystem service following Gardlan et al (2020). Regulating ecosystem services indicators were TOC for climate regulation, soil water repellence for water regulation and MWD for erosion protection. Supporting ecosystem services indicators were $N\text{-}NH_4^+$ and $N\text{-}NO_3^-$ for soil fertility, β-glucosidase, urease and acid phosphatase for nutrient cycling and microbial C biomass for soil quality. We then calculated a standardized value of regulating and supporting services as the average value of the standardized (between 0-1) corresponding variables. Similarly, ecosystem multifunctionality was calculated as the average standardized values of regulating and supporting ecosystem services.

In order to test differences in provisioning of regulating and supporting ecosystem services between post-fire treatments and unburned controls we used one-way analysis of variance (ANOVA) or nonparametric Kruskal-Wallis test when assumptions for ANOVA were not met. One-way ANOVA was used to compare differences in the recovering of ecosystem multifunctionality between post-fire treatments. Analyses were performed with PAST 4.01 (Hammer et al., 2001).

3. Results and discussion

Post-fire treatments aimed at protecting soil (straw mulch and woody debris) improved the ability of the soil to provision regulating ecosystem services (Fig 2). After a high severity fire, high temperatures in the soil reduced soil organic matter content affecting other related properties such as soil aggregate stability (Fernández-García et al., 2019) and water repellence (Marcos et al., 2018). In our study, both straw mulching and addition of woody debris increased TOC and improved the soil structure by increasing the size of the aggregates in the mid-term whereas soil water repellence was only improved where woody debris was added. Short-term studies found no effect of similar stabilisation treatments on soil quality after 16 weeks (Díaz-Raviña et al. 2012) but our results indicate that they can have an impact in the mid-long term. On the other hand, subsoiling afforestation did not have this beneficial effect in regulating ecosystem services although, individually, it reduced soil water repellence. When afforestation was done mechanically with a hole, the impact in regulating ecosystem services was negative because it did not improve any of the indicators analysed. Similar results were found by Mongil Manso and Bengoa Martínez de Mandojana (1997) that found 20% greater soil moisture in plots that were subsoiled than in plots that had been hollowed, as subsoiling favours soil physical properties related with hydrological processes (Fig. 2).

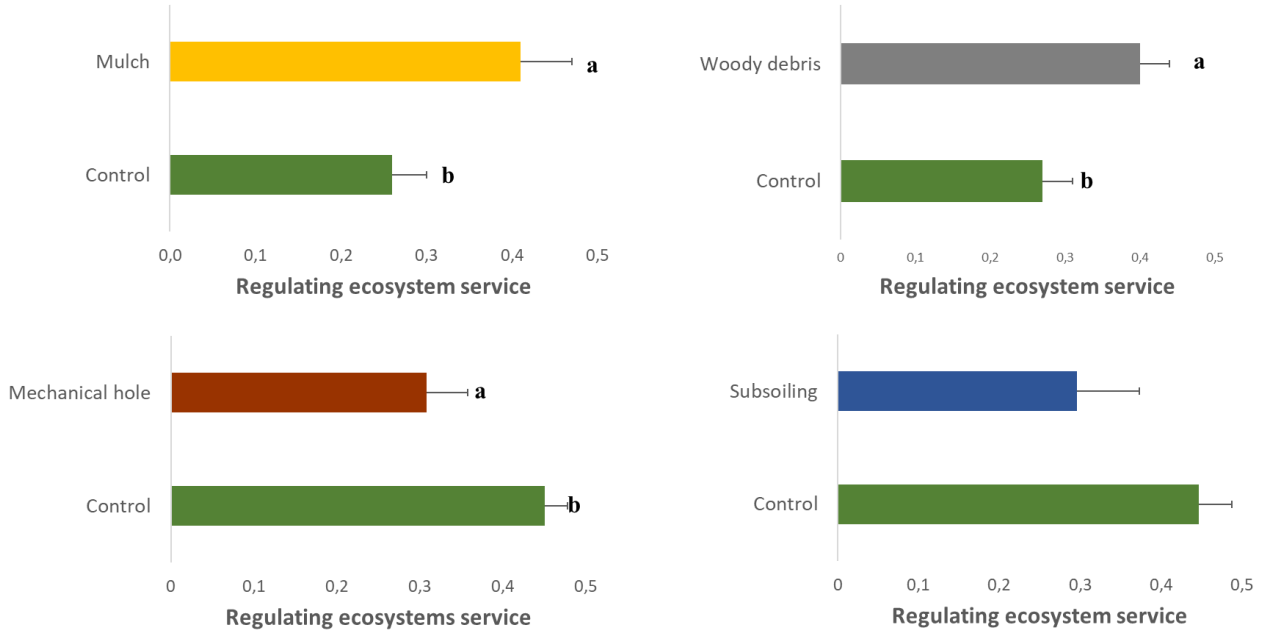

Figure 2. Regulating ecosystem services (Mean and standard error) for post-fire treatments (mulch, woody debris, mechanical hole and subsoiling) and their respective burned controls. Different letters show significant differences at $p < 0.05$.

Supporting ecosystem services were not significantly affected by post-fire treatments and only a slight tendency to improve this service was observed when straw mulching was applied (0.38 in treated plots vs. 0.29 in control plots). Straw mulching tends to improve soil nutrient concentrations (P and N), microbial C biomass and increased enzymatic activities, while in the other post-fire treatments results were not as consistent (e.g. enzyme activities were increased with addition of woody debris and soil microbial C biomass was increased under mechanical hole and subsoiling afforestation treatments). If we compare all treatments together, we observed that those aimed at protecting soil in the short-term were the most effective in facilitating the recovery of the multifunctionality of ecosystems in the mid-term (Fig.3).

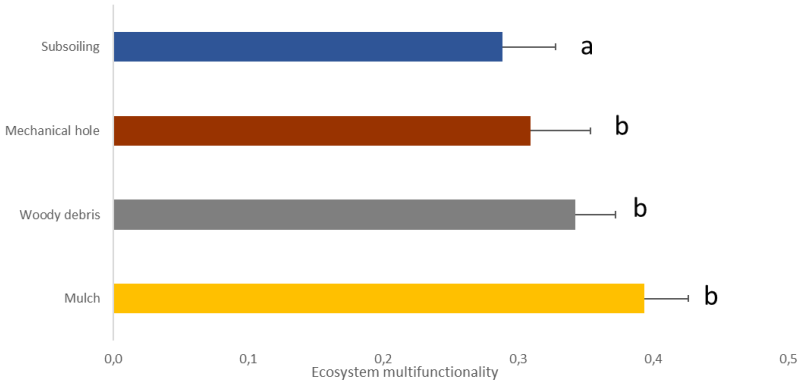

Figure 3. Average value and standard error of ecosystem multifunctionality for each post-fire treatment: mulch, woody debris, mechanical hole and subsoiling. Different letters show the presence of significant differences ($p < 0.05$) among post-fire treatments.

4. Conclusions

This study shows that post-fire stabilisation treatments, and in particular straw mulching, are effective in restoring ecosystem multifunctionality (EMF). These treatments had a significant positive impact on regulating services which may help reduce local and global impacts after a wildfire. However, afforestation with subsoiling or mechanical hole had a negative effect on the recovery of ecosystems functions so these measures are not

recommended with we aim at recovering ecosystem functionality. This type of studies is essential in order to make decisions focused on the recovery of functions and services that are strongly impacted by large wildfires.

Abstract

Smouldering spread of peat fires has been studied by numerous researchers. Experimental work was performed to study the impact of peat layer thickness on horizontal smouldering spread behaviour. The thickness of the peat layer was varied 2 cm, 3 cm, and 4 cm peat thickness. A 3 cm-long coil heater was placed in the centre of the base. For ignition protocol, the coil heater was powered with 100 W of electricity for the first 60 minutes. Smouldering behaviour was observed by the temperature data, that measured using thermocouples and a thermal camera. The thickness of the peat layer and bulk density play important roles in the horizontal spread probability, as it changes the heat balance between the heat generation at the reaction zone and heat loss to the environment. Higher peak temperature was observed for peat 4 cm depth and then decreased by the thickness. The smoldering spread rate increases by peat thickness from 2.01 cm/h to 2.21 cm/h and then reach an asymptotic level. Extinction corresponds to a negative energy balance observed in thickness 2 cm of peat. A self-sustained smoldering front could not be maintained after the igniter was turned off.

1. Introduction

Peat fires remain a serious environmental problem on a global scale (Stracher *et al*. 2015). It releases a large amount of carbon into the atmosphere and causes significant damage to peatland ecology and the landscape (Usup *et al.* 2004). When ignited, peat fires can produce a thick smoke that reduces visibility and causes several health problems. Reduction of peat fire probability has been a high priority through peatland restoration and better early warning systems for the development of fire hotspots.

Peat is a transitional organic soil from plant matter to coal with a high carbon content (Roy *et al.* 1983), consisting of a porous structure that causes smouldering combustion dominated when it burns (Rein 2009). Smouldering combustion is a phenomenon with low temperature and slow propagation characteristics. Ohlemiller (2002) and Rein *et al.* (2009) explained in general that smouldering has four stages while it is spreading: the preheat zone, the evaporation zone, the decomposition zone, and the char-oxidation zone. Zanoni et al. (2018) pointed out that all phenomena in smouldering combustion affect the burning object's energy balance, suggesting a local and global energy balance (Zanoni *et al.* 2018). For the smouldering experiment, the energy balance could be represented by the flow of $\dot{E}in$ as the energy provided by the heater; $\dot{E}oxid$ as the energy released by the oxidation process; $\dot{E}pyr$ as the energy absorbed by the pyrolysis process; $\dot{E}evp$ as the energy absorbed by the water evaporation process; $\dot{E}out$ as the energy removed by the convective gas flow out; and, $\dot{E}loss$ as the energy removed by radial heat loss. Therefore, the net energy rate is:

$$\dot{E}net = \dot{E}in + \dot{E}oxid + \dot{E}pyr + \dot{E}evp + \dot{E}out + \dot{E}loss \quad (1)$$

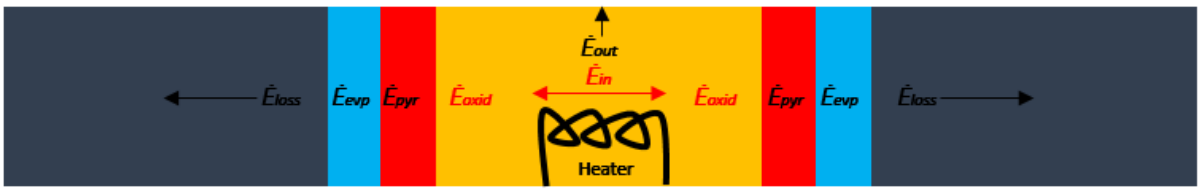

Figure 1- Conceptual model of Horizontal Smouldering Spread

Several studies have been reported before, that includes the upward and downward peat smouldering (Huang and Rein 2018) and the investigation of smouldering combustion propagation of dried peat (Palamba *et al.* 2017). In another work, the results of a modelling work by Huang and Rein (Huang and Rein 2015) reveal that smouldering combustion can spread over peat layers with very high moisture content (>250%) if the layer is thin and located below a thick drier layer. Christensen et al. (Christensen *et al.* 2020) was conducted a novel approach combining lateral and in-depth spread rates as vector components. The questions arise regarding the influence of peat layer thickness from one area to another. This is a challenge whether ignition can occur on peat with different thicknesses. In its natural stage, even though the peat layer is deep and covered by water, as soon as the rainy season is over, the draining process in the upper layer of the peat (1-5 cm) may create a dry surface that is vulnerable to catch fire. In addition, it is still rarely found research that discusses the spread that occurs horizontally on thin layers of tropical peat. This study extends earlier work on the horizontal smouldering spread of a peat sample from Papua, Indonesia (Putra *et al*. 2020). Samples and methods were changed so that the impact of density and peat structure on the phenomenon could be better explained.

2. Experimental Methods

2.1. Peat sample preparations

The peat samples came from the Palangka Raya, Indonesia, with coordinates N: 02°17'21.5412"; E: 114°1'58.492", and called PKY. The results of the Proximate and Ultimate (Table 1), are used to find out the difference in the physical characteristics and chemical components that affect the combustion process. Higher volatile matter, oxygen concentration, and lower bulk density could accelerate the smouldering spread, while ash content and moisture content tend to slow down the smouldering spread. A higher calorific value could produce greater heat energy when the sample is burned.

The PKY was dried in an electric oven at 100 ℃ within 24 hours until the peat samples' moisture was ~ 8%. Scanning electron microscope tests are also carried out to determine the structure and pore sizes of the peat samples. Figure 2b shows that the pore size for PKY is approximately 2.5 μm. This porosity value can affect the drying and combustion reaction processes.

Table 1- Proximate and Ultimate Analysis of Peat Samples

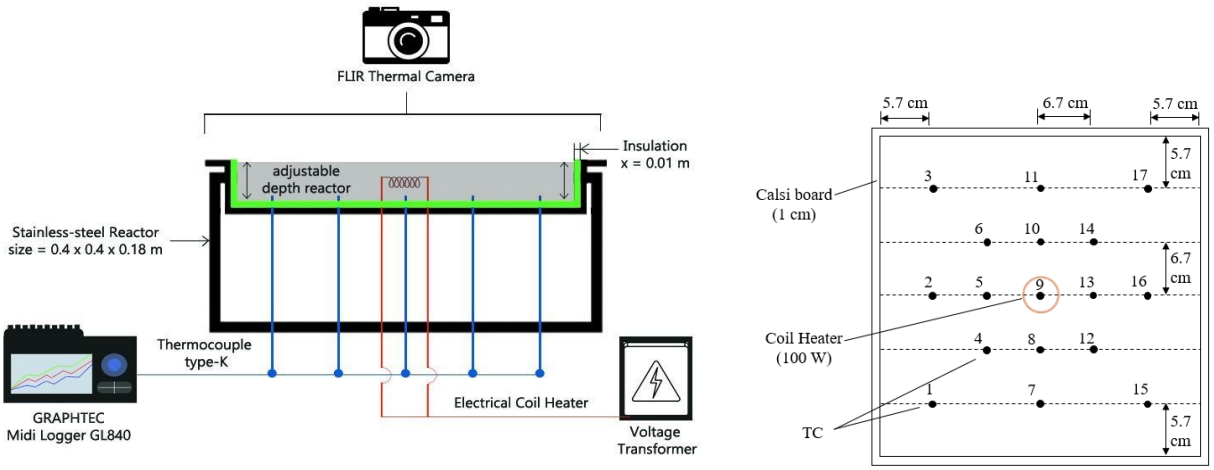
Proximate Analysis		Ultimate Analysis	
Initial Moisture (%)	69.20	C (%)	57.43
Moisture in as-dry based (%)	8.20	H (%)	4.80
Ash (%)	7.50	N (%)	1.10
Volatile Matter (%)	49.80	O (%)	29.01
Fixed Carbon (%)	34.50	Total Sulphur (%)	0.10
Gross Calorific Value (MJ/kg)	4930	Bulk Density (kg/m^3)	360

(a) (b)

Figure 2- (a) PKY before the combustion process, (b) Scanning electron microscope result of PKY.

2.2. Smouldering experiments procedure

The adjustable reactor was developed to conduct the smouldering experiment. It is made of stainless steel measuring 40 × 40 cm isolated by 10 mm thick calcium-silicate board insulation around the reactor side and on the bottom of the reactor. The reactor was designed with an adjustable base so that it can be used for a variety of peat thicknesses. This work investigated the horizontal spread on 4 cm, 3 cm, and 2 cm peat layer thickness. For the ignition protocol, a three cm-long coil heat igniter was placed at the centre of the base and was powered with 100 W of electricity for 60 min. This ignition protocol follows previous work (Putra *et al*. 2020). After the igniter was turned off, the combustion process was self-sustaining smouldering. The seventeen thermocouples (Figure 3b) were inserted from the bottom side and measured using a Graphtec GL840 data logger. The thermocouple tip was located at a depth of 1 cm from the reactor base. The peat samples' mass was weighed before and after the experiment to determine the mass reduction caused by combustion. The experiments were repeated twice on each peat thickness.



(a) (b)

Figure 3- Experimental setup. (a) Device arrangement, (b) Thermocouple arrays.

2.3. Image Analysis Tools

The thermal camera used in this experiment was a FLIR A35x with a resolution of 320 x 256 pixels, temperature range from 50 ˚C to 550 ˚C with accuracy ± 5 ˚C or 5% of reading. The images were taken every 10 minutes after the ignition started. The infrared camera was placed at a distance of 100 cm with angles of 20˚ from the

peat surface to avoid getting too hot from the burning peat. The images obtained from thermal cameras represented the temperature that occurred on the peat surface. In general, every image consists of RGB colour in its pixels. These three colour component combinations will create a specific colour for its pixel. To determine the value of spread rate, two pictures with different time taken were compared. To do this image processing needs to be done on thermal images. Many authors have suggested this method for different scales of application (Stracher *et al.* 2015, Putra *et al.* 2020, Burke *et al*. 2019, Bhattacharjee *et al.* 2017, Christensen *et al.* 2018).

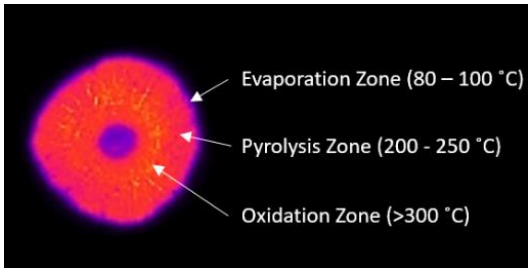


Figure 4- Different zones when the peat combustion process occurs

3. Results and Discussion

3.1. Infrared Images Results

Smouldering on peat with a thickness of 4 cm and 3 cm managed to spread to the side of the reactor, while peat with a thickness of 2 cm failed to sustained-smouldering because it went out shortly after the igniter was turned off. Smouldering fire on peat with a thickness of 4 cm has high sustainability. These caused by the heat generated by the peat fire is higher than heat loss to the environment and to the peat itself for the drying process and pyrolysis process. Therefore the smouldering process will continue until the heat generated could not equilibrate the heat loss. On the thinner thickness of 2 cm on PKY shown in Figure 5c, the smouldering fire did not sustain after the igniter was turned off. This proves that the heat generated by the peat is smaller than the heat loss to the environment (Huang and Rein 2018). This process also happened on Papua peat with a thickness of 2 cm from previous work (Putra *et al.* 2020).

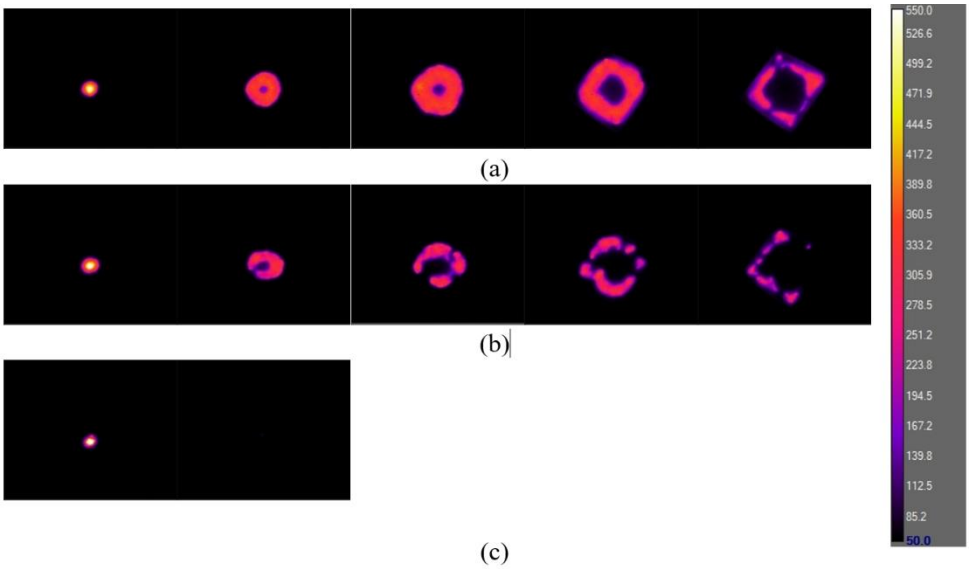

Figure 5- Horizontal Smouldering Spread from PKY Peat: (a) 4 cm thickness, (b) 3 cm thickness, (c) 2 cm thickness. The time between each picture is 2 hours.

3.2. Temperature Profile of Smouldering Peat

Differences were also found in the results of temperature measurements obtained from thermocouple measurements (Figure 6). Moreover, the difference in bulk density and homogeneity can be explained by Figure 7. In this case, peat samples were sieved using a 6 mm wire mesh size. With the sieving process, it is expected that peat approaches closer to more homogeneous conditions in terms of peat grain size. The first sieved peat

shows a more regular temperature pattern compared to the un-sieved one. The regularity of this pattern is also seen in images captured by infrared cameras (Figure 8), where the sieved peat has better homogeneity so that the distribution of heat also occurs more evenly. Different peat grain sizes cause cavities in several areas in the reactor, making a difference in oxygen supply so that the spread becomes less consistent. Whereas on peat that is not sieved, its distribution is often irregular. Sometimes, it suddenly experiences a drastic increase in temperature while in an area with a better fuel and oxygen supply mixture. Peak temperature also differs between sieved and un-sieved peat samples. This is due to the sieved peat sample having a higher bulk density so that the surface area of the peat that experiences a combustion reaction is also greater, causing a higher peak temperature. Table 4 shows the bulk density values of the sieved and un-sieved peat samples used in this study. There are significant differences in the bulk density values of the two peat samples. For un-sieved peat samples, the average bulk density used for the experiment is 278.79 ± 1.4 kg/m^3. After the sieving process, the average bulk density was increased to 299 ± 4.4 kg/m^3. The difference in bulk density values can be seen visibly from peat after being drained, whereas the un-sieved peat tends to be more porous compared to the sieved peat. Lower bulk density causes a faster spread of horizontal smouldering. The cavity between macros between one and another provides a pathway for oxygen to enter, thus accelerating the combustion reaction rate.

Figure 8- Differences in visualization results from surface textures captured by infrared cameras, (a) un-sieved peat samples, (b) sieved peat samples

Table 2- Bulk Density difference between sieved and un-sieved peat

Peat Sample	Preparation	Bulk Density (kg/m^3)
PKY	Un-sieved	278.79 ± 1.4
	Sieved	299 ± 4.4

3.3. Spread Analysis

The smouldering spread from PKY on each thickness can be seen in Figure 9. It can be seen that an increase in the speed of smouldering spreads with increasing thickness of the layer, but the increment is slowly decreasing when a certain thickness level. As the thickness of the peat layer decreases, it increases the surface to volume ratio (Rein 2009). Thus, in a negative energy balance, the heat generated by the combustion process cannot overcome the heat loss released to the environment. This causes the peat to burn to the extinction process. Smouldering combustion fails to survive on peat with layer thickness as thick as 2 cm where the spread of smouldering only lasts shortly after the heater is turned off. The heterogeneous nature of peat causes its smouldering speed to vary. The average smouldering spread rate for PKY includes 2.01 cm/h for 3 cm thick peat and 2.21 cm/h for 4 cm thick peat. In separate experiments, the horizontal smouldering spread rate was found to be about 2.82 cm/h using a 10 cm depth reactor and 2.91 cm/h using an 18 cm depth reactor (Putra *et al.* 2020).

$$v_r = \frac{s_{0\to n}}{\Delta t_{0\to n}} \quad (2)$$

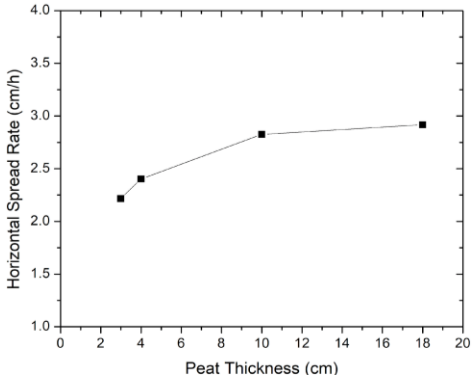

Figure 9- Horizontal spread rate of PKY Peat

4. Conclusion

Self-sustained smouldering depends on a positive energy balance between heat generation due to oxidation reaction and heat loss to the environment. The adjustable reactor used in this experiment was varied to represent 4 cm, 3 cm, and 2 cm peat layer thickness. The thickness and the bulk density of the peat layer play important

roles on the horizontal spread probability, as it changes the heat balance between the heat generation at the reaction zone and heat loss to the environment. The smouldering spread rate increases by peat thickness from 2.01 cm/h to 2.21 cm/h and then reaches an asymptotic level. Extinction corresponds to a negative energy balance that was observed in 2 cm peat layer thickness in which a self-sustained smouldering front could not be maintained after the igniter was turned off.

Keywords

Extreme fire behaviour, vector wind change, complex terrain, fire weather index

Abstract

Wildfire spread is influenced significantly by weather fluctuations. Specifically, wind speed and direction change can drastically alter fire intensity and spread. Vector wind change can result from synoptic or mesoscale weather systems and small-scale meteorological processes, such as thermal circulations and low-level wind shear in complex terrain. These small-scale processes are usually underrepresented in numerical weather forecasting models, usually needing to be resolved by more expensive sub-kilometre grid resolution simulations. Recent New Zealand wildfires, such as 2017 Port Hills and 2019 Pigeon Valley wildfires, experienced wind change due to local sea breezes and strong nocturnal downslopes flows, exacerbating fire behaviour.

The aim of this research is to investigate if vector wind change (VWC) can be a metric to better represent the effect of mesoscale and microscale weather and the subsequent impact in extreme fire behavior. This was achieved utilizing hourly VWC, or the difference in magnitude of the hourly wind vectors, from the Fire and Emergency New Zealand (FENZ) national network of more than 200 weather monitoring stations. An additional variable, wind direction change (WDC), was also calculated to include the degree change of wind direction.

To identify high-risk stations, the top 20% of stations for VWC and WDC were calculated and investigated spatially across the New Zealand landscape. The high-risk stations are located primarily on the South Island, inland and in areas of complex terrain. There is little to no variation of these stations when mapped in each synoptic type, suggesting that the main factor in determining high VWC and WDC is meso and microscale terrain driven meteorology as opposed to larger synoptic regimes. Critically, the current fire risk metric, the Fire Weather Index, does not include wind direction changes at high windspeeds. Therefore, the inclusion of VWC and WDC as additional metrics in fire risk calculations could increase operational understanding of high-risk locations and terrain impacts on extreme and unpredictable fire behavior.

1. Introduction

1.1. Critical Fire Weather

Wildfire behavior is highly dependent on near-surface meteorological conditions such as …"the atmospheric conditions that encourage extreme fire behavior resulting in large and destructive wildland fires." (Werth et al., 2016). Wildfire danger increases with low atmospheric humidity, strong winds, drought, and unstable air conditions (Mills et al., 2020) (Harris et al., 2017). These elements are not simply a sum—they are intertwined and dependent on the other and have a significant impact on extreme and unpredictable fire behavior.

In complex terrain, wildfire behavior can be influenced by dynamically and thermally driven wind systems (Werth et al., 2016). A dynamically driven wind is channeled, directed and amplified by the topography, while thermally driven wind systems are driven by differences in heat flux. New Zealand's complex terrain, including mountain ranges, valley systems and the complex coastal topography, means that near-surface wind systems are a critical variable to understand to better predict wildfire danger (Hilton et al., 2015; Dong et al., 2021).

1.2. Wildfire in New Zealand

Until the last 5 years, large scale wildfires were an infrequent occurrence in New Zealand. However, like many countries around the world, wildfires are increasing in size and frequency with warmer and drier weather

(Langer & Wegner, 2018). These fires are also increasingly encroaching on urban spaces. This trend is illustrated in the recent 2017 Port Hills fire, 2019 Pigeon Valley and the 2020 Ohau fire in New Zealand. All three fires prompted evacuations of residents for multiple days and destroyed residential structures (AFAC, 2017, 2019; Foley, 2020)

To predict fire risk around New Zealand, Fire and Emergency New Zealand (FENZ) and the National Institute of Water and Atmospheric Research (NIWA) collect hourly weather data from over 250 stations. From this weather station data, the Fire Weather Index (FWI) is calculated based on fuel type, temperature, relative humidity, windspeed and precipitation (Mandal et al., 2021; Van Wagner, 1987). The FWI combines individual markers of fire risk, including the Initial Index Spread and Buildup Index, which are combined to give a more comprehensive evaluation of fire risk (Van Wagner, 1987).

1.3. Vector Wind Change

Wind change is an important variable in fire behavior and can drastically alter the fire direction and intensity (Mills et al., 2020). Wind change can occur at time scales of minutes to hours. Many firefighter entrapments are caused by sudden wind changes, happening within a few minutes, and is defined by the metric Vector Wind Change (VWC), or the difference in magnitude of the hourly wind vectors. Two recent wildfires in New Zealand illustrate the significance of understanding VWC for fire behavior; the 2017 Port Hills and 2019 Pigeon Valley experienced a wind direction change due to local sea breezes and strong nocturnal downslopes flows that exacerbated unpredictable fire behavior (Pretorius et al., 2020). Critically, the current fire risk prediction tool the FWI, does not account for wind direction changes and therefore misses critical meteorological and climatological information for predicting and understanding wildfire danger across complex terrain. This research presents an investigation into VWC in New Zealand, and how VWC can be utilized as an additional metric for predicting wildfire risk.

2. Methods

Observations from the Fire Emergency New Zealand (FENZ) weather stations were gathered using the open access data from the Envlib Modeling Consortium using the Tethysis API in Python (Kitteridge, 2021; New Zealand Modeling Consortium Open Environmental Digital Library, 2021). Stations with a complete time series between November 28th 2020 - November 28th 2021 (130 stations) were included. Meteorological data was logged as sub-hourly intervals, between 10 and 50 minutes, but are presented as hourly averages in the database. Vector Wind Change (VWC) was calculated using the hourly wind vector observations. While VWC does account for impact from both windspeed and wind direction changes, it does not clarify the change in wind direction measured in degrees. Therefore, an additional metric, hourly Wind Direction Change (WDC), was compiled for each station to give a more complete understanding of the wind changes at each of the 130 stations. WDC was calculated hourly using the modified degree range of -180 to 180 degrees. VWC is then averaged for each station over the yearlong period. For wind direction change, the kurtosis of the distribution is calculated to quantify the differences between the tails of distribution amongst stations the data. A high kurtosis value corresponds to light tails, indicating small hourly wind direction change.

To determine the highest risk stations, the top 20% of stations for VWC and WDC were identified, and stations present in both the top VWC and WDC were labeled as “high risk”. Stations were also analyzed with Kidson synoptic regime classifications, are based on the original 12 Kidson regimes, which are further split into three main groups based on overall pressure systems: Trough, Zonal, and Blocking. and are labeled with letters describing the pressure system and location (Kidson, 1999). VWC and WDC are further investigated within each synoptic regime in the year of data (Renwick, 2021). The Fire Weather Index (FWI) is calculated daily using the wind speed, temperature, relative humidity and precipitation at each of the 130 stations with a complete year of data. The FWI value was then averaged for each station over the same yearlong period as the VWC.

3. Results and Discussion

3.1. VWC and WDC for a Canterbury Case Study

In the Canterbury region, and out of the 130 stations, the Hakatere station had the highest values for both VWC and WDC indicating that there are both high windspeeds as well as significant wind direction change at high

windspeed (Figure 1A). Given that critical fire weather conditions become more important for both high windspeeds as well as frequent wind direction changes, this suggests that the region around the Hakatere station is likely to experience more wildfire behavior unpredictability in the event of wildfire than the other station locations in Canterbury. In comparison, Godley Head has a low WDC at high windspeed, and therefore experiences more consistent winds, with low hourly changes and a predictable direction. This is likely due to the graduation change of the sea breeze cycle at the coastal location, as compared with the complex topographic influenced meteorology at the Hakatere location (Figure 1B).

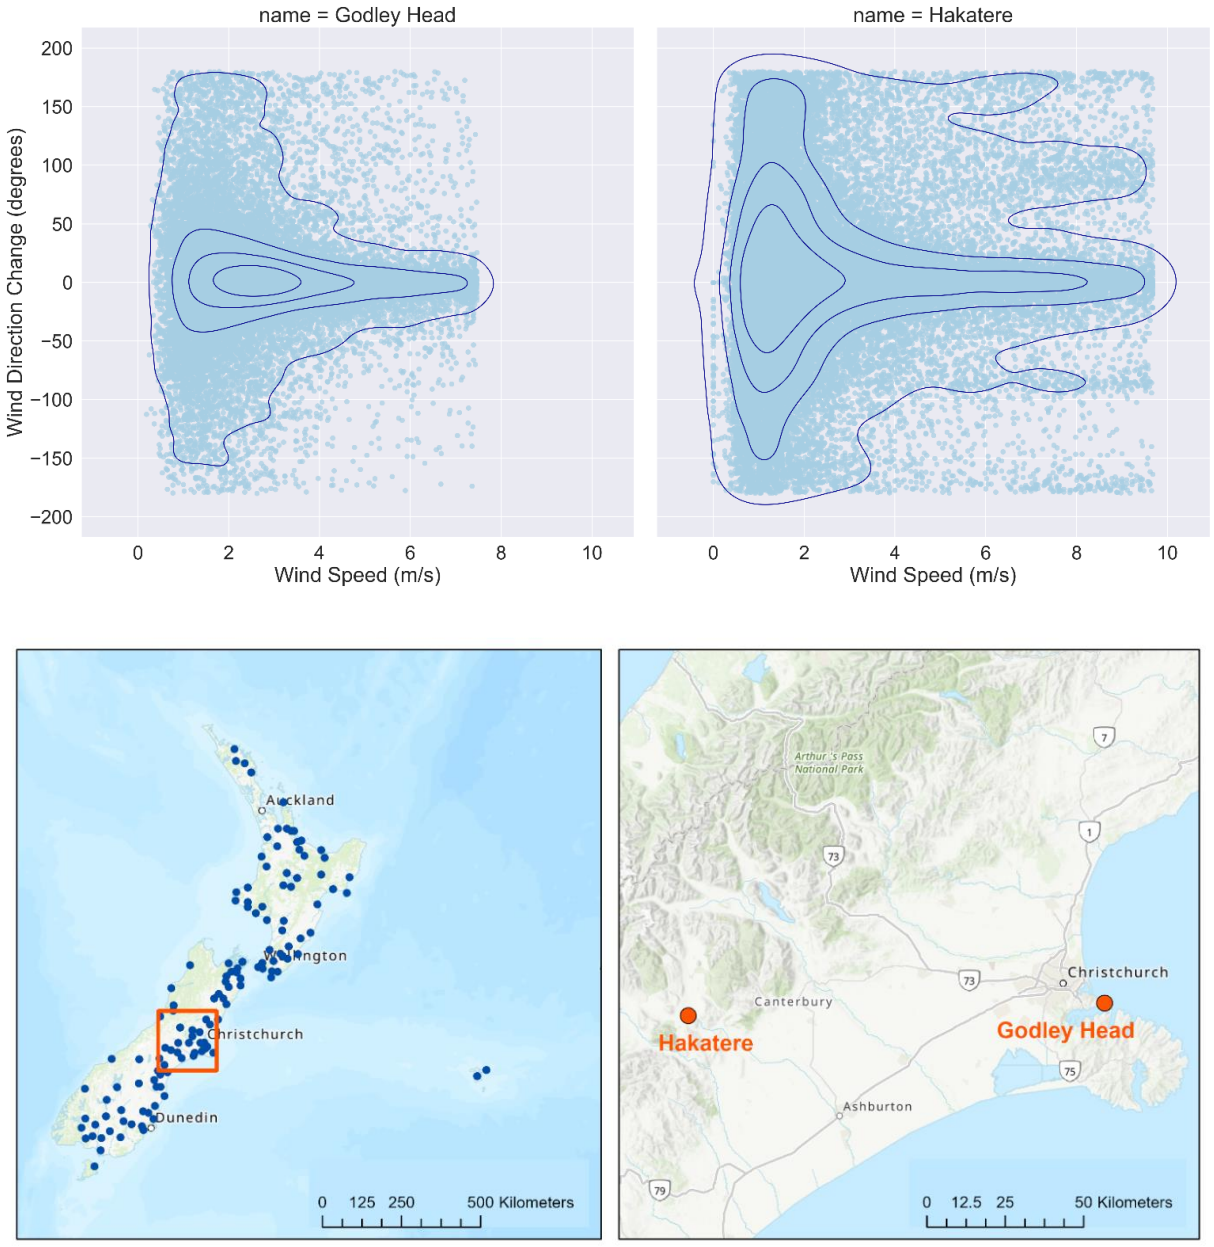

Figure 1- A) Highest and lowest windspeed kurtosis stations in Canterbury, with hourly wind speed plotted against wind direction change. B) Location of national stations, and Hakatere & Godley Head in Canterbury.

3.2. Nationwide wind change distributions

A nationwide analysis of stations shows distinct regional and topographic trends. High-risk stations (Figure 2, red) are located almost exclusively on the South Island, with one exception north of Wellington. Furthermore, all of these stations are located in areas of complex terrain and are not coastal. Similar to the trend in the Canterbury stations, stations in locations of complex terrain, such as the Southern Alps, have high VWC and WDC. This suggests that in New Zealand, there is a correlation between terrain complexity and wind vector

and direction change, and therefore a potential trend to better predict fire spread. The locations with high VWC and low WDC (Figure 2, orange) are still a high risk for critical fire weather with high windspeeds, however do not exhibit as significant wind changes at high speeds. The stations with both low VWC and low WDC (Figure 2, green) are located on the North Island and the Chatham Islands. This suggests costal stations and stations on flat terrain exhibit more consistent wind and wind direction leading to lower VWC and WDC. This is likely due to the more predictable sea breeze cycle.

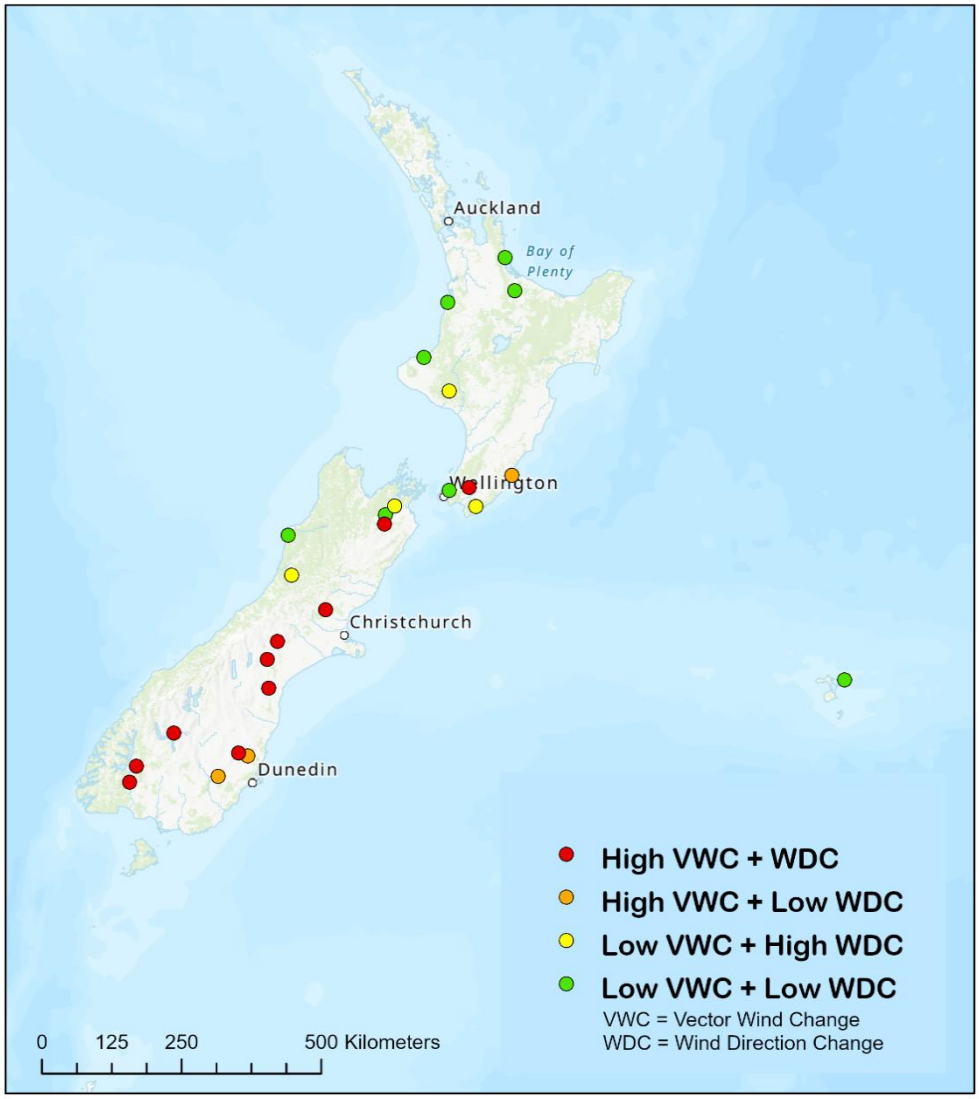

Figure 2- National Stations, highest or lowest 20% of VWC or WDC (based on mean and kurtosis respectively).

3.3. Synoptic Type Impact on Wind Change

In order to better understand the variables affecting VWC and WDC across New Zealand, a synoptic regime analysis was applied to investigate spatial pattern changes of high-risk stations in regard to weather systems. There is some variation between synoptic regimes in the stations identified, however the overall trend is consistent. High-risk stations appear almost exclusively on the South Island, except for a station near Wellington and one in the Central North Island (Figure 3). There are several stations that appear in almost all synoptic types, located in Fiordland, mountainous Canterbury and the top of the South Island. This uniformity in stations with VWC and WDC across synoptic types can suggest that the primary factor in these variables is terrain, not synoptic weather. Therefore, it is likely that some locations in New Zealand are at a higher risk of extreme fire behavior regardless of synoptic type due primarily to location and proximity to complex terrain.

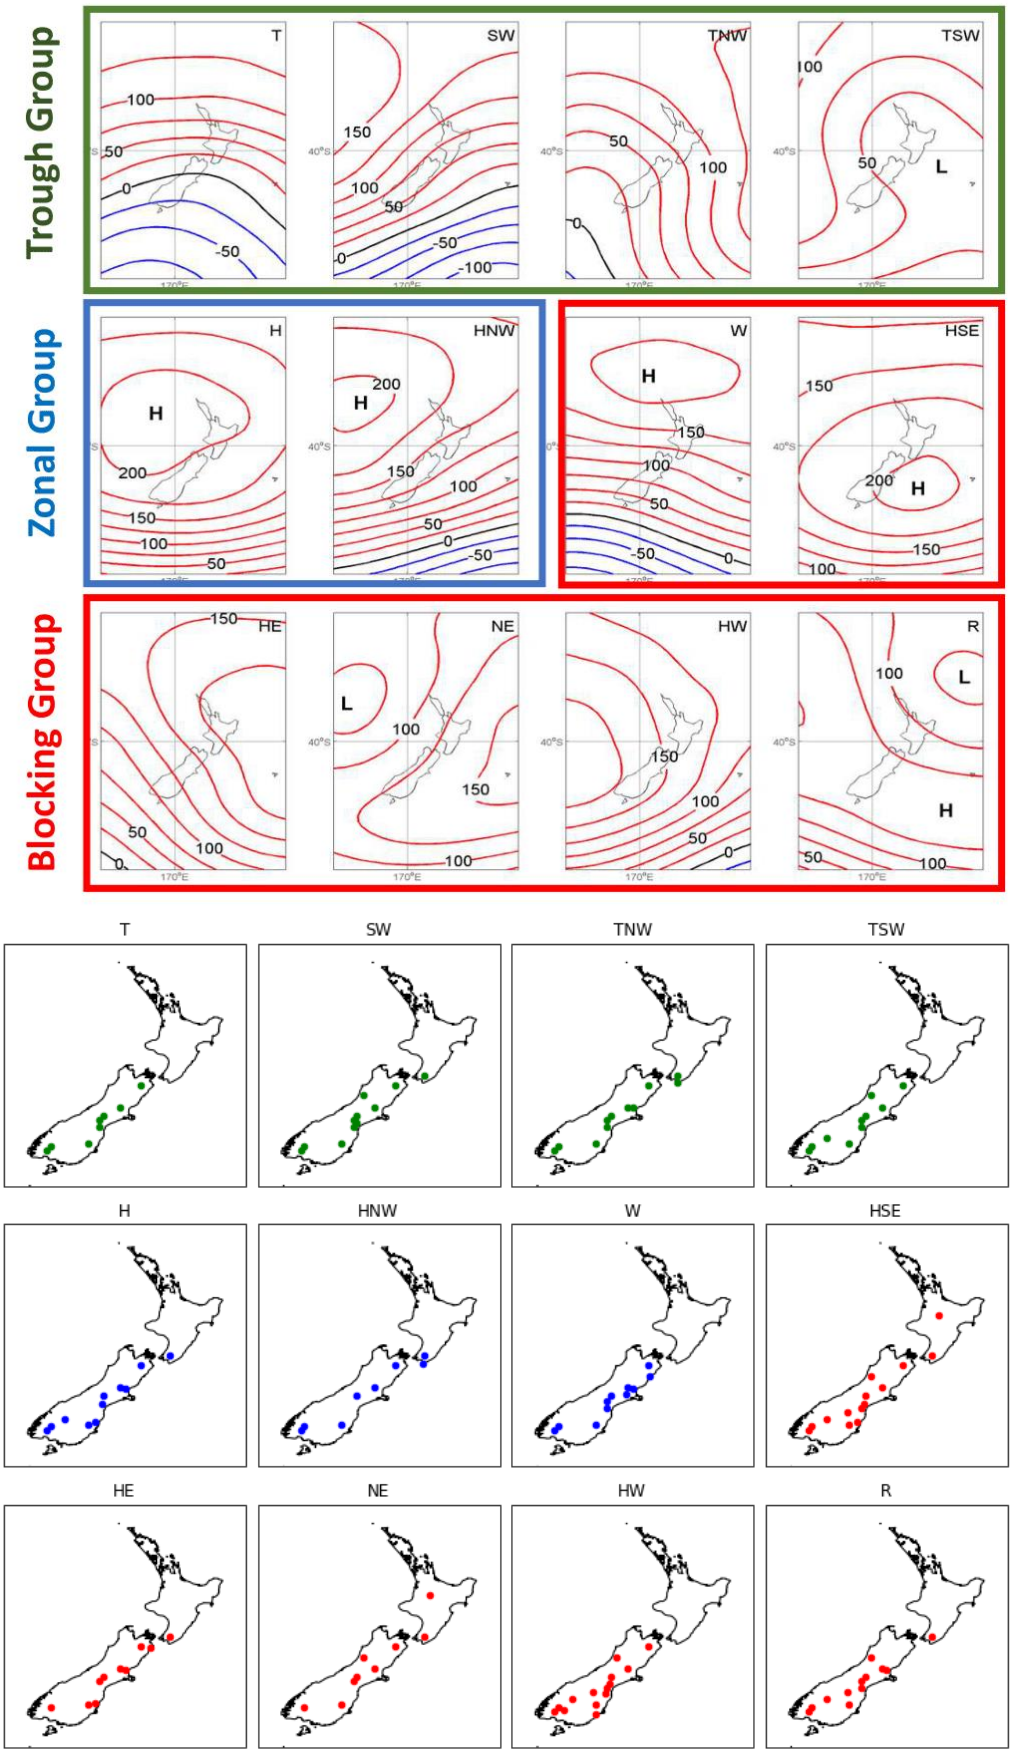

Figure 3- A) Synoptic Regimes in New Zealand (Kidson, 1999; Renwick, 2021). B) High Risk (Top 20% of Vector Wind Change and Lowest 20% Kurtosis) within each Synoptic Type, November 2020-2021.

3.4. Vector Wind Change and Fire Weather Index

The FWI was calculated for the 130 national FENZ weather stations at a daily time scale and averaged over the same period year long period as the VWC. The top 20% FWI stations were then mapped (Figure 4) to compare to the top 20% of the VWC and WDC stations. Interestingly, the same spatial trends appear in the high FWI stations as the high-risk stations, with most of the stations on the South Island. In contrast to the VWC stations, however, high FWI stations are found both coastal and inland. Out of the ten high VWC and WDC stations, four of them also appeared in the high FWI stations. The overlap in stations suggests that VWC and WDC could be useful additional parameters to FWI calculations around New Zealand to provide FENZ with additional information relating to microclimates in complex terrain to better inform fire risk and extreme fire behavior.

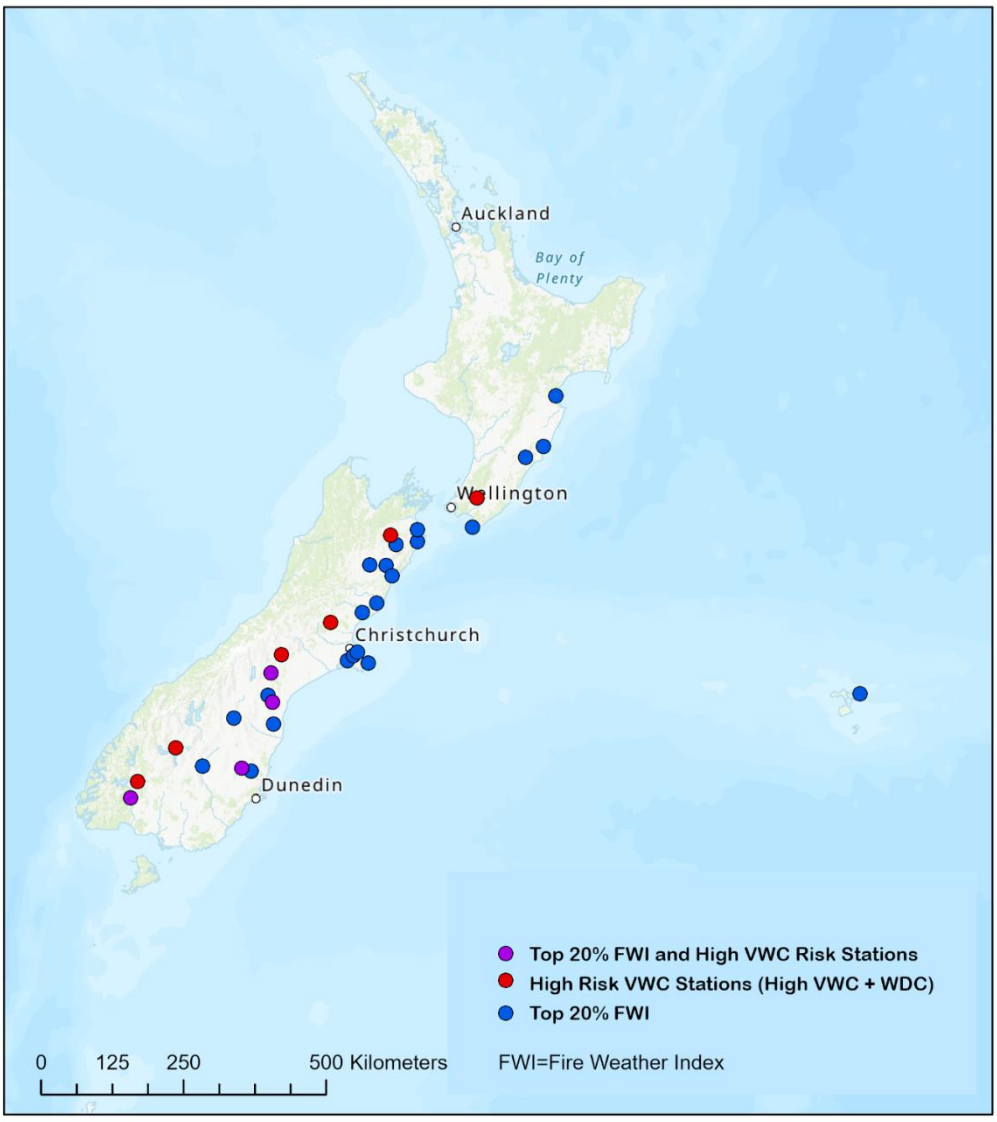

Figure 4- Top 20% VWC and Top 20% FWI Stations around New Zealand, for November 2020-2021.

4. Conclusions

Vector Wind Change, as well as Wind Direction Change, are useful near-surface variables for understanding potential wildfire occurrence conditions and its severity around New Zealand. These metrics are primarily forced by the impact of complex terrain on wind speed and direction and can be studied at the micro- and/or mesoscales and provide insight to the hourly wind changes across New Zealand. Given the importance of windspeed and direction on fire spread as well as extreme fire behavior, VWC and WDC could be important

additional metrics in analyzing fire risk in New Zealand. When combined with Fire Weather Index data, VWC and WDC may provide additional information in predicting extreme fire weather and risk of unpredictable fire behavior. The next step for this project is to complete a comprehensive analysis of New Zealand meteorology using gridded weather data from numerical weather simulations providing 20 years of data to calculate the FWI, VWC and WDC, and analyze the trends spatially and temporally, across both an individual fire season as well as larger inter-annual trends. These trends will be explored further in an upcoming publication.

FireStorm, weather stations, temperature inversions, downslope windstorms, vertical profile

Abstract

In the framework of the FireStorm project, four portable weather stations were installed in the Lousã/Estrela mountain range. The data observed with this equipment, along with two other stations from the Portuguese Institute for Sea and Atmosphere's network of surface weather stations, allows the monitoring of the vertical profile of temperature, relative humidity and wind in the region. Many forest fires in mainland Portugal affect areas with complex terrain, with hills or mountains in the 400-1200 m asl range, where weather conditions strongly influence the fire propagation and lifetime. Therefore, it becomes even more pertinent to study the vertical profiles of temperature, humidity and wind as they often exhibit large variability, namely in the nighttime period. This paper provides an overall assessment of the weather conditions in the nighttime period in selected events in which significant temperature inversions or downslope windstorms were observed. The forecast skill of the two operational numerical weather prediction models used at IPMA is also provided and highlights the challenges of weather forecasting in areas with complex terrain.

1. Introduction

Most of the major forest fires in mainland Portugal occur in the summer period and are located north of river Tagus, in areas with complex terrain, typically with hills or mountains in the range 400-1200 m asl. Often it is considered that in the nighttime period lighter winds, lower temperatures and the recovery of the relative humidity contributes to lower rates of fire spread and reduced fire intensity (Potter, 2012). Although this behaviour is commonly observed close to the surface over plains or plateaus, it is not necessarily the case in complex terrain. Additionally, the effects of complex terrain on the flow must be addressed, particularly in the case of dynamically driven winds, as these tend to be stronger (Sharples, 2009; Werth *et al.*, 2011). Well known effects include flow over mountains with speeding/blocked flow, gap or corner winds, mountain wakes and channelling effects.

Recent work suggests that fire intensity in the nighttime has increased globally, which is linked to warmer and drier nights (Balch, 2022). This suggests that it is highly recommended to carefully monitor the variability of the weather conditions during nighttime, particularly in areas that are prone to large wildfires and where extreme fire behaviour is likely to play a relevant role. In the framework of the FireStorm project, four portable weather stations were installed in the north-western slope of the Lousã/Estrela mountain range. This region has benefits such as the easy access, it is in the middle of the area where most of the forest fires occur and it spans a wide range in altitudes. Additionally, the network of surface weather stations of the Portuguese Institute for Sea and Atmosphere (IPMA) has data at two other locations in the area, which ultimately allows a higher spatial resolution.

In Rio *et al.* (2022) an overview of the weather conditions in the summer 2021 and in the winter 2021/22 was given, with insight into the differences that are observed in the daily cycle of the stations within the slope. An evaluation of the observed weather conditions allowed the identification of significant weather events, such as frequent surface inversions in the valley stations, sharp inversions aloft due to warm air advection or large-scale subsidence and downslope windstorms.

This paper presents further results from the observed data in the Lousã/Seia region. In this paper the overall forecast skill of numerical weather forecasts (NWP) is provided. The forecasts used in this study are from the two operational NWP models used at IPMA. This paper also presents three events, in which significant temperature inversions or downslope windstorms were detected in the area.

2. Location and data availability

Figure 1 shows the area being monitored in this study, with a total of six weather stations. Two of them are from the surface network from IPMA and the other four are the new portable weather stations installed in the Lousã and Seia regions. The location of the new portable weather stations was chosen considering the availability of two other stations from IPMA and the need to monitor the slope in a range of altitudes as wide as possible. Tables 1 and 2 provide details about the weather stations used, respectively, in the Seia and Lousã regions.

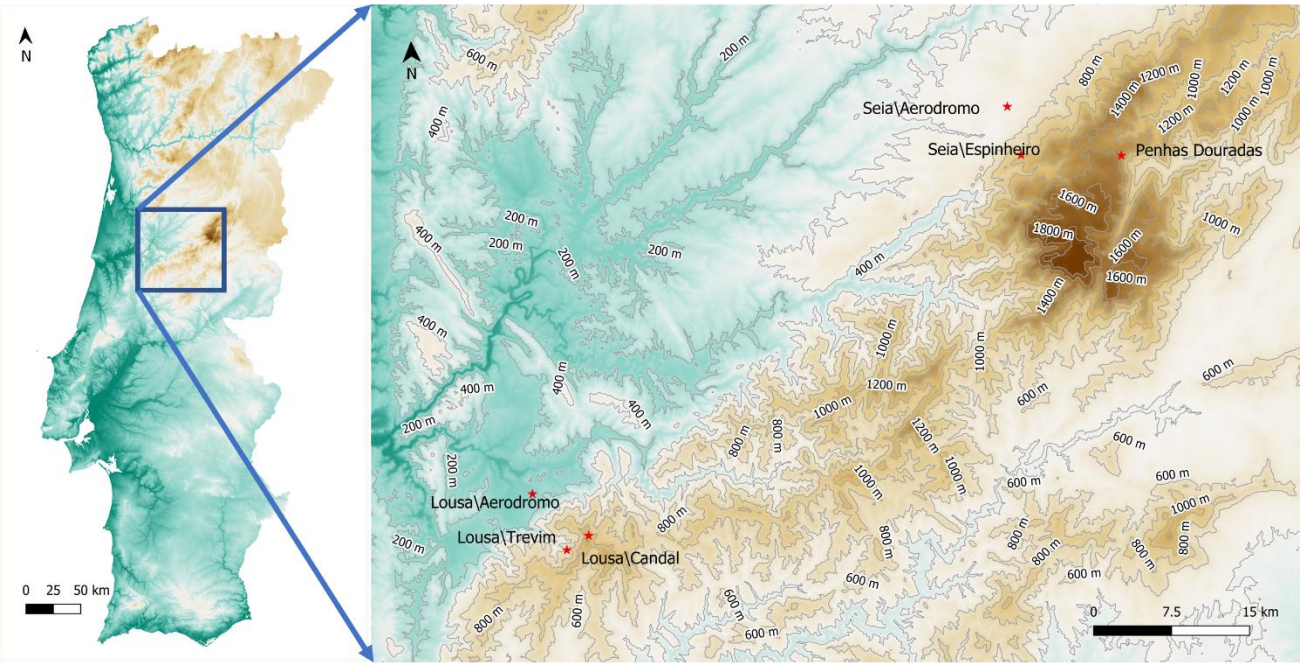

Figure 1 – Location of the weather stations used in this study.

Table 1 – Identification of the weather station in the Seia region.

Station name (short name)	Latitude	Longitude	Altitude [m]	Source	Available since
Penhas Douradas	40.41°N	7.56°W	1380	IPMA	---
Seia-Espinheiro (Espinheiro)	40.41°N	7.67°W	995	IPMA/FireStorm	03.2020
Seia-Aeródromo (Seia-Aero)	40.46°N	7.69°W	438	IPMA/FireStorm	03.2020

Table 2 – Identification of the weather station in the Lousã region.

Station name (short name)	Latitude	Longitude	Altitude [m]	Source	Available since
Lousã-Trevim (Trevim)	40.09°N	8.18°W	1167	IPMA/FireStorm	02.2021
Lousã-Candal (Candal)	40.08°N	8.20°W	621	IPMA/FireStorm	02.2021
Lousã-Aeródromo (Lousã-Aero)	40.13°N	8.24°W	195	IPMA	---

The weather stations in the Seia region were installed in March 2020. In Lousã it was only possible to install the equipment in October 2020, namely due to the pandemic restrictions. Additional unexpected issues with the

power supply and communication systems caused further delays, hence full availability of data from the weather stations in Lousã started only in February 2021.

The station of Penhas Douradas is the historical reference for Serra da Estrela, as it stands nearly at 1400 m asl. The station of Trevim is located at the top of Serra da Lousã, at 1167 m asl, with excellent exposure to the flow. The station of Espinheiro also has very good exposure, but is installed slightly below 1000 m asl. The weather stations of Seia-Aero and Lousã-Aero are both located in the valley (or slightly above it in the latter), in the aerodromes of each city. The station of Candal is installed in a narrow valley with a north-west/southeast orientation.

The data from IPMA's surface weather stations is observed at default heights (wind at 10 m, temperature and relative humidity at 2 m), but in the portable weather stations all the variables are observed at 2 m. To make the wind speed observations comparable, the 2 m data was extrapolated to the 10 m level using a logarithmic profile with a conservative value (0.1). This study only considers hourly data.

3. Forecast verification

The forecast verification shown here uses data from the operational versions of the NWP models used at IPMA. The high-resolution forecasts are from the AROME model (Seity *et al.*, 2011; Termonia *et al.*, 2018), which is run at IPMA four times a day (00, 06, 12 and 18 UTC) with a forecast range of 48 hours. This is a convective-scale limited-area model and is run with a horizontal resolution of 2.5 km. The second set of forecasts is from the global IFS/ECMWF model, namely the high-resolution (ECMWF-HRES), with a horizontal resolution of 9 km. The data used in this study is from the 00 UTC run and it considers hourly short-term forecasts (H+6 to H+30). The results shown here are a broad view of the forecast skill, as it provides only a score for the whole period. The metrics used here are the root mean square error (RMSE) and the bias (BIAS). The meteorological variables are the 10 m wind speed and the 2 m temperature and relative humidity. For conciseness only results for the summer of 2021 are shown (Table 3).

Table 3 – Forecast verification in the Lousã/Seia region, in the summer of 2021.

Station name	2 m temperature				2 m relative humidity				10 m wind speed			
	ECMWF		AROME		ECMWF		AROME		ECMWF		AROME	
	RMSE	BIAS	RMSE	BIAS	RMSE	BIAS	RMSE	BIAS	RMSE	BIAS	RMSE	BIAS
Penhas Douradas	**2,14**	**-0,27**	**1,99**	**0,10**	**17,89**	**-1,08**	**11,91**	**-3,68**	**2,76**	**-1,71**	**2,00**	**-1,21**
Trevim	**3,45**	**-0,78**	**2,39**	**0,24**	**25,08**	**-1,48**	**14,29**	**0,97**	**1,76**	**-0,73**	**1,72**	**0,83**
Candal	**1,84**	**-0,30**	**1,70**	**-0,81**	**15,09**	**0,19**	**9,77**	**0,04**	**1,93**	**1,46**	**1,72**	**0,83**
Lousã-Aero	**1,91**	**-0,47**	**1,47**	**-0,33**	**11,46**	**-6,14**	**10,17**	**-5,93**	**1,20**	**0,73**	**0,94**	**0,26**
Seia-Aero	**3,07**	**2,08**	**2,73**	**1,59**	**14,11**	**-10,95**	**15,39**	**-8,98**	**1,38**	**0,83**	**1,29**	**0,59**
Espinheiro	**1,74**	**-0,25**	**2,05**	**0,41**	**12,19**	**-2,17**	**11,91**	**-3,68**	**1,23**	**-0,17**	**1,22**	**-0,36**

The results show that the RMSE in these stations is larger than what is usually computed in low lying regions in mainland Portugal. The large errors in Seia-Aero, with a strong positive bias in temperature and large negative bias in relative humidity, is mainly due to the fact that in this location the cold-pool effect is very effective in the nighttime period. The highest errors in the 2m relative humidity are in the high slope (above 1000 m asl), which is likely due to the large variability of this variable. For the 10 m wind speed, while there is a negative bias in the locations at higher altitudes, in the valley stations the forecasts over-estimate the observed values. Finally, it should be stressed that these results are only valid for the stations and period in study.

4. Case studies

Since the spring of 2021 several events with large temperature inversions or downslope windstorms have been observed in the nighttime period. In the three events shown below, observed and short-term forecast data is shown only in the nighttime, which is defined as the period between 00 and 06 UTC.

4.1. Temperature inversion in August 2021

On August 5/6th, 2021, an event of strong temperature inversion enhanced by large scale subsidence was observed. Figure 2 shows the ECMWF-HRES analysis of the geopotential, temperature and wind at the 850 hPa, valid at 00 UTC, on August 6th. The Azores high extended a ridge towards the east-southeast, which lead to large-scale subsidence, dry and stable conditions in mainland Portugal. At the 850 hPa level the flow was moderate or strong from the west-northwest.

Figure 3 shows the cross-section of the wind (parallel) and relative humidity over Serra da Estrela, using the H+6 ECMWF-HRES forecast, valid at 06 UTC, on August 6th. This plot shows a strong gradient of relative humidity, over the orographic ridge and on the leeside of the mountain, associated with downward motion of very dry air. At the 860 hPa level, around the real altitude of Penhas Douradas, the relative humidity had values around 15-20%. At the same time, the vertical profile in Lousã-Aero (Figure 4) shows an inversion layer between 800 m and 2200 m asl, where the temperature increases around 5ºC and the humidity decreases around 75%. The downward motion is strongest between 1800 m and 2000 m asl, with vertical speeds around -0.8 m/s. Figure 5 shows the time series of the observed 2 m relative humidity. This suggests that the base of the "real" inversion should be located above and close to the height of Trevim (1167 m asl). Also, the difference between the observed relative humidity in Trevim and Penhas Douradas is larger than the difference of the corresponding forecasted relative humidity, which suggests a stronger inversion in this layer. In fact, at 06 UTC the temperature in Penhas Douradas was 6.4ºC higher than the one observed in Trevim (not shown), while the 2 m relative humidity were, respectively, 13% and 100%.

Figures 6 and 7 show that this event was very challenging for NWP models, even in the case of the high-resolution AROME. While in Penhas Douradas both models suggested dry air reaching the station, they over-estimated the 2 m relative humidity values by around 20%, with AROME in closer agreement with the observations. In Trevim, none of the models suggested the values of 20-30% during the nighttime on August 5th.

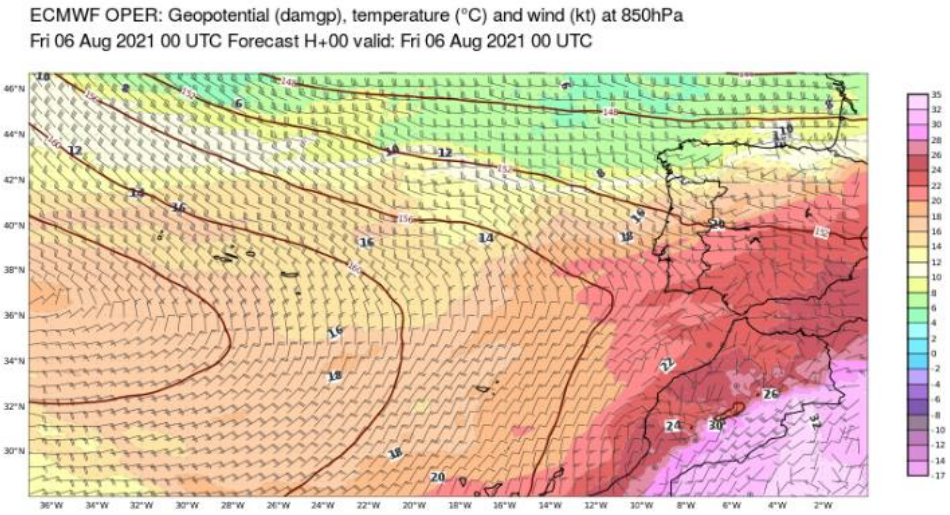

Figure 2 – ECMWF-HRES analysis of the geopotencial height, temperature and wind at the 850 hPa level, valid on August 6th, 2021, at 00 UTC.

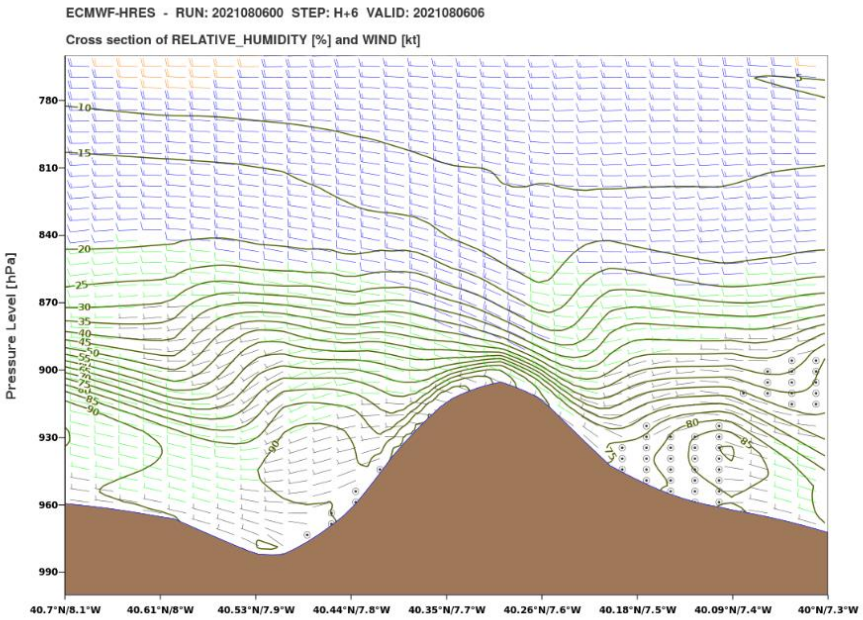

Figure 3 – Cross-section (orientation NW-SE) of relative humidity and wind (parallel) over Serra da Estrela, from a short-term ECMWF-HRES forecast, valid on August 6th, 2021, at 06 UTC.

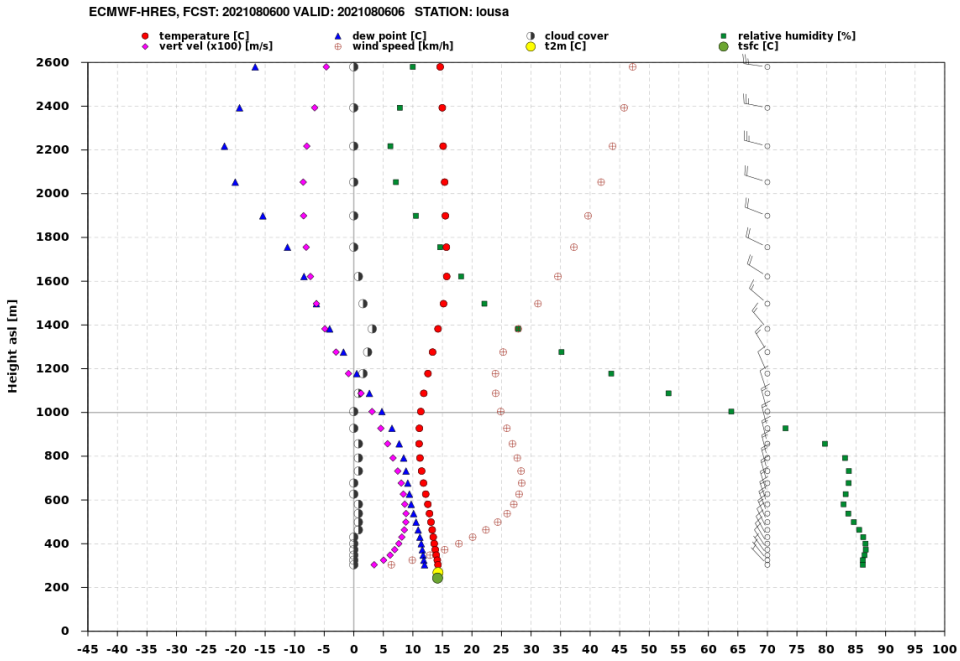

Figure 4 – ECMWF-HRES profile for Lousã-Aero, valid on August 6th, 2021, at 06 UTC.

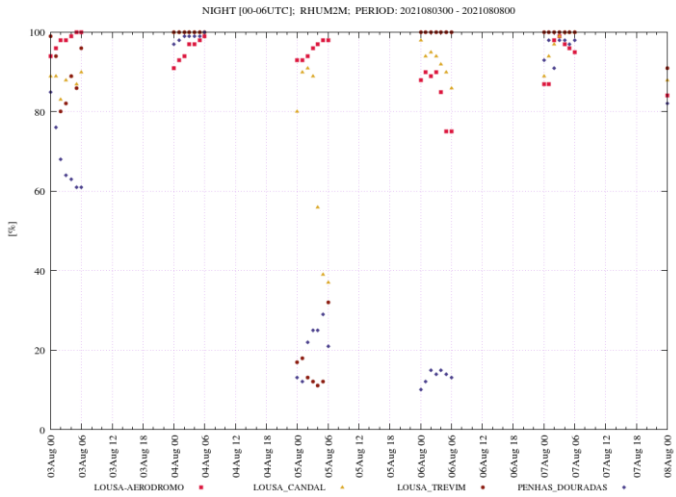

Figure 5 – Time series of the observed 2m relative humidity, in the weather stations located in the Lousã region and Penhas Douradas. Data in the period August 3rd – 8th, 2021.

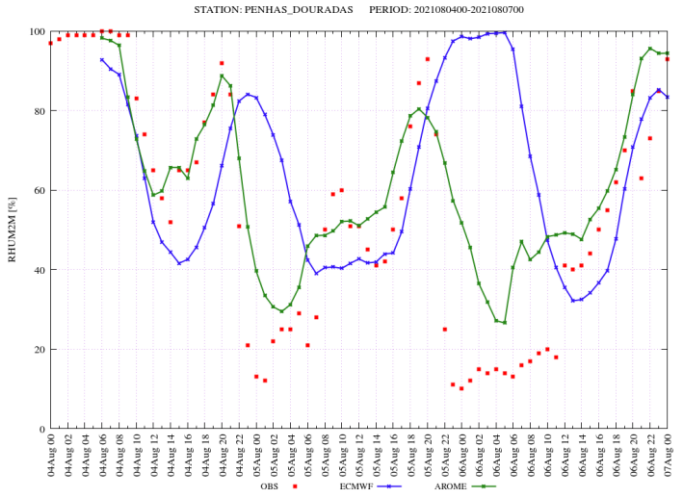

Figure 6 – Time series of observed and forecast (ECMWF-HRES and AROME) 2m relative humidity in Penhas Douradas, on August 4th – 7th, 2021.

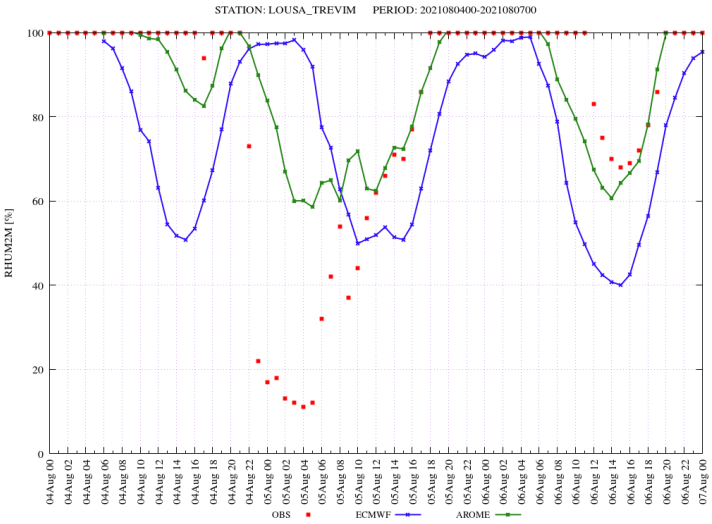

Figure 7 – Time series of observed and forecast (ECMWF-HRES and AROME) 2m relative humidity in Trevim, on August 4th – 7th, 2021.

4.2. Downslope windstorms

The two downslope windstorms briefly described in this paper were observed on March 31st, 2021, and March 28th, 2022. Figures 7a and 9a show the 00 UTC analysis of the geopotential, temperature and wind at the 850 hPa. Figures 7b and 9b show the cross section of the wind and relative humidity over Serra da Estrela, with a NW-SE orientation, using short-term ECMWF-HRES forecasts (H+6), valid at 06 UTC in each event. Figures 8 and 10 show the AROME forecasts of the 3 hour maximum 10 m wind gust and the 2 m temperature, valid at 03 UTC on each date.

In both events, a low pressure system was centred southwest of Iberia, close to Madeira, which originated a moderate or strong south-easterly flow. The cross sections show that the short-term ECMWF-HRES forecast was able to provide guidance into the strong downslope wind. In both cases, this model suggested much lighter wind speeds close to the valley. The AROME forecasts suggested south-east winds (not shown), with wind gusts in the 70-80 km/h range in the north-western slopes of the mountain range. The observed 2 m temperatures (not shown) were much higher than expected for the time of the year, mainly on the event in March 2022.

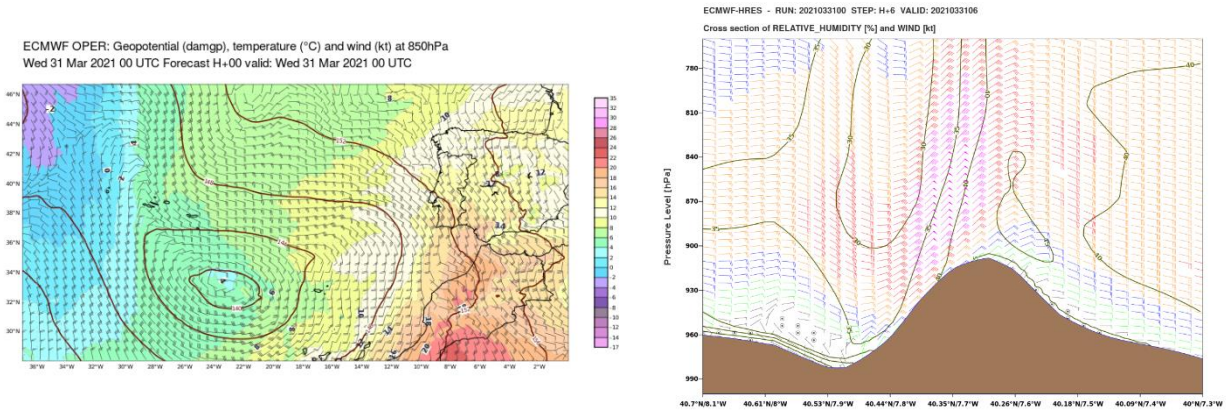

Figure 7 – ECMWF-HRES analysis of the geopotencial height, temperature and wind at the 850 hPa level, valid on March 31st, 2021, at 00 UTC (left). Cross-section (orientation NW-SE) over Serra da Estrela, from a short-term ECMWF-HRES forecast, valid on March 31st, 2021, at 06 UTC (right).

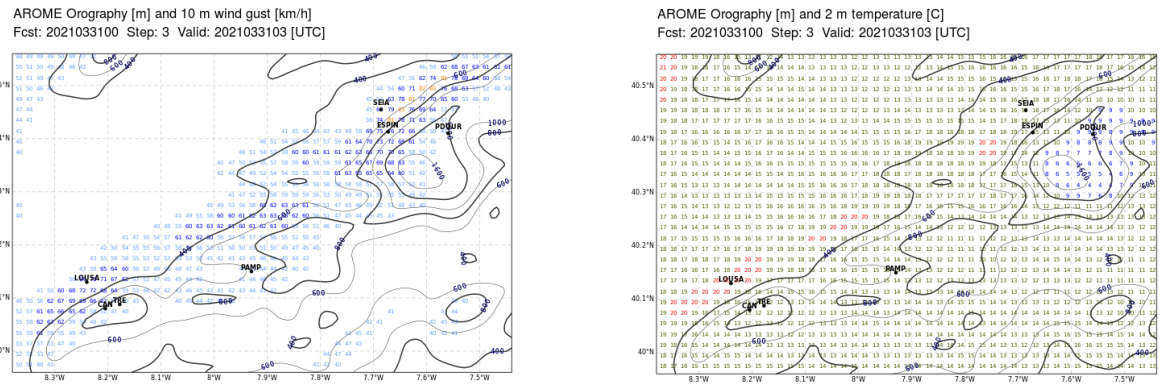

Figure 8 – AROME forecasts (H+3) of the 3 hour maximum 10 m wind gust (left) and 2 m temperature(right), valid on March 31st, 2021, at 03UTC.

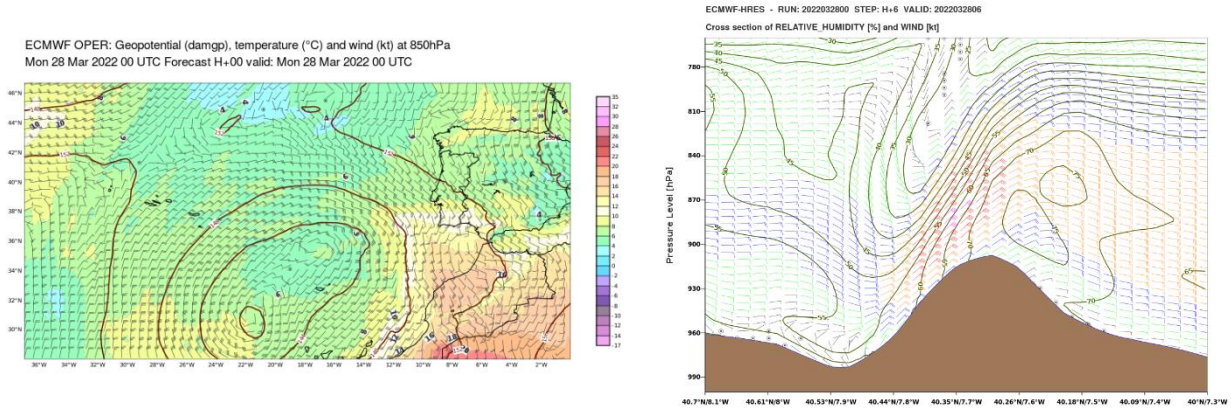

Figure 9 – (a) ECMWF-HRES analysis of the geopotencial height, temperature and wind at the 850 hPa level, valid on March 28th, 2022, at 00 UTC. (b) Cross-section (orientation NW-SE) over Serra da Estrela, from a short-term ECMWF-HRES forecast, valid on March 28th, 2022, at 06 UTC.

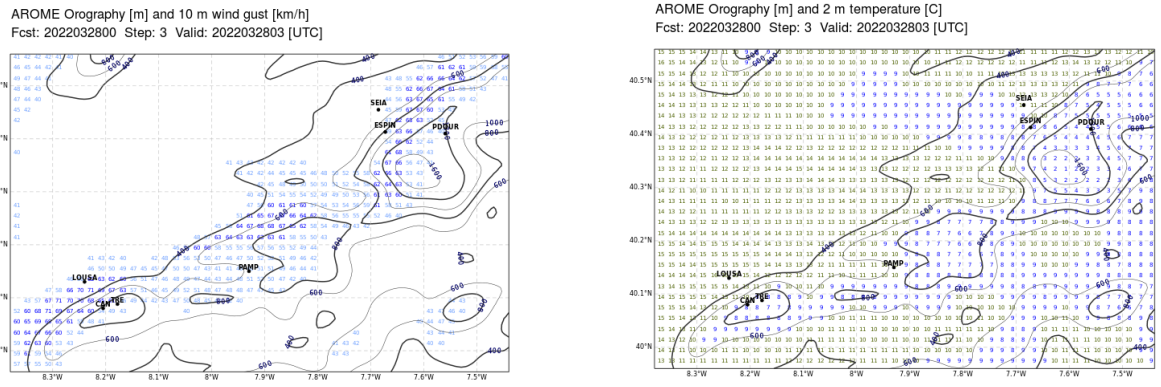

Figure 10 – AROME forecasts (H+3) of the 3 hour maximum 10 m wind gust (left) and 2 m temperature(right), valid on March 28th, 2022, at 03UTC.

The discussion above on downslope windstorms shows that ECMWF and AROME forecasts provide useful guidance in the broad features of these events, at least in the Lousã/Estrela mountain range. However, it must be stressed that these circulations are extremely challenging for NWP models (Haraldur *et al.*, 2021), as they are very sensitive to the initial conditions, namely the wind profile, atmospheric stability, direction of the flow into the mountain range and model horizontal resolution. Additionally, as turbulence plays a key role in these circulations, extreme caution is advisable if NWP direct model output is to be used operationally, as large differences between forecast and observations at specific locations are most likely to occur.

5. Final remarks

The results shown in this study highlight the challenges of weather forecasting in complex terrain. Even though NWP data provides useful guidance on the broad features of many events, comparing forecasts and observations clearly shows that large difference are very common. Therefore, these results show that extreme caution is advisable when direct model output of NWP data is used as a guidance for the weather data at a specific site.

6. Acknowledgments

The work was only possible in the framework of the FireStorm Project (Weather and Behaviour of Fire Storms), Project Reference PCIF/GFC/0109/2017- FCT. The installation of the portable weather stations was only possible with a very close and fruitful cooperation between IPMA (Jorge Neto, João Rio, Ilda Novo), ADAI (Luís Reis, Daniela Alves and Professor Domingos Xavier) and the Municipalities of Lousã and Seia.

Abstract

Wildfire, as a global phenomenon, is an integral part of the Earth system that affects different regions in diverse ways resulting in variable levels of long-lasting impacts to environmental, social, and economic systems. In a context where extreme and high severity events are becoming more frequent, it is crucial to respond with a more robust preparedness and planning, identifying the risks posed by wildland fires, fostering better fire management policy tools, and developing mitigation strategies accordingly. However, scope and methods for wildfire risk assessment vary widely among countries leading to different regional/national approaches not always comparable, although wildfires are often transborder events and may affect several countries simultaneously. The elaborateness of these assessments is often related to the impact of fires in the corresponding regions, with countries more often confronted with wildfires being more prepared by having more elaborated and detailed wildfire risk maps at country/regional level, although based on the specificities of each country. To integrate currently incompatible approaches, harmonised procedures for wildfire risk assessment are needed at the pan-European scale, enhancing planning and coordination of prevention, preparedness, and cross-border firefighting actions to mitigate the damaging effects of wildfires. The development of a pan-European approach follows from a series of European Union (EU) regulations requiring the European Commission (EC) to have a wide overview of the wildfire risk in Europe, to support the actions of its Member States and to ensure compliance in the implementation of EU regulations related to wildfires. The conceptualization of the European Wildfire Risk Assessment (WRA) as the combined impact of wildfire hazard on people, ecosystems, and goods exposed in vulnerable areas, explicitly accounts for the multiplicity of risk dimensions and sources of uncertainty. Already serving as an integrated framework for gathering the European countries' experience on fire management and risk, it will support the inter-comparison of WRA among countries, with the aim to complement existing national WRA with a simpler, but harmonised, methodology. A semi-quantitative approach, designed to be robust to uncertainty and flexible in ingesting new components, is currently under development in close cooperation with the EC Joint Research Center (JRC), other Commission services, and the Commission Expert Group on Forest Fires which is now composed of fire management representatives from 43 countries in the region. Additionally, the harmonised framework can serve as a first approach to assess wildfire risk in those countries that have not yet performed a national WRA, and as a guideline for extending the approach to larger areas, where data coverage may be scarcer and more uncertain.

1. Introduction

Given the projected increase of fire risk in the Mediterranean-type climate regions due to climate change (Pechony et al., 2010), wildfire risk assessment is fundamental for developing prevention, mitigation and preparedness plans, but also as a key element to disentangle the complex relationships between fire occurrence, drivers, and impacts caused by fires at different levels (Oliveira et., 2021; Moreira et al., 2020). Many countries have customized approaches to assess wildfire risk, widely varying based on different variables and methodologies (San-Miguel-Ayanz et al., 2003, 2017). Usually, these different approaches are not only related to the frequency/impact of fires, level of preparedness, and data availability, but also to how risk components

are incorporated in the decision-making processes at different levels, such as landscape management or risk governance. Hence, this process repeated at multiple scales, for very different territories and specific purposes has led to different regional/national approaches, difficult to compare at the European scale, although wildfires are often transborder events and may affect several countries simultaneously. Fire-risk terminology is far from standardized, and even the concept itself is subject to several (sometimes incompatible) definitions (Hardy et al., 2005). A noticeable share of published fire risk systems only considers wildfire likelihood and behaviour, usually ignoring the damage caused by fire impacts in operational fire danger assessment systems (San-Miguel-Ayanz et al., 2003). Some other systems integrate fire danger and vulnerability, as two essential risk components (Calkin et al., 2010; Chuvieco et al., 2010, 2012; Tutsch et al., 2010; Thompson et al., 2011; Oliveira et al.,2020). However, much work is still needed to converge on a clear and concise terminology and harmonise quantitative risk analysis in the context of wildland fire management and of disaster risk management (Bachmann et al., 2001). The main goal of this work is to describe the development of a pan-European wildfire risk assessment (WRA) based on the definition of risk adopted by UNISDR (2009) which was also followed by the European Commission (EC) Joint Research Centre (JRC) reports (San-Miguel-Ayanz et al., 2017, 2019; Oom et al., 2021) by presenting a first set of data that would enable the implementation of the proposed assessment. Quantitatively, wildfire risk is defined as the product of the probability of wildfire occurrence/propagation (hazard) and the damage potentially caused (exposure and vulnerability) (Finney, 2005; Scott et al., 2013). This involves three main fire research areas: fire ignition/occurrence, fire behaviour/propagation, and fire effects (exposure and potential loss of assets/resources in vulnerable wildfire-prone areas). The harmonised WRA will support the inter-comparison of methods and needs among countries and be complementary to existing national WRA. Additionally, it can serve as a first approach to assess wildfire risk in those countries that have not yet performed a national WRA.

1.1. Pan-European risk assessment in the context of EFFIS

The development of the pan-European approach follows from a series of EU regulations that require the EC to have a wide overview of the wildfire risk in the European region, to support the actions of its Member States and to ensure compliance in the implementation of EU regulations related to wildfires. The process is closely linked with the Expert Group on Forest Fires (EGFF), composed of fire management representatives from 43 countries in the region and part of the European Forest Fire Information System (EFFIS) which was established jointly by the EC services (DG ENV and JRC) and the relevant fire services from the EU Member States, other non-EU European countries and Middle East and North African countries (Figure 1).

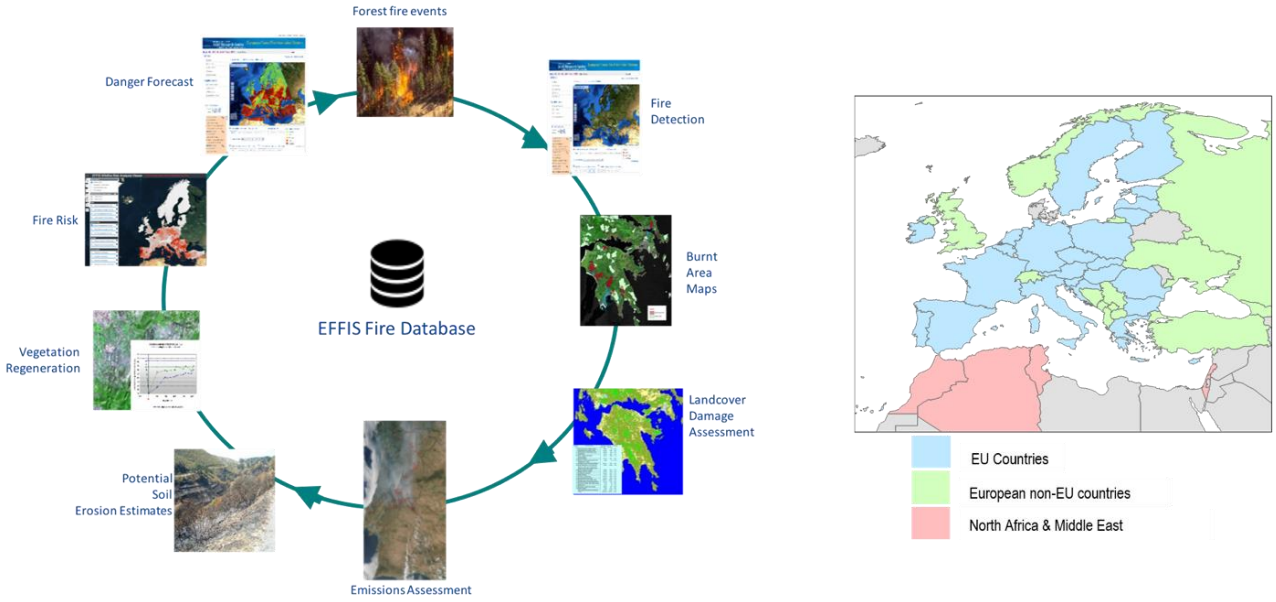

Figure 1- European Forest Fire Information System (EFFIS) services (left); map of countries that are currently part of the Expert Group on Forest Fires (EGFF) (right).

1.2. Wildfire risk scheme

An integrated framework of interconnected components associated with the fire process (Chuvieco et al., 2012; Xi et al., 2019) should support risk modelling to provide an integrated view of both fire likelihood and consequences (Dunn et al., 2020). Figure 2 illustrates the WRA scheme here proposed, designed to be scale-independent and easily applicable to local, regional, and global scale. Two main groups of components are defined by considering the fire danger (or hazard) and the vulnerability on three categories: people, ecological, and economic values exposed in vulnerable areas.

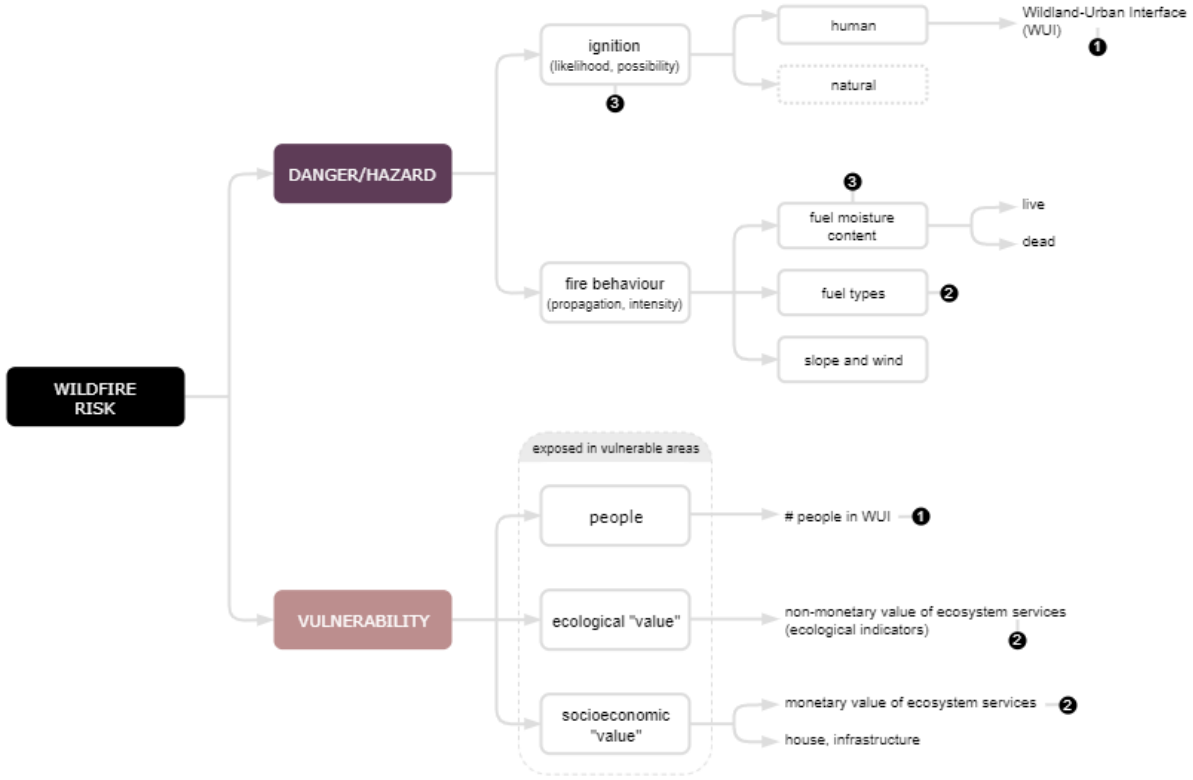

Figure 2- Basic components of the Pan-European Wildfire Risk Assessment scheme (from Oom et al., 2021).

The scheme follows a classic quantification of "risk", based on the probability or possibility (*P*) of negative outcomes (damage, *D*)

$$R = P \times D \quad (1)$$

The probability for a fire to start at a given location and time (*P*,fire danger/fire hazard) depends on the likelihood for ignition sources and local conditions to start and spread a fire (fire behaviour), namely it depends on the fuel availability, type and pre-conditions of the fuel, the prevalent meteorological conditions, and on the presence of an event triggering the initial ignition. In Europe, the vast majority of wildfires is linked to human causes, either deliberate or due to accident/negligence (de Rigo et al., 2017). Therefore, *P* is not only a function of fuel and weather, but prominently also of human behaviour *P*(*fuel*, *weather*, *human*). The expected outcomes/impacts on people, landscape/ecosystems, assets exposed in vulnerable areas (*D*, vulnerability) refer to the susceptibility to suffer damage by fire: "the conditions determined by physical, social, economic and environmental factors or processes which increase the susceptibility of an individual, a community, assets or systems to the impacts of hazards" (UNISDR, 2009). Vulnerability, which is also associated with exposure (people, ecosystems, goods *exposed* in *vulnerable* areas, so that in the following the two entwined concepts are referred to as the overall "vulnerability" component of wildfire risk), should be assessed based on relevant proxy indicators and data. The impact of wildfire hazard on vulnerability is typically estimated as a *structural* assessment, also known as *climatological* risk (San-Miguel-Ayanz et al., 2017) and should explicitly consider the variability and uncertainty of the conditions historically observed. Given that even the damage by fire is a key function of human behaviour (fire prevention, firefighting, post-fire recovery policies) and depends prominently on policy, economic, social and cultural aspects, then even the second component of eq. 1 is a

function of human factors for which there is an overwhelming lack of data. Therefore, *P* and *D* cannot be fully estimated "probabilistically", but they might with a simpler semi-quantitative risk ranking (where *P* is a simpler fuzzy possibility subject to uncertainty analysis).

2. Data

The development of an operational fire risk assessment system for the pan-European scale requires the generation of multiple datasets for each component, and a method to integrate them into a risk ranking. Table 1 describes the datasets for each component in the WRA.

Table 1- Datasets for the components of the fire risk assessment system (grey boxes are variables that are not yet operational, being still the object of exploratory research)

Risk components		Components detail	Variables used	Source
DANGER /HAZARD	Ignition	Human cause	Historical fire data	EFFIS burned area (2003-2020)[1] MODIS thermal anomalies (2003-2020)[2] Corine Land cover[3]
		Natural cause	lightning	
	Fire behavior	Fuel moisture content	Live Fuel Moisture Content (LFMC)	[4]
			Dead Fuel Moisture Content (DFMC)	Fire Weather Index system[5,6,7]
		Fuel types	vegetation types	Corine Land Cover[3] Fuel Map of Europe[8]
		Climatic conditions	- wind, humidity, precipitation and temperature	Fire Weather Index system[5,6,7]
		Terrain	slope, aspect	Elevation data[9]
VULNERABILITY	People	# People in WUI	wildland–urban interface (WUI)[10]	Population density[11,12] Built-up areas[13]
	Ecological "value"	Ecological indicators	- irreplaceability score[14] - protected area - potential burnable land	Nature 2000[15] Protected area[16]
	Socioeconomic "value"	Monetary value of land cover and vegetation	Wildfire-damage restoration costs [17,18,19]	Corine Land Cover[3], vegetation age (restoration time) [17,18,19] restoration costs [17,18,19]

3. Methodology

To identify areas where vegetation fires could occur, a high-resolution mask was developed ("Potential Burnable Area", PBA) (Figure 3) acting as a filter to avoid false alarms, avoiding observations that do not correspond to vegetation fires. The Global Human Settlement Layer (GHSL) built-up product (Corbane et al., 2018) jointly with the JRC's Global Water Layer (Pekel et al., 2016)[1] and PROBA-V 333m Difference Vegetation Index (NDVI) product generated by the Global Land Service of Copernicus[2] were used as input. The data processing was implemented with spatial resolution of ~30 meters, and then aggregated at the spatial resolution of the WCRP[3].

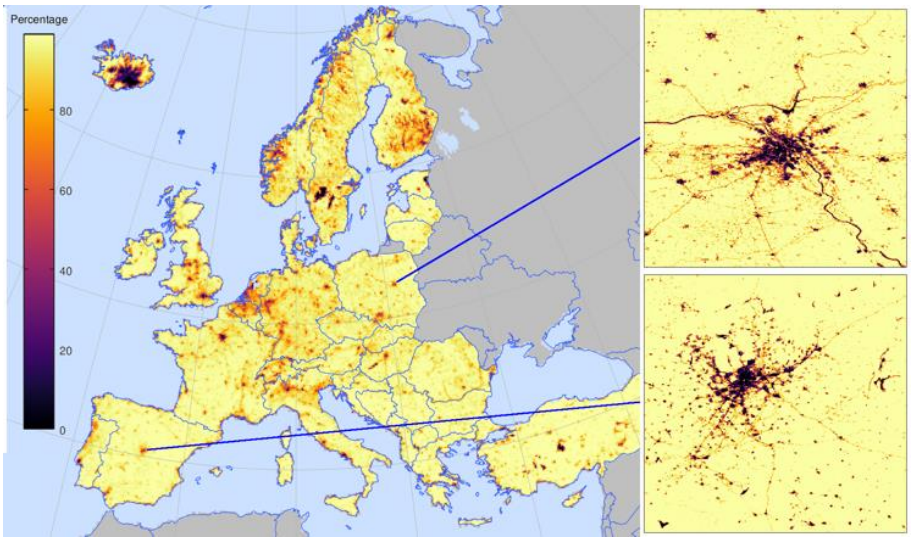

Figure 3- Potential Burnable Area proportion (0-100%) in each 12.5 km cell. Right inside are examples of the cities of Madrid and Warsaw.

The WRA was assessed through a semi-quantitative approach by using the available quantitative data presented in Section 2, as proxy information for the wildfire danger and vulnerability components, along with a qualitative aggregation of them in classes of importance (from low to high importance).

Virtually all the layers discussed above (Table 1) as components of the fire risk are associated with an intrinsic uncertainty, so that their non-linear integration (Figure 2) to estimate the final risk magnifies the cumulative aggregated uncertainty.

Therefore, this structural uncertainty is at the basis of a *robust* method for identifying the areas to prioritise, where the estimated risk is consistently higher than in other areas. This robust risk assessment is computed by considering multiple simulations of the uncertainty – as explored in a corresponding set of multiple model instances (where each instance is a bootstrap statistical resampling repeated for all the uncertain components). The degree of agreement between model instances can be easily estimated, thereby identifying the *high-priority areas* where most instances agree on these areas being at high risk. Analogously, areas with relatively low risk (*lower priority areas*) can also be identified, where most instances agree on the same low-risk classification. Not always the model instances agree, because in some areas the extent of bootstrap uncertainty might generate a higher noise in the model instances. In the worst case (*un-assessable areas*), the risk level in some areas may be too uncertain to assess: this happens if the model instances classify these areas with contradictory levels of risk. This risk-level ranking yields a robust method for integrating the *noisy signal* provided by the various

[1] https://global-surface-water.appspot.com/

[3] European grid of the Coordinated Regional Climate Downscaling Experiment (CORDEX) by World Climate Research Programme (WCRP). Archived at https://tinyurl.com/y85nxfdw. The standard grid EUR-11 is used (grid cell resolution of approximately 0.11 degrees, or about 12.5 km).

components considered in the wildfire risk assessment, offering users a robust estimation of the WRA stability (or conversely its potential fragility) in each area.

However, it should be underlined how the proxy layers available in a harmonised way at the European scale forcefully supply less detailed and accurate information compared with that available only at the national or sub-national scale. Therefore, a trade-off exists between the aim of offering a European-wide harmonised WRA, and its potential degree of fitness for many specific purposes at national/sub-national level. Although some of the available European-wide components do not provide a proper assessment on their uncertainty, a distribution of equi-possible instances of each of the uncertainty-aware components can be modelled. This is the case of data displaying a marked variability in different years. Examples are weather data, and their derivative estimates of fire danger by weather, the fire weather index (De Groot at al., 1987; Wan Wagner et al., 1987; Vitolo et al., 2020) and the observed historical fire activity including large fires mapped in EFFIS (Sedano et al., 2012, 2013) and MODIS thermal anomalies (Giglio et al., 2020).

Wildfire risk may be assessed by considering the vulnerable areas where people, ecological, and socioeconomic values are exposed to fire danger. An aggregated wildfire risk index is proposed, which prioritizes the risk for human lives, while also considering ecological and socioeconomic aspects. This is done by ranking as high-risk areas those where people may be exposed to wildfires, and secondarily other areas where ecological and socioeconomic aspects are at stake. The mathematical mechanism for this ranking relies on standard long-established lexicographic sorting algorithms (Fishburn et al., 1974; Ben-Tal, 1980; Weber et al., 2002).

Looking at Figure 2, in some branches of the WRA tree graphical representation, proceeding from right to left, more than one input component needs to be aggregated into a single output. In these cases, a classical Pareto ranking aggregation (Ben-Tal, 1980; Fonseca et al., 1993; Tracey et al., 2018) is used, so that a semi-quantitative prioritisation can be derived, irrespective of any particular preference on how input components could be weighted[4]. Pareto ranking is a standard methodology to derive a robust ranking (invariant for *any* monotonic transformation of the input components) where the Pareto frontier between the values in each area of two or more components defines higher priority areas, and iteratively the Pareto frontier of the remaining areas defines progressively lower priority areas. For example, aggregating the danger components from (a) the observed historical fire activity, and (b) the monitored fire danger by weather, a Pareto ranking would de-prioritise areas where negligible or no fire activity was historically observed, *and* a time series of fire danger by weather was locally monitored verifying it to be much lower compared with the danger by weather in other regions. Overall, the proposed WRA approach is designed to respect the semantics of the arrays of proxy data sources and their inherent uncertainty (Figure 2, Table 1) through their intermediate data-transformations, up to aggregate them in a final risk-class ranking. The robust semi-quantitative modelling integration is based on the semantic array programming paradigm (deRigo et al., 2012, 2015) and explicitly designed to ease the support for a future climate change analysis (de Rigo et al., 2017; Costa et al., 2020).

4. Preliminary results

A wildfire risk map was generated as an index to summarize the combined effect of wildfire danger and vulnerability. The format of the risk map allows risk classes (from low to high risk) to be identified, with a simple score ranging from 0 % to 100 %, which could then be aggregated in three levels of risk: low, medium and high (Figure 4). High risk may be expected where high wildfire danger affects the most critical areas for people, and secondarily for the other ecological and socioeconomic aspects.

[4] as this may subjectively vary depending on political and society values which are inherently non-technical and cannot be delegated to others than policy makers – with decision makers in different countries and sub-national regions being able to display a very diverse range of preferences.

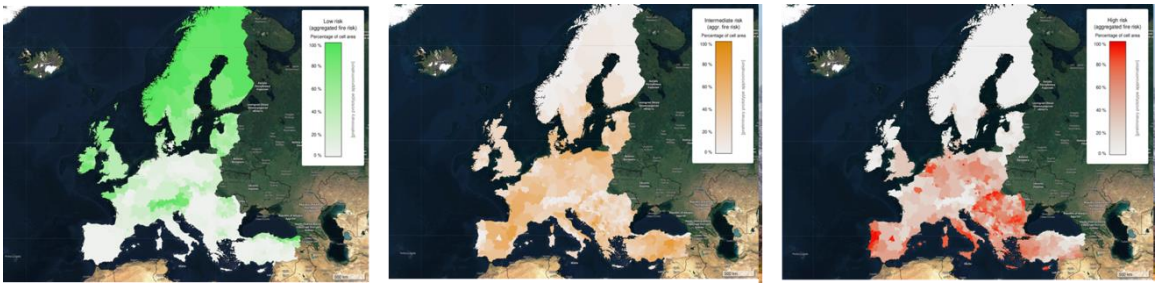

Figure 4- Final aggregated wildfire risk by administrative units. Prevalence of the lower-risk class (left); intermediate-risk class (centre); and higher-risk class (right) in each EURO-CORDEX spatial cell. Percentage based on the risk classification in each EURO-CORDEX cell of 100 equi-possible model runs, to integrate the uncertainty sources. Average aggregation by administrative units, expressing the prevalence of each risk class at the administrative level.

A preliminary version of the pan-European Wildfire risk map viewer was built to include all the input data and the final risk on a pixel (circa 12.5 km) and administrative level basis. This version is displayed in Figure 5 with two examples of the layers included in the viewer.

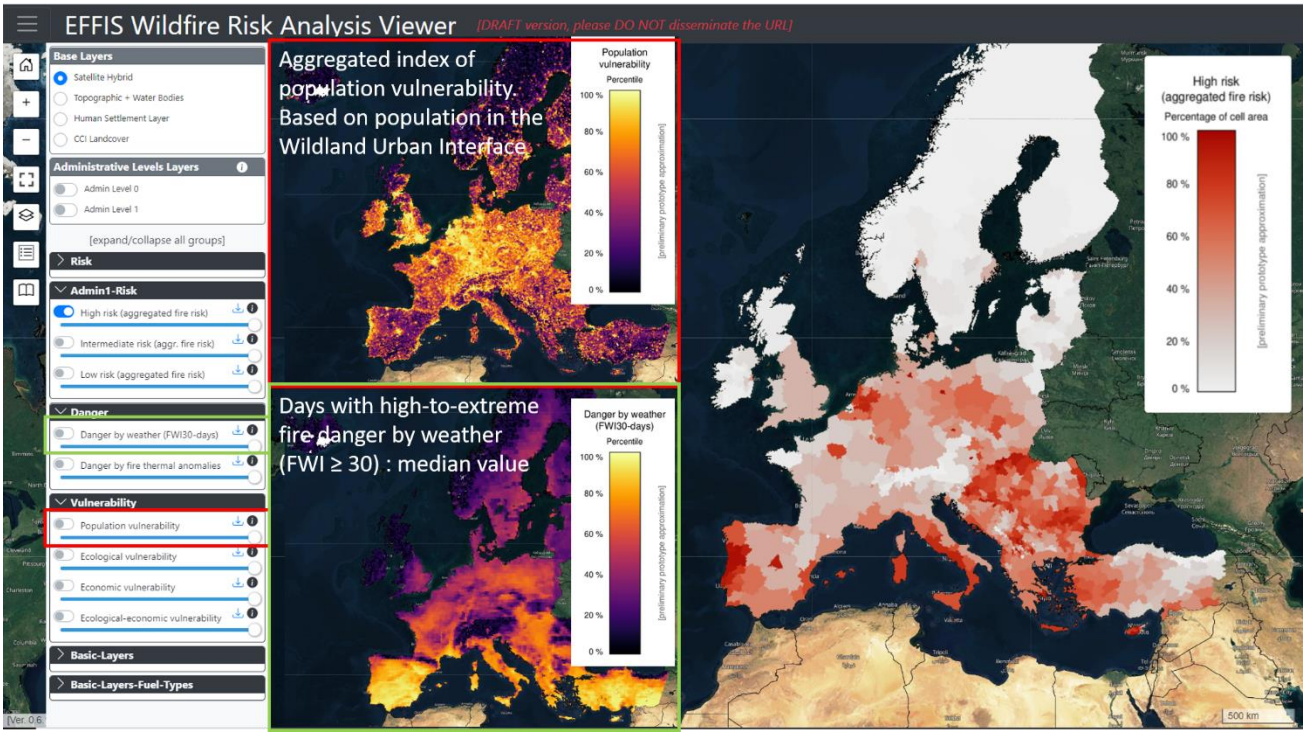

Figure 5- EFFIS Wildfire Risk Viewer (preliminary version). Values displayed in the map correspond to the high-risk class at administrative levels, based on GADM (https://gadm.org/index.html). As an example of some of the layers included on the viewer, the inside boxes display the Danger by Weather (green) and the aggregated index of population vulnerability (red). On the left panel are displayed the layers available in the viewer and on the right inside the legend for the two examples aforementioned.

5. Ongoing research

The above sections set the input data and the basic criteria for the WRA. Also, lessons learned from previous critical fires must be taken into consideration (San-Miguel-Ayanz et al., 2013), as these are becoming more frequent in Europe and worldwide. Next steps foresee testing and validating the WRA and will be undertaken in close collaboration with the EGFF. At the same time, research is ongoing on both deriving enhanced datasets and methods such as fuel classification, socio-economic components, or live fuel moisture content.

Abstract

Peatlands are essential terrestrial carbon pools. Due to climate change and human activities, peatlands are more prone to large-scale fires than ever, especially deep underground fires. However, most current smouldering researches focus on small-scale smouldering behaviour in relatively shallow layers, posing a research gap. This work explores in-depth (up to 60 cm) smouldering behaviour, such as persistence, propagation and emission. The commercial organic peat soil from Netherland was chosen for lab experiments. Reactors with good thermal insulation conditions were built to simulate the natural smouldering environment. Experimental results demonstrate that smouldering underground fires can sustain in deep soil layers for more than a week without any additional oxygen supply. Because of the competition of oxygen supply and heat losses, a critical depth of 55 cm for smouldering propagation was obtained, below which smouldering cannot self-sustained propagate. This work will help connect lab-scale experiments with natural underground smouldering peat fires and understand smouldering dynamics in deep soil layers.

1. Introduction

Peatland, as a type of wetland, accumulates a considerable amount of organic matter decomposed from vegetation material (Hugron et al. 2013). Peatlands are essential terrestrial carbon pools, storing one-third of the world's soil carbon (500-600 Gt C), as much carbon as surface vegetation globally, and may be of similar magnitude to the atmospheric carbon pool (~850 Gt C) (Ballhorn et al. 2009; Turetsky et al. 2015).

Due to climate change and human activities, peatlands are more prone to large-scale fires than ever before (Jolly et al. 2015; Lin et al. 2021a). Especially, at certain times and in certain areas, such as hot, dry summers and regions with a high diversity of plants, the fire risk is significantly increased (Evtyugina et al. 2013). Frequent peat fires have caused serious ecological and climatic damage, as well as significant economic losses. For example, in 2019, the slash-and-burn activities in southeast Asia (Goldstein et al. 2020) resulted in mega-scale peatland wildfires that burned for several months, leading to severe air pollution and causing many health issues to residents (Normile 2019). Peat fires are started by flaming fires in forests, lightning strikes, and human activities and are dominated by smouldering combustion. Smouldering wildfire requires less ignition energy than flaming combustion and can persist in wetter and lower oxygen conditions. Once ignited, smouldering can propagate vertically and horizontally in a deep and wide soil layer, thus sustaining the largest and most persistent fire on Earth (shown in Fig. 1). For such underground fires, it's challenging to detect and extinguish them. Even though fires on the soil surface was extinguished, hidden underground smouldering fire may spread at a very low propagation rate and re-spreading to the surface in some conditions (Rein 2013). However, this kind of in-depth smouldering behaviour is poorly understood. Smouldering wildfire and the relevant ecological problems have attracted much research attention. Still, most of them focus on smouldering propagation in relatively shallow soil layers in terms of smouldering ignition, propagation (Huang and Rein 2017, 2019), extinction (Lin

and Huang 2021; Lin et al. 2021b), and firefighting (Ramadhan et al. 2017; Santoso et al. 2021). So far, there is a lack of both lab-scale and field-scale smouldering research to reveal the in-depth smouldering propagation behaviour, thus bringing a considerable knowledge gap.

This study aims to conduct a lab-scale series of in-depth smouldering experiments to understand the deep-layer smouldering propagation behaviour. This work will help better connect small-scale laboratory experiments with natural underground smouldering peat fires.

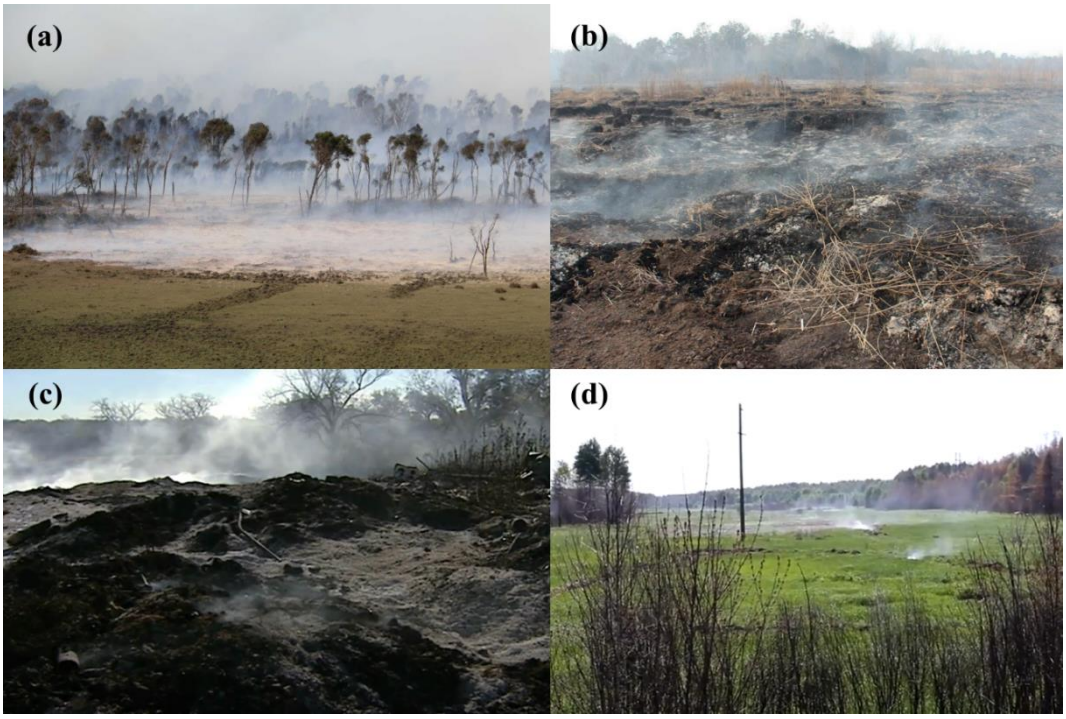

Figure 1- Underground smouldering fire in (a-b) Southeast Asia, (c) North America, and (d) Eastern Europe

2. Methodology

2.1. Peat sample

The commercial moss peat sample from Estonia with high organic content (~97%), uniform density, and homogenous particle size was chosen in this study. Before the tests, the peat soil was first oven-dried at 90 ^{o}C for 48 h to reach an equilibrium with the air of MC = 10% (Huang and Rein, 2017). The measured peat bulk density and porosity were 145 ± 10 kg/m^3 and 0.90 ± 0.01. Elemental analysis shows that its mass fraction of C/H/O/N/S is 45.6/6.0/48.0/0.5/0.3%, respectively.

2.2. Experimental setup and procedure

Fig. 2 shows the schematic diagram of the experimental setup for the peat fire initiation and spread. In order to simulate a natural peat underground fire, the smouldering reactor needs to have good insulation. The smouldering reactor in this study was built of 1 cm-thick insulation ceramic fibreboards to contain the peat sample and had different heights (30 cm – 60 cm). The aluminium foil was attached to the outer surface of the insulation board to reduce the radiative heat loss. The top of the reactor was open to supply oxygen and release emissions. An array of K-type thermocouples with an interval of 3cm was inserted into the reactor to record the temperature history at a different height. The coil ignitor inserted into the sample was used to initiate the smouldering combustion.

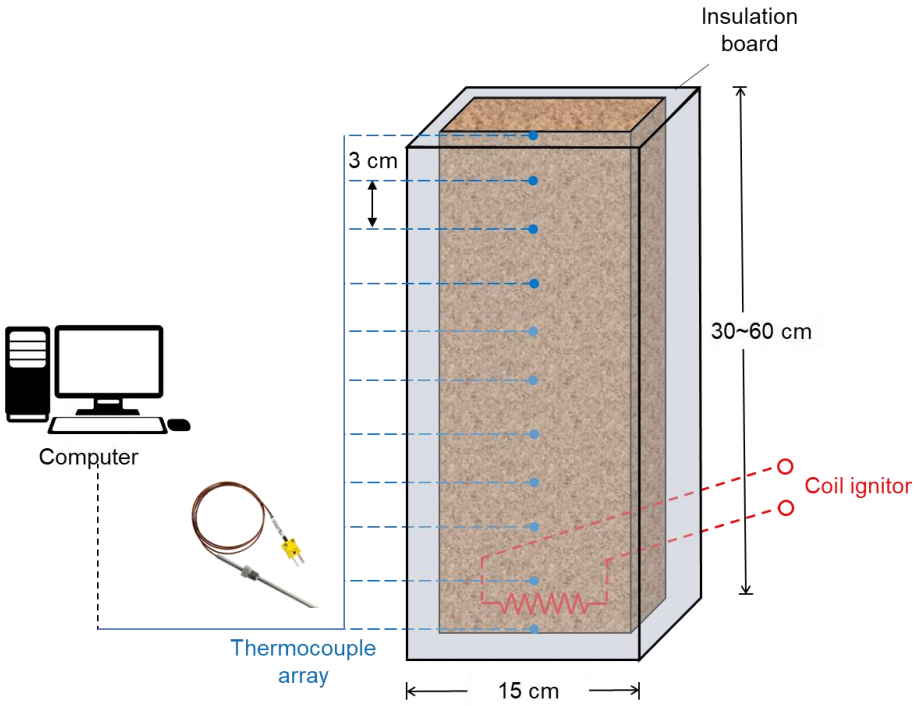

Figure 2- Experimental setup for in-depth smouldering peat fire

In order to initiate the peat and form a robust smouldering front, the ignition protocol was fixed at 100 W for 60 min. The tests are stopped until all peat has returned to room temperature for 2 hours, which indicates the end of smouldering. The test started with ignition at the bottom. Subsequently, tests with different reactor heights were conducted, and all the tests were repeated at least twice to ensure repeatability.

3. Results and Discussion

3.1. Smouldering phenomenon and critical depth

Fig. 3 shows the thermocouple measurements of (a) smouldering propagation and (b) no propagation in reactors with different depths of 50 cm and 60 cm, respectively. Taking (a) as an example, the ignition was started from the bottom (-50 cm). After 60-min heating, the temperature at the corresponding height exceeds 250 ºC, which is the minimum smouldering temperature and suggests a robust smouldering front formation. Afterward, it shows that smouldering propagated upward with a very low propagation rate (~4 mm/h). A noticeable change occurred after 3.5 days. Smouldering no longer continued to propagate upward but instead propagated downward with a similar propagation speed and higher smouldering temperature (> 400 ºC). Then the smouldering fluctuated around the bottom before final extinction. Notably, a peat layer of 50-cm depth maintained continuous smouldering combustion for about a week.

A completely different phenomenon occurs if the depth is increased to 60 cm (Fig. 3 (b)). The temperature near the bottom (-60 cm) still exceeded 250 ºC after 60 min heating, but no smouldering propagation was observed. Even though a few thermocouples near the bottom showed a short-term temperature increase, this is probably the effect of heat transfer since the duration was short and the temperature was low. Repeated tests have demonstrated that at this depth, even if the ignition power is further increased or the ignition time is extended, no smouldering propagation can be observed.

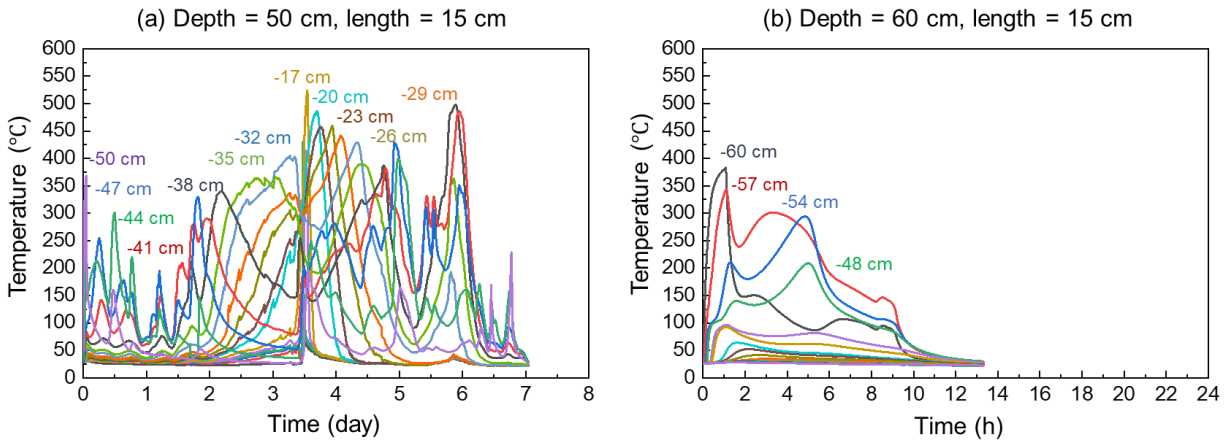

Figure 3- Thermocouple profiles in different depths. (a) shows a typical smouldering phenomenon while (b) indicates no smouldering propagation after ignition (The negative sign means that the thermocouple is below the reactor's top free surface).

3.2. Critical depth

Experimental results show that at this reactor size (length = 15 cm), smouldering can only propagate when the depth is less than 50 cm. Continue to deepen the depth, even if smouldering is still able to be ignited under a strong ignition, it cannot self-sustained propagate. Thus, the critical smouldering depth for this reactor size is 55 cm.

Critical depth exists due to the limitation of the oxygen conditions. Oxygen can only be provided by diffusion into the deep peat layers, and it may not be sufficient to support the oxidation processes necessary for smouldering below the critical depth. According to Darcy's law,

$$q = \frac{k}{\mu L}\Delta p \qquad \text{(Eq. 1)}$$

where q is airflow flux (or the air supply per unit area) in (m/s), k is the permeability of the porous medium in m^2, μ is the dynamic viscosity of the fluid in (Pa·s), and Δp is the pressure drop in (Pa) over a given distance L (m). Thus, given a heat transfer condition and minimum oxygen supply for the oxidation process of smouldering, the critical depth for smouldering can be determined. Future research could explore the critical smouldering depth in different insulation conditions or even smouldering in field-scale.

4. Conclusions

In this work, we conducted a series of lab-scale experiments to investigate the in-depth smouldering peat fire. We experimentally demonstrated that smouldering underground fires could sustain in deep soil layers for more than a week without any additional oxygen supply. In the current experimental setup, a critical depth of 55 cm for smouldering propagation was obtained, below which smouldering cannot self-sustained propagate. However, reducing heat loss, such as using a reactor of a larger size, will make smouldering sustain in a deeper peat layer. This work will help better connect small-scale laboratory experiments with natural underground smouldering peat fires and understand smouldering behaviour in deep layers.

Future fire risk, climate change, Fire Weather Index, Central Europe, Wildland-Urban Interface

Abstract

Fire risk is projected to increase under future climate change. Most projections focus on fire-prone regions, such as the Mediterranean-type ecosystems, whereas little attention has been paid to regions of low fire risk such as Central Europe. Here, future projections of fire risk which are tailor-made for its specific conditions are scarce. With our study we aim to fill this gap. We use meteorological station data and interpolated climate datasets to compute future fire risk for Central Europe (covering Germany, Poland and the Czech Republic) using the Fire Weather Index. In a next step, we analyse the spatial distribution of reported fire ignitions to identify additional drivers that can explain the spatial pattern of fire ignition and risk, or accelerate fire risk under climate extremes (drought or extreme heat). We analyse how transport infrastructure and proximity to settlements have influenced fire ignition in Central Europe and compare it against relationships known from fire-prone regions. We aim to build on recent adjustments of the FWI to account for respective increased fire risk and apply it to our study area.

In a next step, downscaled future climate scenarios (CMIP6) are applied to compute changes in future fire risk for the entire study area as well as selected sites in Central Europe. Uncertainty ranges of future fire risk projections will be covered by using several climate scenarios for the entire study region.

1. Introduction

Central Europe is until now characterized by relatively low fire risk. Fire occurrence is rare and most fires remain small. For example, the mean annual total burned area in Germany was around 800 ha in 1991-2019 (European Forest Fire Information System). Fires occur mainly in dry lowland pine forests in eastern Germany and in Poland, especially in young to medium forest stands (< 40 years) (Müller 2019). The low level of fire occurrence is caused by the temperate climate conditions and by the development of various forest fire protection measures over the past century. Fire monitoring and forest fire protection has a long tradition in those regions (König 2007). For example, the first fire lookout tower was invented and patented in eastern Germany in 1902. Several forest management practices, forest fire protection measures and public education initiatives were introduced during the 1970s and 1980s that resulted in a general public awareness about forest fire risks and ultimately in a decline in fire occurrence (König 2007). Many past forest fires were caused by military activities and the occurrence of such fires dropped after 1990 (Müller 2019). As most of the pine forests are now in older age classes and thus have less ladder fuels, the occurrence of large devasting crown fires was declining further. Given those developments in forest management and fire protection, societies and foresters are rarely confronted with forest fires in Central Europe.

Despite those past developments, unexpected large fires occurred in Germany during the drought of 2018, which had similar burned area like fires back in the 1970s. Although the dry and hot conditions promoted those recent fires, the large burned area is explained with the impossibility to fight those fires because they occurred at areas contaminated with old ammunition (Müller 2019). However, those recent fires demonstrate that extreme dry and hot weather conditions can suddenly increase fire risks also in forests of Central Europe and that fire occurrence at former military sites or close to public infrastructures are indeed a risk to society and a challenge for fire fighters. We assume that fire risks will increase in future in central Europe because regional climate warming and a possible increased occurrence of droughts will increase fire danger conditions. Currently, there

is no recent assessment of fire risks in Central Europe that accounts for the specific regional patterns and developments of forest fire protection and for future climate change conditions. Here we aim to develop a comprehensive assessment of present and future fire risks in Central Europe (Germany, Poland, Czechia).

2. Analysis of fire risk under current climate

The fire season in Central Europe is characterized by short dry and hot spells in the order of a few days during the summer months. Plant productivity (via phenology) is limited by temperature and light, making the growing season to last from spring (April) through early autumn (September). Therefore, enough fuel is available throughout the fire season, while the fire risk is limited by climatic conditions. Due to its continental climate, sandy soils and fire-prone pine forests, fire risk is slightly elevated in eastern Germany and in Poland or in some lowland sites in Czechia, while the mountain sites in those countries generally experience less fires because of the colder and moister site conditions that are largely dominated by spruce forests. Interannual climate variability is relatively low compared to Mediterranean or semi-arid regions and lightning is in most cases associated with storms and rain. Hence almost all fires in Central Europe are human-caused and occur in a managed agricultural and forestry landscapes. An analysis of the drivers determining these ignitions is important to manage future fire risks.

2.1. Analysis of settlements and transport infrastructure on current fire risk

We use data on reported fire events to analyse the spatial structure of observed ignitions in the study area and relate them to fire risk under current climate conditions. To achieve this objective, we compute the Fire Weather Index using data from meteorological stations as well as interpolated climate data sets, e.g. climate re-analysis data from GLDAS. We analyse differences obtained from both data sets to verify possible error propagation. We then compare the spatial pattern of observed ignitions against climate and land-cover data to determine their importance in explaining observed pattern using spatial statistical methods. Recently, the FWI was extended to account for risk stemming from urban areas. Since the extension was developed for fire-prone Sardinia, we analyse how the modelled influence of proximity to urban areas can be applied to the central European fire regimes under temperate climate conditions. Fire fighters in Central Europe recently reported that forest fires were caused by forest machinery, an effect which was also investigated for Sweden (Sjöström et al. 2019). In a next step we analyse the implication for fire risk.

3. Towards improved estimates of future fire risks

Changes in future fire risk are usually quantified based on fire weather indcies such as FWI using seasonal forecast and future climate scenario data. In EFFIS, the respective risk is computed for the EU member states and is reported regularly. However, such approaches do not account for changes in vegetation types, fuel loads or socieconomic effects. At continental to global scales, fire-enabled Dynamic Global Vegetation Models (DGVMs) can be used to assess the effects of climate change and vegetation dynamics on climatic fire risk, ignitions, spread and effects of fire. DGVMs simulate the composition, amount and characteristics of live and dead fuel and form the input to the fire module. Similarly, fire effects, including combusted dead and alive biomass and post-fire mortality, affect the regeneration of the simulated vegetation. Composition and dynamics of the vegetation, including fuel composition and fuel load, depend on the fire sensitivity of the affected vegetation and resulting vegetation productivity. Therefore, bi-directional feedbacks establish between fire and vegetation in the model.

However, because of the low fire risk in Central Europe, model quality of fire-enabled DGVMs to match observed spatio-temporal pattern of fire occurrence has been rarely assessed. Building on the data analysis and application of the FWI for present fire risks, we will evaluate model simulations and analyse uncertain model functions to suggest ways of improving respective model components. Specifically, we will apply the LPJmL-SPITFIRE model (Thonicke et al. 2010, Drüke et al. 2019) with downscaled climate input data (9 km resolution). We will compare the simulated climatic fire danger and fire ignitions against the FWI computations in the study area. Spatial and temporal patterns will be analysed using respective statistical methods to quantify model error and benchmarking techniques.

We will analyse how the adjusted ignition component in the FWI calculation is changing under projected changes in land cover in the study area. We conduct a factorial analysis to identify the influence of land-cover change against climate change on fire ignition. We will attribute the influence of a changing fire season, which is expected to increase in length and/or intensity under high fire risk, against the influence of land-cover change on potential human-caused ignitions. We will compare changes in spatiotemporal pattern against contemporary pattern and identify areas of increased high fire risk and actual ignitions.

In a second step, projected changes in climatic fire danger and fire ignitions applying the improved LPJmL-SPITFIRE model will be analysed. We will compare the influence of changes in vegetation dynamics on future fire risk and fire ignitions using LPJmL-SPITFIRE against FWI computations. Finally, the maps of future fire risks will be used as updated input to the mapping of fire risk areas at the wildland-urban interface.

Abstract

In Romania forest fires have a strong annual and seasonal variability, having a distribution pattern correlated with human activities like stubble burning practices. The most fire affected region is located in the southwest of Romania, in the counties of Mehedinți and Gorj with a mosaic landscape of forests with agricultural land and human settlements. Although the year 2021 was generally a mild fire season at national level, almost 60% of the forests burned area occurred in Mehedinți, county whose surface covers 2.06% of the national territory. The reported affected area is determined by measurements with GPS receivers or by an approximate estimate of the percentage of affected area in a forest parcel. The accuracy of those determinations is not being verified through other procedures like remote sensing-based methods, thus there is a need for independent evaluation of the reported fire impact. The aim of this research is to perform a quick robust enough assessment of the areas affected by forest fires in August 2021 and their severity in a forested area covered mostly by black locust (Robinia pseudoacacia), located in the southwestern part of Mehedinți county, using Sentinel 2 imagery and in field validation. In order to assess the degree of damage of the forest stands, Sentinel 2 satellite images were used, before, during and after the fire events. Additionally, official RGB and CIR aerial orthophoto images with a spatial resolution of 0.5 m from 2015 were used together with ultra-high resolution orthoimages obtained by processing RGB aerial photographs taken post-fire event with an UAV. Several remote sensing-based indices mostly used in forest fire-science literature were tested in order to extract the affected burn area and burn severity, among which the difference Normalized Burn Ratio (dNBR) proved to give the best estimates. A field inspection was carried out in order to verify whether the burn severity classes are corresponding to the ground truth impact of the fires. By comparing the dNBR mapping with terrain observations, we found that burn severity is corelated with canopy cover and height of the trees, at least in black locust stands, who naturally have lower canopy cover than other deciduous tree species. The correlation between dNBR and the canopy cover is negative, that means low canopy cover shows a false high severity on dNBR map and vice versa because the burnt grass and understory layer is more visible from above and denser in sparse forest stands. Also, low height of the trees induces high severity on the dNBR, the flames and heat produced by the burnt understory reaching easily to the canopy level. These observations were afterwards used to adjust the burn severity map.

1. Introduction

According to the last national disasters risk assessment (IGSU, 2016), forest fires in Romania have a low impact in terms of physical, economic and psychosocial consequences and a high probability of occurrence. In the last 65 years, Romania has recorded an average of 176 forest fires per year, with an average area of 917 ha per year and 5.2 ha per forest fire. However, since 2000 there was a significant increase in manifestation of this hazard, both in term of frequency and affected surface. The average number of forest fires per year increased to 319, while the affected area averaged 1867 ha. Since 2010 there was an appreciable increase in forest fires that affected areas over 25 ha. Most forest fires occur due to human activities, such as uncontrolled burning of stubble and dry grass in the fall and spring, on agricultural land in the forest neighborhood.

In Romania forest fires have a strong annual and seasonal variability, revealing that the distribution pattern correlates with human activities that are the predominant cause, while also influenced by prolonged periods of droughts which induces reduced combustible humidity (Lorent et al, 2018).

The most fire affected region is located in the southwest of Romania, in the counties of Mehedinți and Gorj, a region with a climate with Mediterranean influences, with mosaic landscapes of forests with agricultural land and human settlements. Although the year 2021 was below average in terms of the number of fires recorded at national level and the affected surface, out of a total of 278 forest fires which affected a surface of 2101.14 ha, 71 of them covering a surface of 1238.81 ha occurred in Mehedinți county, whose surface covers 2.06% of the national territory.

Even though Mehedinți is known as a fire prone area, 2021 was an exceptional year in terms of vegetation fires, which occurred with an unprecedented frequency, amid a period of drought and strong winds, coupled with the local practices of burning stubble and dry grass for clearing the land. According to the Inspectorate for Emergency Situations of Mehedinți county, between 1st of July and 30th of September 2021, there were 852 fires that started from brambles, shoots and dry vegetation, of which 35 fires occurred in the forests. Out of the 35 fires, 24 were surface fires and 11 damaged forest plantations. Practically, in July and August (and to some extent in September), military firefighters intervened daily to extinguish vegetation fires, which endangered community areas and even spread to several households.

After each forest fire intervention, a report is drawn up by the military firefighters and the forestry personnel in which the area affected and the damages caused are evaluated. The affected area is determined by measurements with GPS receivers or by an approximate estimate of the percentage of affected area in a forest parcel. The accuracy of those determinations is not being verified through other procedures like remote sensing-based methods, thus there is a need for independent evaluation of the reported fire impacts.

The aim of this research is to perform a quick and robust enough assessment of the areas affected by forest fires in August 2021and their severity in a forested area covered mostly by black locust trees (*Robinia pseudoacacia*), located in the southwestern part of Mehedinți county, using Sentinel 2 imagery and in field validation.

2. Materials and methods

2.1. Study area

The study area is located in Southwestern Romania, in Mehedinți county (Figure 1), being covered mainly by black locust forests installed on the river dunes in the high terrace of the Danube, where the forests are interspersed with cultivated or uncultivated agricultural land. The obligation to demonstrate that the agricultural lands are being cultivated (for obtaining subsidies in agriculture) makes the local practice, such as cleaning of dry grass and vegetable waste (after harvesting cereals) to be often based on the burning of stubble and of the uncultivated land. In conditions of prolonged drought and strong wind, during August – September 2021, these repeated fires led to the spread of dry vegetation fires in the forest stands, resulting in thousands of hectares of burned agricultural fields and forests, with varying degrees of damage.

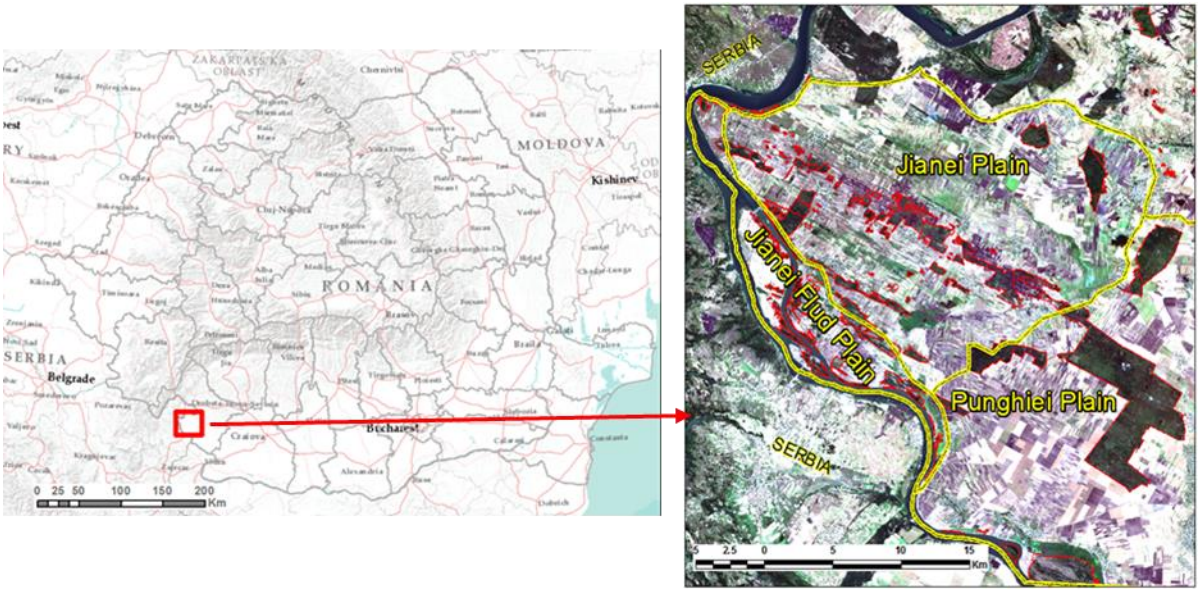

Figure 1 - Location of the study area

2.2. Materials

In order to assess the degree of damage of the forest stands, a methodology for estimating the severity of the forest fires was adopted, using Sentinel 2 satellite images recorded before, during and after the fire events. Additionally, official RGB and CIR aerial orthophoto, captured in 2015 with a ADS80 camera, with a spatial resolution of 0.5 m, were used together with ultra-high resolution orthoimages obtained by processing RGB aerial imagery taken with a DJI Mavic 2 Enterprise Dual drone about a month after the fire events.

Sentinel 2 satellite imagery were downloaded from Copernicus Open Access Hub (https://scihub.copernicus.eu/dhus/#/home). A total of 9 images of 2A processing level (bottom-of-atmosphere reflectance ortho-image product) have been found and used within the study, covering the period between 1st of August and 8th of September 2021, in which most of the forest fires occured. All imagery was stacked by bands (except B1, B9 and B10), clipped for study area and re-projected into Stereografic 1970 *(*national Romanian cartographic projection). For rapid evaluation were picked up two images, one before fire (2021-08-01) and another one after fire was finished (2021-08-11). In Figure 2 is displayed a representative detail from study area on both images.

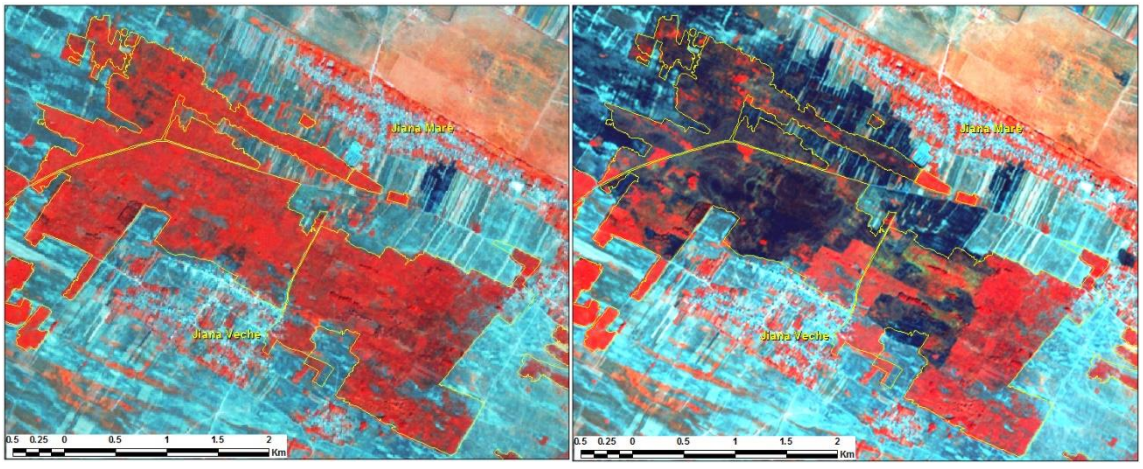

Figure 2 - Sentinel 2 images from study areas: 2021-08-01 (left – before the fire events), 2021-08-11 (right – after the fire events). Color combination: RGB = B8, B3, B2. Yellow line – forest limits

Forest fires incidents reports, containing detailed information about the fire events reported by the forest districts, were obtained from the Ministry of Environment, Waters and Forests. In total there were 8 forest fire events in August 2021 for the study area, totalizing 518.8 hectares of fire affected forests.

Forest management maps and plans were used to inform about the stand characteristics and to delineate the managed forest area within the study site.

2.3. Field data collection

After mapping the severity of forest fires based on satellite images, a field inspection was carried out in order to verify whether the burn severity classes are corresponding to the ground truth impact of the fires. For this purpose, several stands with different degrees of severity and with different characteristics in terms of height and canopy cover were identified on the map of severity degree obtained. The categories of land without forest vegetation, plantations, young, short trees, with height of up to 10 meters and mature trees with a height of over 10 meters, all with low, medium and high densities, were taken into account. They were then visited in the field to estimate of the actual degree of damage. The filed data collection was carried out in October 2021, one month after the forest fires took place.

In order to establish the degree of damage to the stand, a severity scale was developed to systematize and standardize the way it is evaluated according to the visible effects on the ground and on aerial images on the stand, broken down by the size of the stand (correlated with age) and stand density. The burn severity represents the degree or extent of the change in the environment caused by the fire. The change can be represented by simple or multiple biophysical variables on a continuous scale from no change to major changes. No universal standards are defined for describing the severity from an ecological point of view, although there are attempts to structure it in accordance with estimation based on remote sensing methods. For the field estimation of severity, 5 severity classes, similar to Key C.H and Benson N.C., 2006, were considered: unburned, low, moderate-low, moderate-high and high. The severity of fire was visually assed in the field for the four strata: substrate, herbs and low shrubs, tall shrubs and low trees and tall trees assigning a value ranging from 0 (unburned) to 4 (high severity). In total, 40 field plots with a surface of 20X20 meters were established. The classes were adapted to the specifics of the black locust stands from the study region and presented in Table 1.

Table 1 – Synthetic criteria for assessing forest fire severity in the field

Severity class	**Field classification criteria – synthetic description**
unburned	• The soil and the vegetation strata are unaffected by fire Substrates—Inert surface materials of soil, duff, litter, and downed woody fuels.
low	• duff is unaffected • burnt litter and herbs layer, shrub layer and seedling up to 1m high are partially affected • seemingly unaffected plantations • short (young) trees with unaffected foliage • tall (mature) tree with blackened trunks up to 0.5 m
moderate-low	• duff layer is partially affected • burnt litter and herbs layer, shrub layer and seedling are heavily affected • plantations are visibly affected • short (young) trees with the foliage partially dry • tall (mature) tree with blackened trunks up to 1 m
moderate-high	• the organic soil is charred • burnt litter and herbs layer, shrub layer and seedling are charred • the plantations are charred, return possible only after the cutting above the collar • short (young) shrub with crown affected by scorch or girdle • tall (mature) shrub with blackened trunks up to 2 m, the lower part of the crowns affected by scorch or girdle
high	• the soil organic layer is transformed into ash • litter and herbs layer, shrub layer and seedling are transformed into ash • plantations are torched, the stems are consumed by fire • short (young) shrub with crown affected by scorch or girdle, the stems are carbonized • tall (mature) shrub with blackened trunks over 2 m, more than 50% dry or burnt foliage in the upper part of the crown

Representative areas were aerial photographed with a DJI Mavic 2 Enterprise Dual UAV system at the same time with the field sampling campaign and high resolution (i.e., 40 cm) orthoimages were derived. The field observations were used afterwards to adjust the predefined burn severity classes according to the severity classes depicted in the field.

2.4. Image processing

First step was to calculate several remote sensing-based indices recommended by forest fire-science literature using formulas adapted for Sentinel 2 (Mallinis et all, 2018) such as: NBR, NDVI, GNDVI, NBRn, NDVIRE1, NDVIRE1n, CIRE1, MSRRE1, MSR, RE1n and PCA (PC1) for each of both images and, also bitemporal indexes: dNBR, RdNBR, RBR, dNBRn and dNDVI, dPC1. Each result was studied visually, by comparing between them and the satellite imagine from 2021-08-11. Visual inspection of the results indicated that the differenced Normalized Burn Ratio (dNBR) index showed the best results in estimating the fires severity for the study area. The dNBR severity classes were firstly classified according to Key and Benson (2006) thresholds. In Figure 3 the burn severity classes derived from the dNBR index are showed for one of the area most affected by fire.

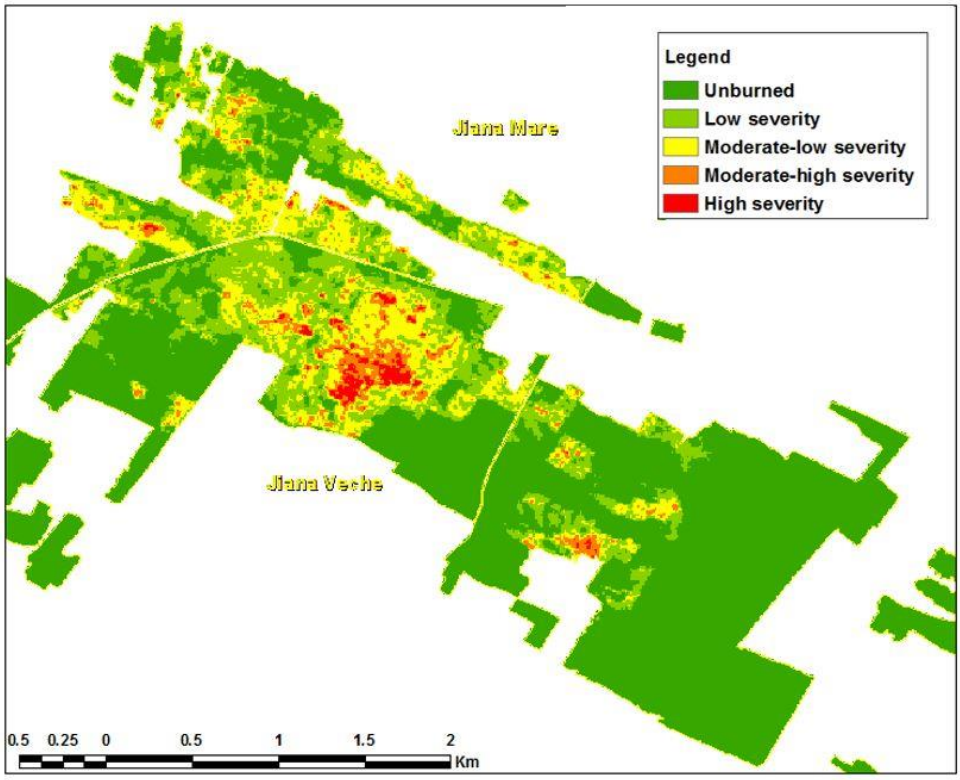

Figure 3 - dNBR: images S2 2021-08-01 (before), 2021-08-11 (post). Yellow line – forest limits

After a detailed visual inspection in accordance with S2 image from 2021-08-11 it was observed that the dNBR thresholds of Key and Benson (2006) are not very appropriate for this area. Consequently, using data collected from the field, the thresholds were adjusted to fit as best as possible the severity classes depicted in the field. In the Table 2 are shown the thresholds used in this study compared with the Key and Benson's thresholds.

Table 2 – The dNBR fire severity thresholds

Key and Benson's thresholds	Thresholds used in this study	Severity class
-0,360 – 0,100	-0,364 – 0,139	Unburned
0,100 – 0,269	0,139 – 0,319	Low severity
0,269 – 0,439	0,319 – 0,456	Moderate – low severity
0,439 – 0,659	0,456 – 0,568	Moderate – high severity
0, 659 – 0,999	0,568 – 0,999	High severity

In figure 4 is presented a detail of the severity map adjusted with the terrain.

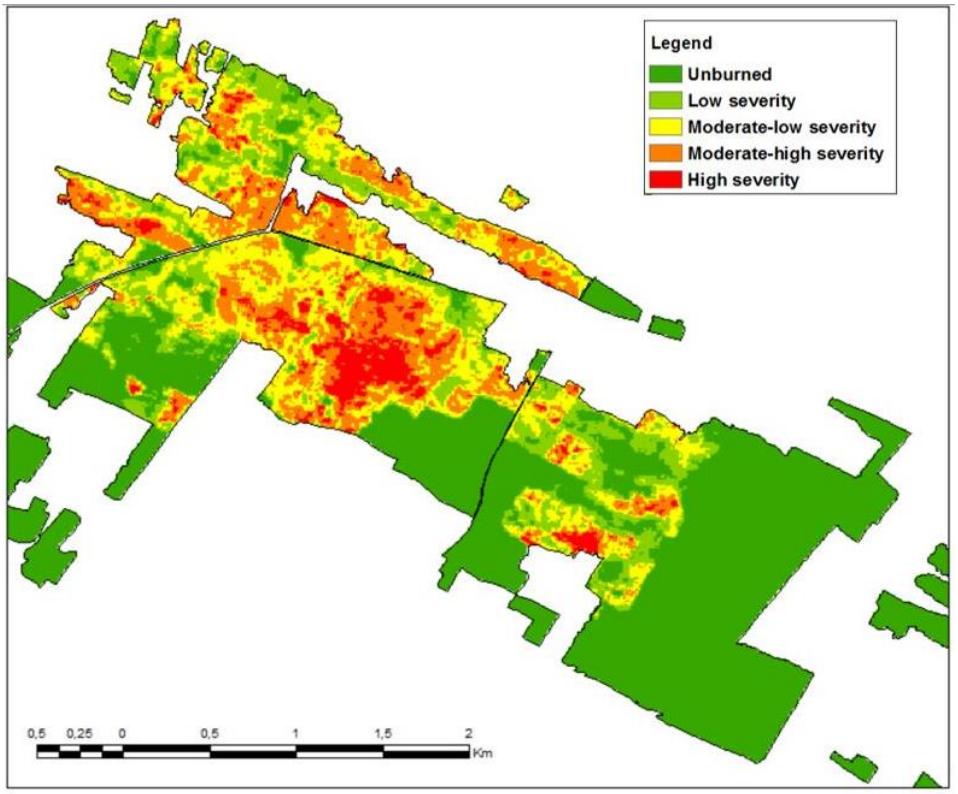

Figure 4 – dNBR: Result of using the adjusted thresholds.Images S2 2021-08-01 (before), 2021-08-11 (post). Black line – forest limits.

First visual inspection of the result, by comparing with S2 image before the fire (see figure 2) and then a field inspection was carried out in order to verify whether the burn severity classes are corresponding to the ground truth impact of the fires, we found that burn severity is in accordance with canopy cover and height of the trees, at least in black locust stands, who naturally have lower canopy cover than other deciduous tree species. The correlation between dNBR and the canopy cover is negative, that means low canopy cover shows a false high severity on dNBR map and vice versa because the burnt grass and understory layer is more visible from above and denser in sparse forest stands. Also, low height of the trees induces high severity on the dNBR, the flames and heat produced by the burnt understory reaching easily to the canopy level.

In order to increase the accuracy of the fire effects map, based on dNBR, a digital map of canopy closure and height of the trees was produced, within GIS environment, based on the aerial, colour infrared (CIR) of 0.5 m spatial resolution captured in 2015. The classes were delineated through manual vectorization and the canopy closure and height classes were visually established through photo-interpretation.

For the height of the trees, three classes were considered, namely plantations (artificial culture of young trees, with the canopy not yet developed), short trees (height below 10 m), tall trees (height over 10 m). The classes were established after it was found in the field that the vulnerability to the fires was inversely proportional to height of the trees. For canopy closure four categories were established: without canopy, low 0.1-0.3, medium 0.4-0.6 and high de 0.7-1.0. The stands with low canopy closure appear to be more severely affected than in reality on satellite images.

It has to be mentioned that for the studied area are not any managements plans and maps to provide such information. Beside this, in the management plans, the canopy cover and height of the trees are given as an average for the entire parcel or subparcel which is not useful for the study. Within figure 5 an example on an aerial CIR image is presented.

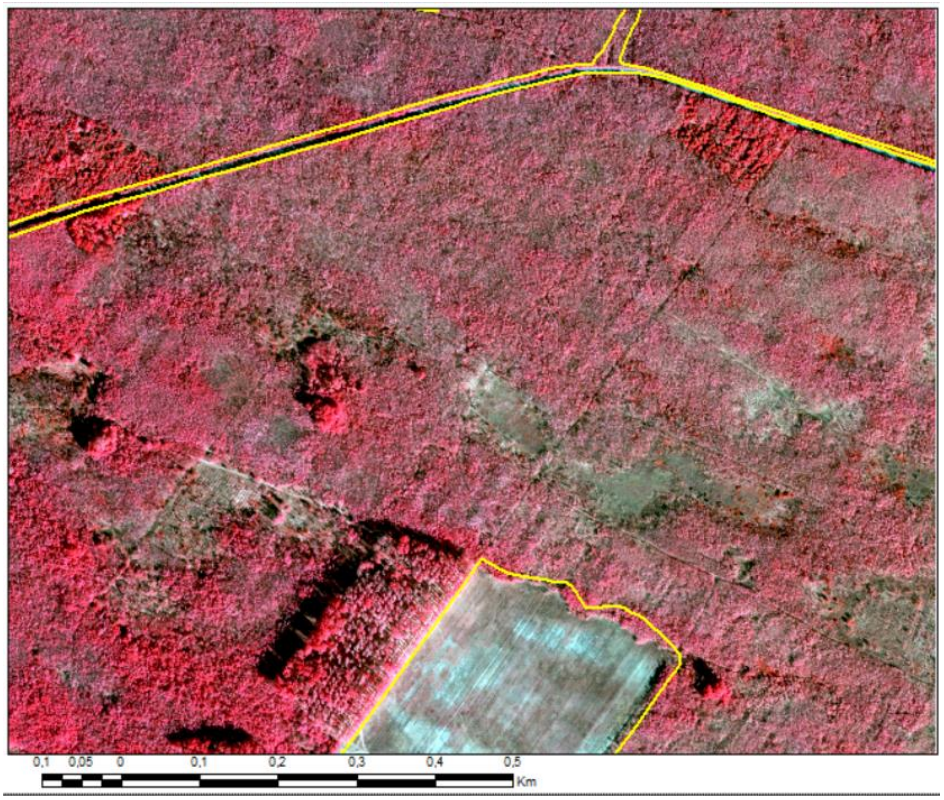

Figure 5 – Aerial image (CIR), 0.5 m, within the area (detail) showing high inhomogeneity of the canopy cover and trees height. Yellow line – forest limits

Moreover, it was found that in the young black locust stands (young trees were considered to be those with a height of up to 10 m, this being the approximate limit to which the heat released by surface fires affects the foliage) are most affected by surface fires (fed by tall, dry grass, litter and sometimes shrub state). Shrubs with an average height of more than 10 m were the least affected, as the thicker bark and the height of the canopy make them less vulnerable. Estimation of severity on images tends to be overestimated in the case of low stands and underestimated in the case of tall stands compared to that estimated in the field. In the stands with a lower canopy closure (as is the case with black locust), the grass developed more, providing more fuel for burning, being seconded by a higher visibility from the air / space of the burned soil. In dense trees, which cover the ground well (in the case of trees with oak species), grass and shrubs do not grow, so the surface fire is fed only by litter and the green canopy can hide the real severity. The estimation of severity on images tends to be exaggerated in the case of rare trees and underestimated in the case of dense trees, compared to that estimated in the field. A special case is the one of the plantations, which are very vulnerable due to their small age (and size), large amounts of fuel (tall, dry grass), which have no canopy and in which the soil is exposed. This is the case where the estimated severity on aerial or satellite images is usually underestimated, as they can be severely affected even by low-intensity surface fires. The presence or absence of fire-affected foliage is the factor that makes the estimation of severity based on aerial / satellite images different from the ground truth severity. This makes the estimate closer to reality in the case of deciduous trees and in leaf-off periods. A key proposal for correcting the estimated severity on aerial / satellite imagery based on the criteria set out above is presented in Table 3.

Table 3. Key for correcting the estimated severity derived from Sentinel 2 imagery (the dNBR index)

Sentinel 2 severity Based on dNBR index	**Plantation**	**Real ground severity correction**					
		Short stand (tree heights ≤ 10 m)			**Tall stand (tree heights >10 m)**		
		canopy cover			**canopy cover**		
		low 0,1-0,3	medium 0,4-0,6	high 0,7-1,0	low 0,1-0,3	medium 0,4-0,6	high 0,7-1,0
1 unburned	unburned	unburned	unburned	unburned/ low severity ↑	unburned	unburned	unburned / low severity ↑
2 low severity	moderate – low severity↑	low severity	low severity	low severity	low severity	low severity	moderate – low severity ↑
3 moderate–low severity	moderate – high severity↑	low severity ↓	moderate -low severity	moderate – low severity	low severity ↓	moderate – low severity	moderate-high severity ↑
4 moderate–high severity	high severity↑	moderate – low severity↓	moderate – high severity	moderate – high severity	moderate – low severity↓	moderate-high severity	high severity ↑
5 high severity	high severity	moderate – high severity↓	high severity	high severity	moderate – high severity↓	high severity	high severity

The dNBR raster map of was converted into a vectorial map of severity (5 classes). This strata was afterwards intersected with the layer representing the canopy cover and the trees height classes. The severity classes were adjusted according to the correction key from Table 3. Within figure 6 it is shown a detail of the new severity map, thus obtained.

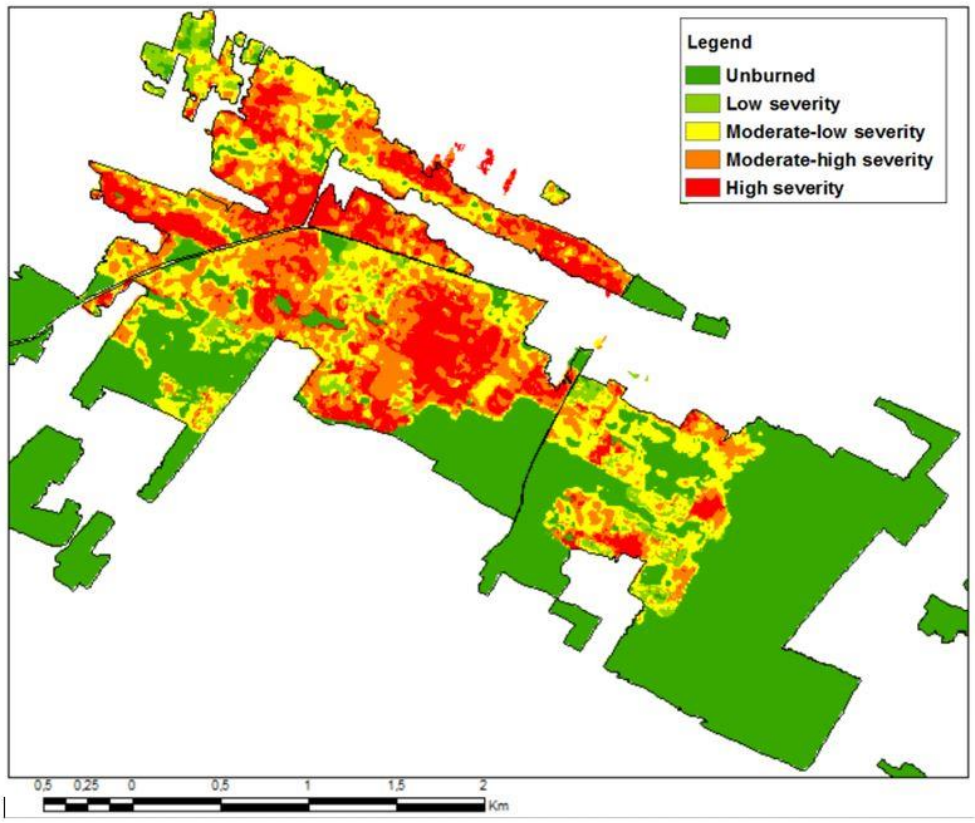

Figure 6 – The new severity map corrected based on canopy cover-trees height map. Black line – forest limits

The final adjusted severity map shows that the severity was lowered in the case of stand with low stand canopy cover considering the fact that the dNBR tends to amplify the severity because the pixels receive much of the signal from the ground level and higher in case of dense and tall stands.

3. Results and discussion

The analysis of different indices found in specialty literature (Llorens, R. et al. 2021, Mallinis G. et al. 2018, Llorens, R. et al. 2021) showed that the dNBR index was the most suitable for burn severity estimation, showing more accurate results, at least for our study area.

The dNBR map shows a severity distribution apparently close to the severity visually estimated on Sentinel 2 image from 2021-08-11 date. A more detailed analyze showed that burn severity depends on the canopy cover and height of the trees, at least in black locust stands, who naturally have lower canopy cover and subsequently canopy density than other deciduous species. This was first observed on Sentinel 2 imagery before fire (2021-08-01), on the aerial imagery (2015-05-30) and also was confirmed in the field. The relation between dNBR and canopy cover confirm that low canopy cover shows a false high severity on dNBR map and vice-versa, due to the burnt grass and understory layer is more visible from above and denser in sparse forest stands. Also, low height of the trees induces high severity on the dNBR, the flames and heat produced by the burnt understory reaching easily to the canopy level. This observation had to be used to adjust the burn severity map. The stands with low canopy cover, but high trees, could have in reality lower severity resulting from dNBR because if only surface fuel is burned and the trees are not really affected, on the imagery the signal coming from ground will be dominant for this spatial resolution and dNBR will be high. Into the dense and taller stands, with the same surface burned severity, the signal will be dominated by canopy, which is less affected. These stands could show on dNBR "unburned severity level", even the real severity could be different (from "low" to "medium-low" or even higher), if the upper canopy was not affected. Concerning low height forest stands with, the situation will be different even if density is high or low, because the tree crowns could be highly damaged by surface fire and the severity could be high, which is not the case of high trees stands. In the case of other tree species from the area, like Scots pine (*Pinus sylvestris*), the effect was more serious, stands were burned up to the top and severity put into evidence by dNBR was closer to the reality. Gibson et al. (2020) also found, using Sentinel imagery to evaluate the fire severity in eastern Australia that higher canopy cover and higher topographic complexity was associated with a higher rate of under-prediction, due to the limitations of viewing the burnt understorey of low severity classes. In terms of the fire affected area, we found that the affected area reported by the forestry districts was close to that obtained from Sentinel 2 imagery.

Concerning the forest surface affected by fires, a total of 8 fire incidents were reported by the forestry districts for the study area between the period of 04-11 August 2021 with a total forest affected surface of 518.8 ha. Our satellite imagery analysis showed that in total there were affected 756,3 ha, thus resulting an underreported surface of 237.5 ha. A one-to-one evaluation comparison of each forest fire incident in terms of affected area could not be carried out due to the relatively low temporal resolution of the Sentinel imagery (i.e., 5-day revisit time) and because it was hard to distinguish on imagery with high confidence what was the surface affected by each fire because some of the fire merged together in a single, bigger one.

4. Conclusions

Sentinel 2 imagery can by successfully used to estimate the burned area and the burn severity in stands dominated by black locust. For a more accurate estimation of burn severity levels for black locust stands more situations need to be considered in terms of density cover and height of the trees. Moreover, the study reveals only a first step for the assessment of the areas affected by fires, presenting a quick and robust enough assessment method.

Rate of spread, DGVM, fuel characteristics, Europe, forests

Abstract

Rate of spread (RoS) is a key determinant of a fire regime and rate of spread models have a long tradition in fire research. Initially they were used to assess fire risk on a local to regional scale. Latest approaches combine them with scalable models to investigate fire risk globally. However, correctly simulating RoS across large spatial extents requires good knowledge of how fuel characteristics vary across the region of interest. For this purpose, both observed fuel characteristics and effective model representation of the characteristics are indispensable. To facilitate investigation of RoS dynamics and fuel characteristics, dynamic global vegetation models (DGVMs) can link vegetation characteristics (e.g., biomass composition, vegetation type) to fuel characteristics and simulate rate of spread over various spatial and temporal scales. Earlier studies compared rate of spread models for various sites of different biomes. Insights in site specific performance thereby supported decision-making regarding the choice of the model. Here, we address this issue for modelled forest types and biomes across Europe incorporating fire-vegetation interaction by a DGVM. We investigate two common rate of spread models: The widely used Rothermel rate of spread model (Rothermel, 1972) as well as a related modified approach proposed by Wilson (1990). Using the global dynamic vegetation model LPJ-GUESS with the fire module SPITFIRE, we show that the two RoS models lead to substantially different rates of spread and area burned in some parts of Europe, while the differences are small in other parts. After further evaluation, such results might guide the choice of RoS model for different regions.

1. Rate of spread models

The study investigates two rate of spread (RoS) models: The Rothermel's Rate of Spread model (Rothermel, 1972) and the related modified approach proposed by Wilson, (1990). In both models, the rate of spread is represented by ratio of the heat received by unburned fuel from the flame (power density of propagation flux) to the heat required to ignite the unburned fuel (Rothermel (1972); Wilson (1990)). More specifically, the rate is calculated by the reaction intensity I_R times the propagation flux ratio ξ, divided by the overdry bulk density ρ_b, the effective heating number ε and the heat of ignition multiplied by a term that includes the wind factor ϕ_W and a slope factor ϕ_S. Both lead to a higher rate of spread in steep terrain where fuel in the upper part is more exposed to flames from further below, as well as forest fires that propagate rate of spread based on flame-exposing down winds.

$$RoS = \frac{I_R \cdot \xi \cdot (1 + \phi_W + \phi_S)}{\rho_b \cdot \varepsilon \cdot Q_{ig}}$$

While the overall equation structure seems quite similar between the Rothermel and Wilson formulations, the rate of spread models differ in the definition and interpretation of the parameters listed above. Main differences can be found in the reaction intensity, propagation flux ratio, and heat of ignition (Weise & Biging, 1997; Wilson, 1990).

The reaction intensity I_R is a measure of energy release per unit area within the combustion zone (Rothermel, 1972; Wilson, 1990). Rothermel interprets this variable as the rate of change of organic matter from a solid to a gas. The approach of Wilson narrows this term focusing on the energy release of the flames driven by

pyrolyzed gases only (explicitly excluding energy release from burning char). Minor additional changes of Wilson are the exclusion of the optimal packing ratio in the reaction velocity. Furthermore, fuel moisture is no longer included in the reaction intensity as a source of fire extinction. Instead it affects the rate of spread as a separate term by a probability function.

The propagation flux ratio ξ represents the proportion of the fires power that drives the fire (Rothermel, 1972; Wilson, 1990). Both approaches, Rothermel's and Wilson's, are based on fitted equations, related to field data of surface to volume ratio σ and the packing ratio (measure of how dense fuel is spatially distributed). The equation provided by Rothermel is mainly dependent on σ, as it is considered as a nonlinear driver in multiple equation terms. Wilson aims to simplify that equation based on physical principals of energy transport.

Originally, Rothermel relates the heat of ignition Q_{ig} to the change in specific heat from ambient to ignition temperature and the observed latent heat of vaporization of the moisture (Rothermel, 1972). In turn, Wilson approximates this heat dependent on observations of heat for pyrolysis and heat of vaporization measured in the field (Wilson, 1990).

2. Modelling concept and simulation setup

In this study we use the dynamic global vegetation model LPJ-GUESS, which integrates eco-physiological processes, such as photosynthesis, autotrophic and heterotrophic respiration, and plant growth with individual-based tree population dynamics and biome biogeography (Smith, Prentice, & Sykes, 2001; Smith et al., 2014). The detailed representation of vegetation dynamics enables insights in local forest ecosystem composition as well as large scale spatial trends of vegetation - bridging the gap from stand level to continental scale.

The rate of spread equations are implemented in the fire-enabling module SPITFIRE (SPread and InTensity of FIRE, (Thonicke et al., 2010)). The process-based fire model explicitly considers fuel characteristics by combining environmental fire drivers and linking vegetation traits to fuel class characteristics (fuel classes are live grass and dead 1hr, 10hr, 100hr fuels). SPITFIRE has been proven to be a useful tool to explore fire regimes explaining broad geographic patterns of annual fractional burnt area. For instance, in combination with the LPJ DGVM, the fire regime of boreal forests could be investigated in more detail (Thonicke et al., 2010). The SPITFIRE fire modelling approach has been adopted by several DGVMs, e.g. Yue et al. (2018). Most recently, SPITFIRE has been integrated in LPJ-GUESS (Smith et al. 2014, Forrest et al., (in prep.)), which has been used here. The model was run without land use, i.e. the potential natural vegetation was simulated.

The model setup includes global plant functional types (PFTs) simulated across Europe from 1700 to 2018. While fire processes in LPJ-GUESS SPITFIRE are simulated daily, vegetation dynamics are updated annually. Climate forcing was provided by the daily CRU-JRA data at a 0.5° resolution. This dataset includes monthly maximum and minimum air temperature, precipitation, wet days, wind, and cloud cover from the CRU database (Harris, 2019) merged with a reanalysis product (Harada et al., 2016; Kobayashi et al., 2015), which provides the sub-monthly temporal disaggregation. Slope was not considered.

3. Simulated fire patterns

In this study we compared the rate of spread based on Rothermel (RoS_R) and on Wilson (RoS_W) simulated by LPJ-GUESS. Overall, the RoS_W was higher than RoS_R (Fig. 1), but the differences were generally low between 45 and 55 degrees north. Deviations regarding the underlying calculation increased from Central to Northern Europe. In Southern regions (e.g., Portugal, Western Spain and Greece) comparison also showed spatial clusters in which RoS_R was higher (Fig. 1).

Similarly, to the rate of spread, the fraction of burned area of Wilson was higher than that by Rothermel (Fig. 2). The general pattern of burned area in Europe (with most fires in Mediterranean areas (Chuvieco et al., 2018)) was reproduced by both approaches, but there also exists clear discrepancies between the satellite-derived estimates and the model results. For example, the Rothermel approach has resulted in too sparse burning in Eastern Europe (Fig. 2). In turn, the mountain regions in northern Italy and Sweden are much more pronounced.

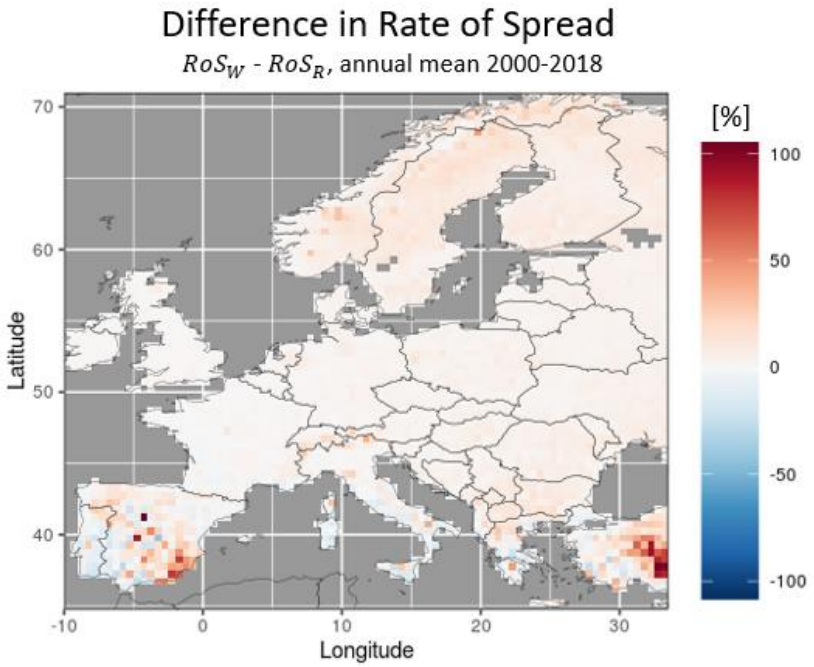

Figure 1- Percentage difference in mean annual rate of spread. Red pixels indicate a higher rate of spread for the Wilson approach than for Rothermel's, blue pixels indicate a lower one.

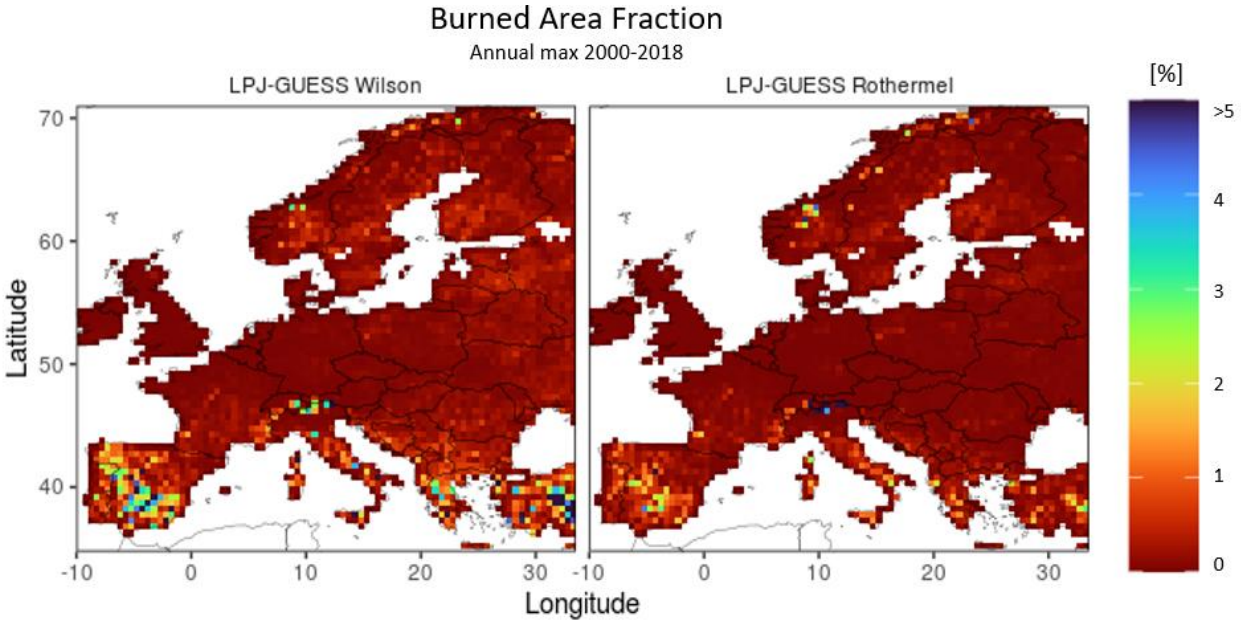

Figure 2- Simulated burned area fraction.

4. Discussion

When embedded in the LPJ-GUESS DGVM, the two RoS models lead to substantial differences in terms of RoS and area burned in some parts of Europe, while the differences were minor at intermediate latitudes. Where the differences are large, the choice of RoS model becomes more crucial. Further evaluation of model results will be necessary to derive suggestions for which model should be used were.

To use the full potential of the coupled vegetation-fire modelling approach, another important next step will be to use the vegetation model with a more regional vegetation representation of Europe (e.g. Hickler et al., 2012)

and land use. Only with the actual vegetation in the vegetation model, a detailed evaluation, e.g. of the area burned presented here in Fig. 2, makes sense.

The choice of the RoS model should also depend on regional data to parameterize the RoS model. The equations of Wilson (1990) were parameterised about two decades after Rothermel's first calculations (1972), with more data points included by that time. Therefore, Wilson's function coefficients might have a higher accuracy for the region where the model has been parameterized. However, since the Rothermel model has a long tradition in forest fire research, many observational data are still tailored for the original Rothermel approach.

Abstract

Accounting for multiple changing systems in environmental decision making is challenging and requires balancing several competing priorities. In fire risk, one approach which is increasingly used to capture uncertainty within multiple systems and to prioritise management efforts is Bayesian Network (BN) analysis. Here, we have used a BN to understand the interactions between ignition likelihood, containment probability, fire behaviour, and fire weather, alongside the subsequent risks to people and property. We developed, populated and tested a BN which classifies the likelihood of outcomes for each of these systems. We then apply this BN to grid of 72,000 potential ignition locations accross Victoria to predict house and life loss values under conditions capturing the top ten worst ranked weather days in the history of each location. We use Phoenix fire behaviour simulations and landscape scale raster data to populate the parent nodes for each ignition and extract the expected values for predicted nodes under different weather scenarios and varying levels of suppression. We found values predicted by the BN broadly matched the spatial patterns of risk produced in Phoenix i.e., areas where risk was highest and lowest in terms of fire area and house loss aligned. However, the values are rescaled by the BN as it takes into account the influence of ignition likelihood and containment probability on risk estimates. The BN is also able to capture uncertainty around the values presented from across the top ten Phoenix simulations, so the recorded values represent the likely outcome for each node given the range of potential weather conditions in those scenarios. We show that BNs can be a useful management tool for estimating fire risks across a range of weather scenarios and locations while still considering ignition likelihood and suppression effectiveness.

1. Introduction

Fire is a globally significant environmental disturbance which increasingly presents risk to people, property, infrastructure, and biodiversity (Banks et al. 2011; Moritz et al. 2014; Filkov et al. 2020; Borchers Arriagada et al. 2020; Higuera and Abatzoglou 2021). Managing wildfire risks is complicated as decision makers need to account for several interacting systems which may vary spatially and temporally (Thompson and Calkin 2011; Penman et al. 2020).

Weather conditions conducive to ignition and spread, as measured by both temperature and the forest fire danger index (FFDI; Noble et al., 1980), are expected to increase under climate change (Olson et al. 2016; Clarke and Evans 2019). Therefore, improved understanding of ignition likelihood will provide managers with some of information about where and when potential wildfire risk is highest. Additionally, understanding the factors that contribute to containment probability is also essential as suppression efforts play a critical role in limiting wildfire spread and reducing risk to people and assets (Penman et al. 2015; Dunn et al. 2017). The likelihood of ignition and containment both intersect to influence how a fire spreads and the potential risk it poses to lives, infrastructure, property, and biodiversity.

Current wildfire management frameworks in Australia generally only consider containment probability and ignition likelihood in isolation and do not account for interactions between them. This makes it difficult for managers to prioritise areas of highest concern for different fire weather or environmental conditions. One tool that is increasingly being used to support environmental decision-making within multiple systems is Bayesian Network Analysis (Penman et al. 2011, 2014, 2020; Hradsky et al. 2017; Marcot and Penman 2019). Bayesian Networks (BNs) are statistical tools uniquely capable of managing the suite of uncertainties which arise in complex environmental systems, making them ideal for risk analysis research (Pollino et al. 2007; Dlamini

2010; Johnson et al. 2010; Johnson and Mengersen 2012; Kelly et al. 2013). A major advantage of using a BN in structured decision making is that it allows the use of data from multiple sources on different scales (Pollino et al. 2007; Penman et al. 2014; Marcot and Penman 2019). They can also be applied at various spatial resolutions which is an important aspect of managing risk, particularly for disturbances such as fire which impact both local and landscape scales.

Here, we aimed to understand how ignition likelihood, containment probability and subsequent fire behaviour impacts the distribution of wildfire risks across the state of Victoria, Australia. We build, parameterise, and test a Bayesian Network to answer two questions 1) how are the risks to people and property distributed across the state given a range of weather scenarios? and 2) how do ignition likelihood and containment probability influence the distribution of these risks for a range of weather scenarios? We combine our Bayesian Network with PHEONIX Rapidfire (hereafter Phoenix; Tolhurst et al. 2008) fire behaviour simulations. Phoenix is an application which simulates one or more fires using a characterisation model to capture the details of fire spread such as flame height, rate of spread and ember production etc. Here we use Phoenix simulations to generate fire impacts for ignitions across the landscape and to compare current risk estimates, which do not consider the likelihood of ignition or containment, with our estimates of risk from a Bayesian approach.

2. Model framework

Our modelling framework involved three key stages. First, we developed a conceptual model combining ignition likelihood, containment probability and fire weather to predict risk to houses and lives accross a range of scenarios and landscapes. This conceptual model (Figure 1) includes two random forest models fit to state wide datasets of historical ignition events and suppression efforts in Victoria. We took the top six most important variables from each of these models to include in our Bayesian Network. The second stage of our modelling framework expands the conceptual model into an influence diagram capturing the variables important to each of our sub-models, and from our Phoenix fire behaviour simulations, as nodes in our network. Lastly, we populated the conditional probability tables within the model using real data to learn the relationships between nodes through Bayesian inference (Korb and Nicholson 2010).

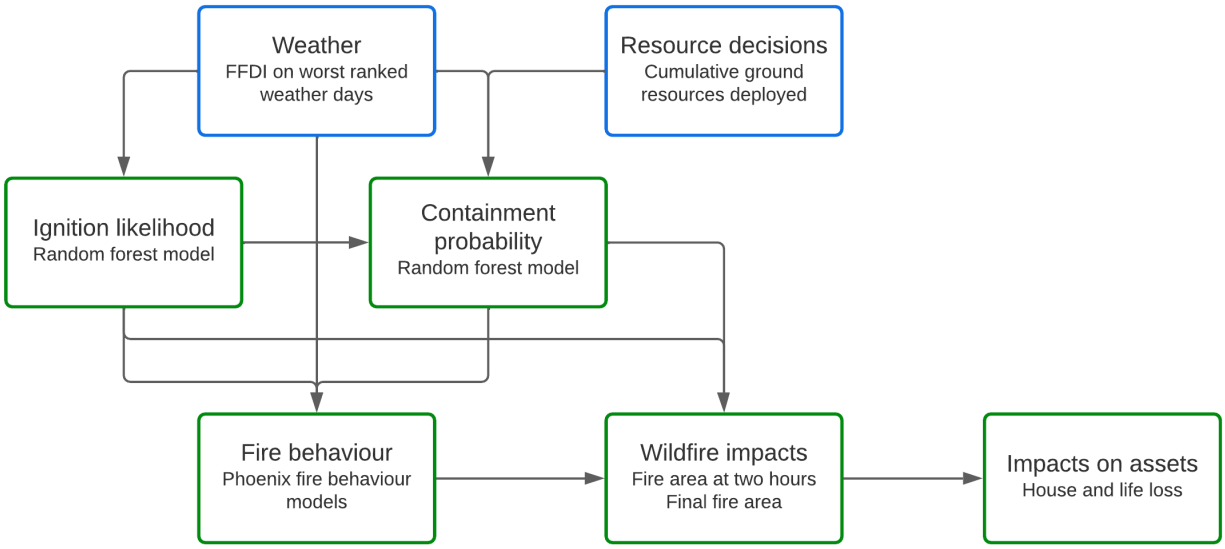

Figure 1: Conceptual model underlying the final Bayesian Network used in this study. Green boxes show sub-models and output nodes in the network. Blue boxes show decision nodes in the network.

We applied the network in R (version 3.6.2) to 71808 ignition locations across Victoria. Data on the top 50 FFDI values in history observed at each ignition location was provided by the Victorian State Government's Department of Environment, Land, Water and Planning (DELWP), who also provided us with Phoenix fire simulations under the top ten of these 50 FFDI values. To apply the BN to these locations we cycle through all locations individually. Using the FFDI values, and ten example Phoenix runs, we set the probabilities of getting each FFDI, fire area, fire area at two hours, and house loss value at that location. For each location we extract the predicted ignition likelihood, and containment probability, alongside the rescaled fire area at two hours, final fire area, house, and life loss. We compare the outputs from our BN to those

produced by Pheonix runs to determine whether accounting for containment probability and ignition likelihood, as well as the range of possible phoenix outcomes, influences the predictions of risk.

3. Results and implications

The estimates of fire risk produced by Phoenix and those predicted by the BN are spatially consistent. The ignitions with the largest predicted fire area tend to occur in the same locations in both methods and therefore hotspots are easily identified using either approach. However, the BN produced rescaled values when considering the likelihood of ignition and probability of containment in its risk estimates for some areas. The fire area values, as well as the predicted house loss and life loss were far lower in the BN as compared to Phoenix. The extent to which values were rescaled also varied across the state (Figure 2). When considering ignition likelihood and containment probability the greatest reductions in fire area occurred in the north west and eastern parts of Victoria (Figure 2; A). Probably because ignition likelihood is lower in these areas as they are less populated and prone to human ignitions. Comparatively, house loss declined most in the central areas of Victoria close to the major settlements of Melbourne and Geelong (Figure 2: B). This is probably because ignition likelihood is lower than expected by Phoenix and suppression efforts are most targeted and effective in these areas. Areas with little change in house loss indicate either low predicted values using both methods or little effect of ignition likelihood or suppression on outcomes. This could provide managers with a useful tool for prioritising allocation of suppression resources to these areas.

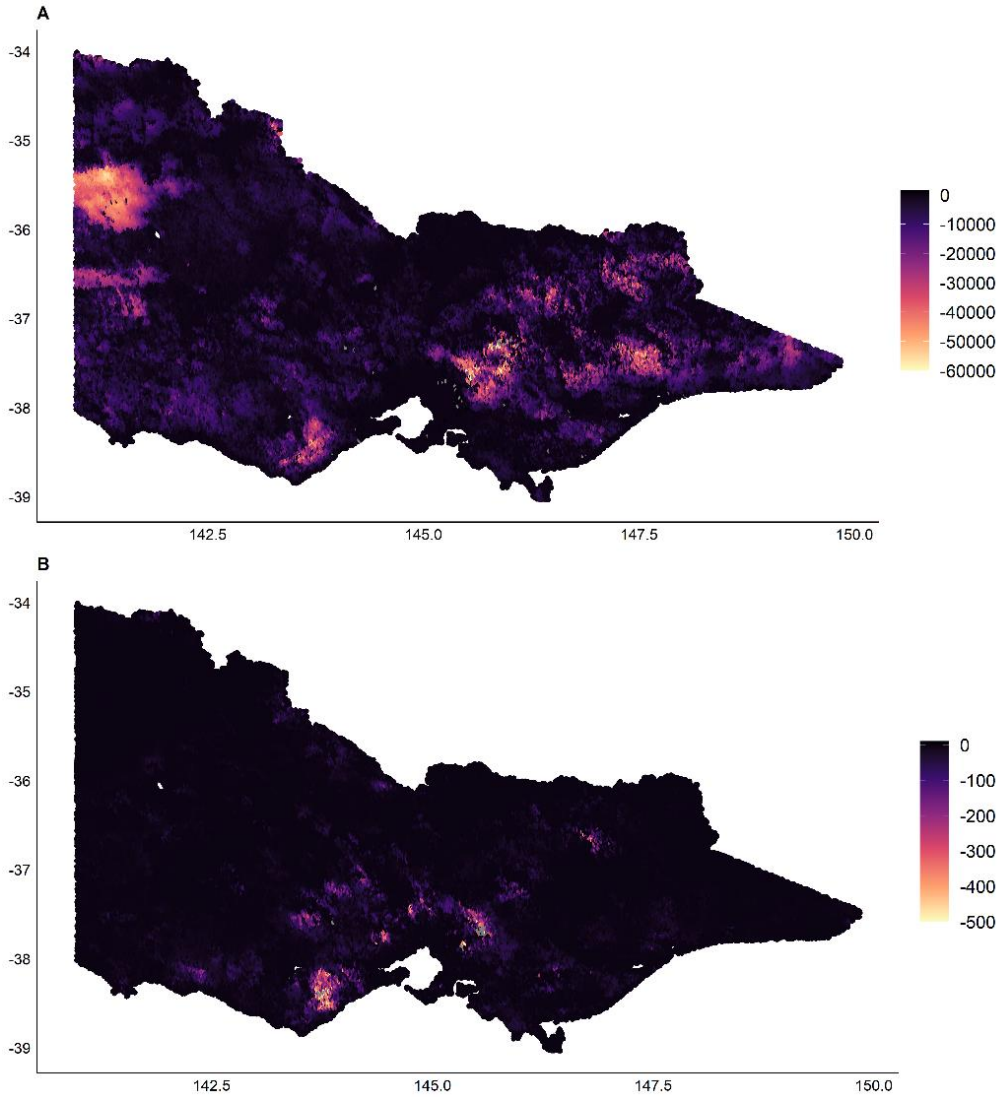

Figure2: Maps showing where the values predicted by Phoenix were different compared to those predicted by the BN for Final fire area (A) and house loss (B) nodes. Negative values indicate the Phoenix predicted values were higher than those predicted by the BN. The colours indicate the extent of these differences accross the state with dark purple indicating no or little change and light yellow showing the maximum predicted change.

4. Conclusions

Our results highlight the importance of considering multiple systems in fire risk analysis. Ignition likelihood and containment probability, as well as the environmental variables and management decisions which may influence these systems, provide essential insight into where in the landscape fires may be most impactful. While the results of our BN broadly matched the spatial patterns produce by Phoenix, the rescaled values, and the spatial differences in where rescaling was most pronounced, may offer managers nuanced insights into where resources may be most needed or most effective. This approach is also able to better account for uncertainty in multiple competing systems and can be applied to a wide range of weather scenarios and management decisions. Applying a more holistic approach to fire risk analysis will be required in the future as climate mediated shifts in ignition likelihood and fire behaviour change the patterns of fire risk to people and property. Understanding these changes will allow managers to better allocate resources to fuel management and suppression efforts.

Abstract

Spatial wildfire ignition predictions are needed to ensure efficient and effective wildfire response but robust methods for modelling wildfire occurrence have not been fully evaluated. Here we leverage high resolution, static spatial data to predict the ignition locations of human and naturally-caused wildfires across the state of Montana (USA). We leveraged a 25-year historical wildfire dataset (1992-2017) and four high resolution spatial variables that capture fuel availability, topography, geographic location and human transport infrastructure. We combined these data to train spatial logistic regression Generalized Additive Models (GAM) designed for big datasets (BAM) for both human and natural ignitions and we tested the efficacy of incremental changes in model complexity. Results showed that the best human and natural-caused ignition models were highly capable of distinguishing locations with and without new wildfire occurrences statewide (AUC = 0.89 and 0.84 respectively). Natural-caused ignitions were strongly influenced by slope and location, while human-caused fires were best predicted by distance to roads as well as terrain and fuel availability. Finally, these spatial fire occurrence models can be combined with temporally-variant data to predict the spatial and temporal distribution of wildfires across the state with the view that these methods can be used to develop predictive models at larger scales.

1. Introduction

Wildfires are present in all vegetated environments worldwide (Krawchuk et al. 2009; 2011; Archibald et al. 2013), where they would otherwise be beneficial, are suppressed to limit or prevent immediate human-related loss (Riley et al. 2018). Although effective wildfire planning requires early information about where new ignitions are likely to start (Belval, Stonesifer, and Calkin 2020), this information is generally not available at high spatial resolution.

New wildfires start when there is an ignition source, sufficient fuel and suitable weather conditions. Natural ignitions are mainly caused by cloud-to-ground lightning strikes and depend on the timing and lightning characteristics in relation to fuel condition (Mitchener and Parker 2005; Schultz et al. 2019). Negligence causes are the most common ones (Prestemon et al. 2013) being favored by road networks (Faivre et al. 2014; Benefield and Chen 2022). Therefore, differentiating the spatial distributions of wildfire ignitions is crucial to designing and implementing source-specific prevention and mitigation strategies.

Wildfire ignition likelihood may be modelled if proxies are included to represent the fuels, weather, topography and human presence that control their spatial distribution (Barreto and Armenteras 2020). Although fuels are seasonally dynamic, static factors such as loading and continuity may limit the wildfire location where insufficient fuels prevent propagation (Briones-Herrera et al. 2019). Road networks affect fire activity in two

ways: first, making wildlands accessible to humans, thus promoting anthropogenic wildfire ignitions (A. Syphard et al. 2007; Narayanaraj and Wimberly 2012); and second, roads enable ground-based firefighting resources to quickly respond to new events (Thompson, Gannon, and Caggiano 2021). Thus, if ignition sources are differentiated and adequate spatial biophysical-demographic drivers are identified, wildland fire ignition likelihoods could be modeled, mapped and predicted across large areas.

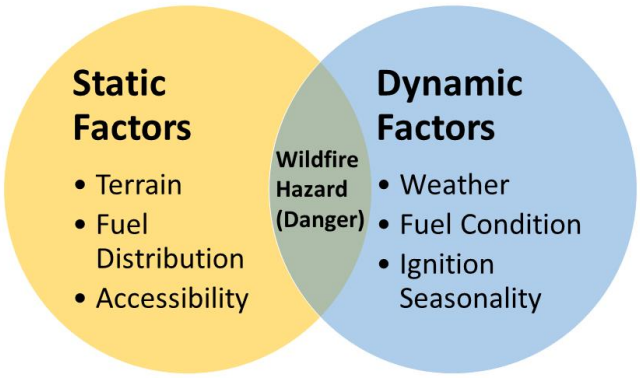

Figure 1. Conceptual scheme of the dual component of wildfire hazard or danger: the static factors and the dynamic factors.

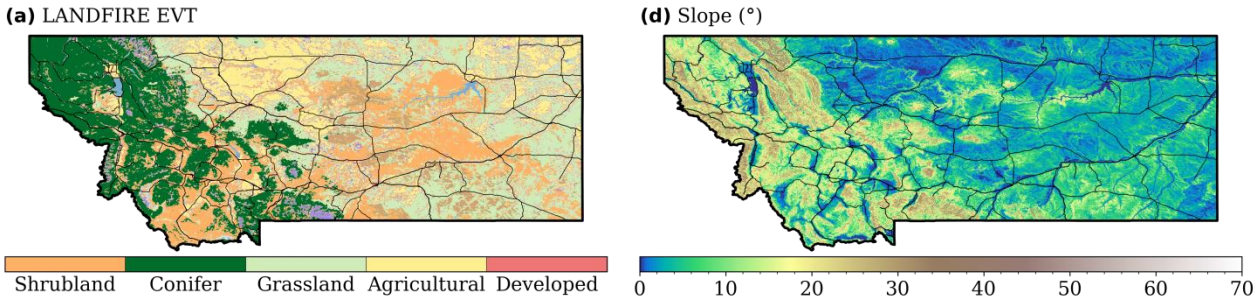
In this study, we develop and evaluate several spatial models of wildfire occurrences to predict ignition likelihood across the state of Montana (US). To do this, we focus solely on constructing static ignition models by combining fire records with a suite of temporally invariant factors (Figure 1). We evaluate the efficacy of increasingly more complex models to map human and natural ignition probabilities. Our main objectives are: a.) to evaluate the contribution of different environmental-human factors considered crucial to wildfire ignition, b.) select the best predictive models' parameters configuration, and c.) map static human-natural wildfire ignition likelihood.

2. Material and Methods

2.1. Study area

Montana covers an area of 376,962 km^2 and it is characterized by west-to-east gradients in climate, topography, vegetation cover and wildfire causality (Figure 2).



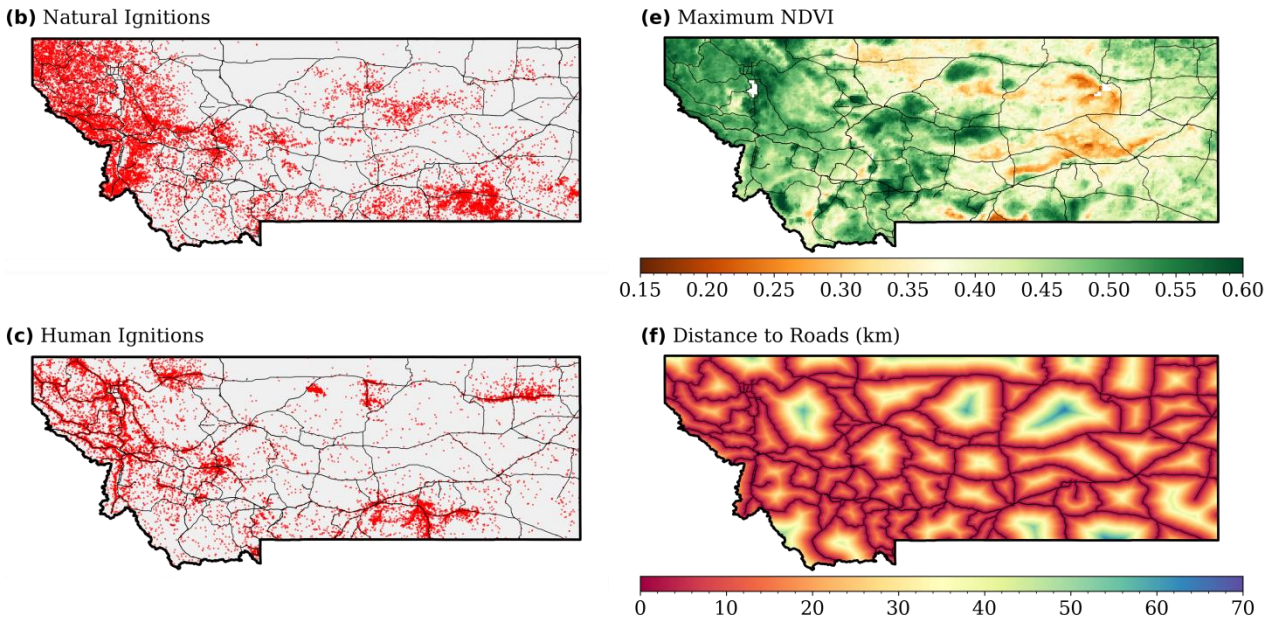


Figure 2. Maps of Montana shown with the road network. (a) Existing Vegetation Type (EVT). (b) and (c) Locations of natural and human ignitions (1992-2017). (d) Slope. (e) Maximum NDVI (1996-2017). (f) Distance to roads.

2.2. Data preparation

Wildfire point records from 1992-2017 were obtained from the Fire Program Analysis Fire-Occurrence Database (Short 2014), containing geographic coordinates of the origin, discovery date, ignition cause and final fire size. Wildfires were partitioned according to their causality (natural or human, excluding the unknown). The dependent variable (presence-absence) was obtained from the 30m binary masks of new wildfire reports. Several static potential covariates were explored (Figures 2d - 2f). To represent fuel availability, smoothed rasters of NDVI were retrieved from the Blended Vegetation Health Product (Kogan 2001; Yang, Kogan, and Guo 2020). Maximum-NDVI was chosen to capture the peak amount of above ground live biomass (Xu et al. 2012). Topography was represented by slope, obtained from the 30m resolution Digital Elevation Model (Rollins 2009). Distance from roads was used to represent accessibility, by downloading a road shapefile from the United States Census Bureau (US Census Bureau 2015), and creating a raster of distance to roads at 30m resolution.

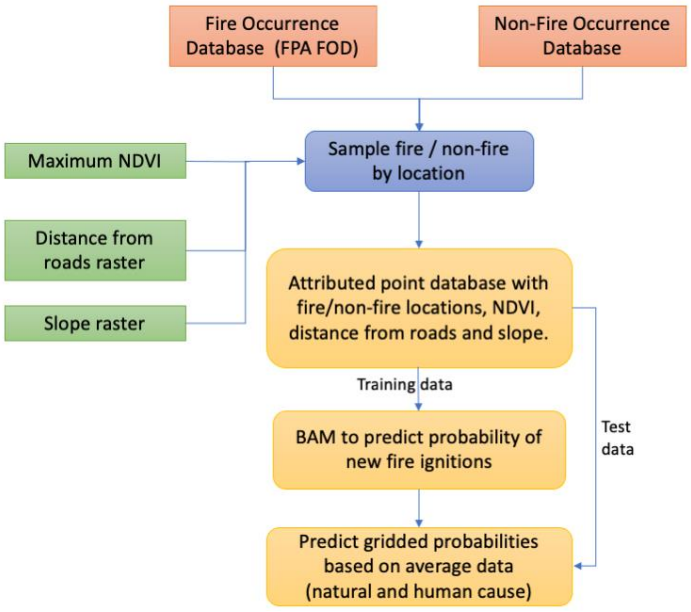

Figure 3. General workflow for model building and evaluation including inputs, sampling of wildfire presence-absence, extraction of covariates, creation of a point wildfire database, model fitting, and the final spatial predictions of wildfire ignition probabilities.

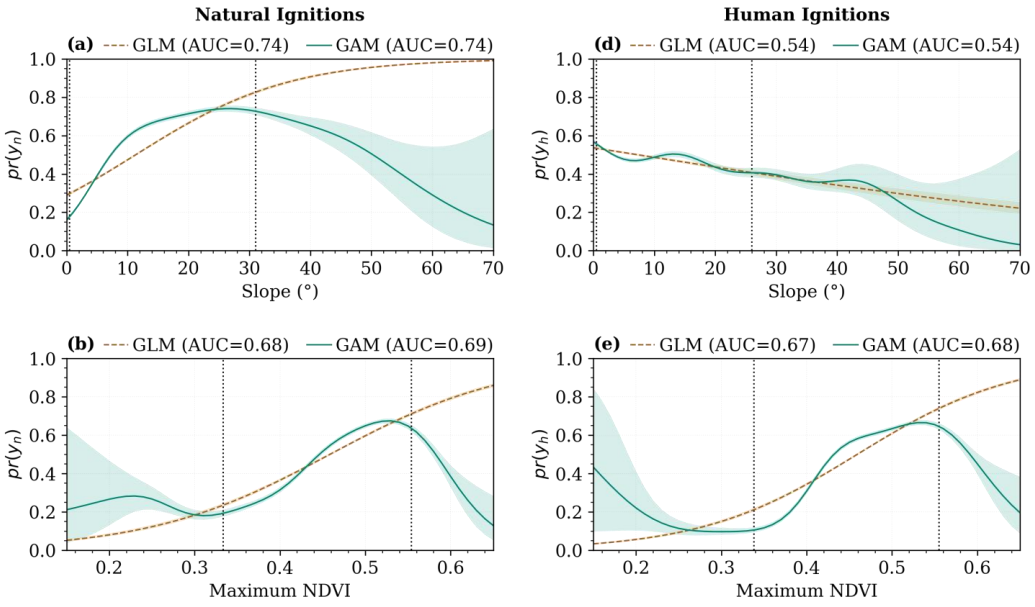
The datasets used were derived from the presence/absence masks of wildfires and the covariables' rasters (Figure 3). First, presence only datasets were created by using the grid cells containing a new wildfire report. This produced two presence only datasets (one for cause), together with their associated value for slope, maximum-NDVI, distance to roads and longitude-latitude. The presence only datasets were then split into training (70%) and testing (30%) datasets. Absence only datasets were created by randomly selecting grid cells from the binary masks at locations without any wildfire recorded. To provide balanced datasets, the number of absence grid cells was equal to the number of presence ones. After using the absence grid cells to extract the covariates, the absence only datasets were themselves spit again into training and testing datasets. Combining the presence and absence datasets for each ignition source yielded four datasets: the natural-caused training and test datasets, and the human-caused training and test datasets.

2.3. Model construction and evaluation

We included Generalized Additive Models (GAMs) (A.D. Syphard et al. 2008; Bar Massada et al. 2012) apart from Generalised Linear Model (GLMs), since the former overcomes the apriori assumption of linearity by replacing the linear terms with smoothed (Vilar et al. 2010). In this work, a suite of logistic-GLMs/GAMs were built in R (R Core Team 2021), starting with simple logistic-GLMs/GAMs to examine the isolated effects, using slope, maximum-NDVI and distance-to-roads as the sole explanatory variables. Then covariates were procedurally added using the default basis dimension (k = 10) to create increasingly more complex models with the goal of achieving the best fit with the fewest explanatory variables necessary. Additional variables were retained if they were statistically significant and if the percent deviance explained increased by more than 0.1%. Once added, the basis dimension in the spatial-GAM were iteratively increased to ensure that the smoothed terms had sufficient degrees of freedom without being overly complicated or computationally intractable. After fitting the models, each one was applied to the held back testing datasets to predict the natural and human-caused wildfire probabilities. Receiver operating characteristic (ROC) curves (Bradley 1997) and the area under the ROC Curve (AUC) were used to assess the models accuracy.

3. Results

Simple logistic-GLMs/GAMs built with one covariate illustrate the isolated effects of slope, maximum-NDVI and distance-to-roads on the probability of a new wildfire ignition (Figure 4). In contrast to the GLMs, the GAMs capture nonlinearities in the response, particularly at the lower and upper limits of slope and maximum-NDVI. Although there are strong differences between the GLM and GAM fits at the extremes, only a small fraction (5%) of the natural and human-caused ignitions in the training data had a slope >30º or a maximum-NDVI > 0.56. Moreover, both (GLM and GAM) fits exhibit monotonic behaviour over most of the range of the covariates, thus obtaining similar AUCs.



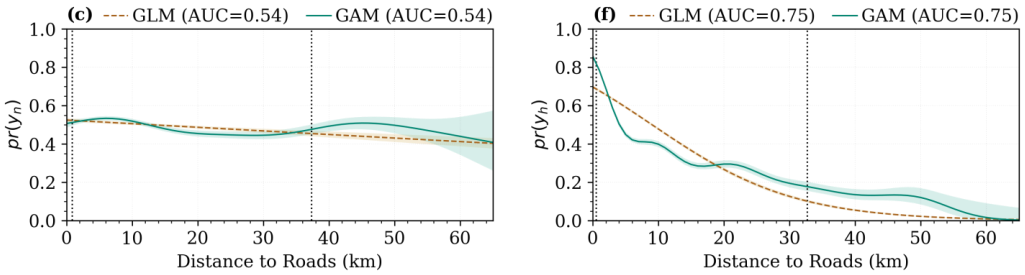


Figure 4. Simple General Linear Models (GLMs) and simple General Additive Models (GAMs) built with one covariate to predict the probability of natural ignitions (left column), and human ignitions (right column). The dotted vertical lines indicate the 5th and 95th percentiles of the covariates and capture 90% of the training data.

In the simplest version, all covariates were statistically significant ($p \leq 0.01$) and the percent deviance explained increased when spatial coordinates were added. However, whereas all variables were significant in the spatial-GAM of human-caused ignition probability, distance-to-roads was not significant in the spatial-GAM of natural ignition probability and was therefore excluded (Table 1). Initiating spatial-GAMs, the basis dimensions (k) were iteratively increased for all the smoothed terms. However, for slope, maximum-NDVI and distance to roads this had little effect on the percent deviance explained compared to the values of k for the geographic coordinates. Ultimately, the basis dimension for the smoothe geographic coordinates was increased until k = 50 and k = 35 for the natural and human-caused ignition models, respectively.

Table 1. Development from the General Linear Model (GLM) to the General Additive Model (GAM) and spatial-GAM. Formulas are presented, where α is the intercept, υ1= slope, υ2= maximum-NDVI, υ3 = distance to roads, x = longitude and y = latitude. The "s()" functions indicate the smoothed terms in the GAMs.

Version	*Cause*	*Formula*	*AUC*
GLM	Natural	$pr(y_n) = \alpha + \upsilon1 + \upsilon2 + \upsilon3$	0.75
	Human	$pr(y_h) = \alpha + \upsilon1 + \upsilon2 + \upsilon3$	0.77
GAM	Natural	$pr(y_n) = \alpha + s(\upsilon1) + s(\upsilon2) + s(\upsilon3)$	0.76
	Human	$pr(y_h) = \alpha + s(\upsilon1) + s(\upsilon2) + s(\upsilon3)$	0.80
Spatial GAM	Natural	$pr(y_n) = \alpha + s(\upsilon1) + s(\upsilon2) + s(x,y)$	0.84
	Human	$pr(y_n) = \alpha + s(\upsilon1) + s(\upsilon2) + s(\upsilon3) + s(x,y)$	0.89

According to the held-back testing (Figures 5 and 6), the logistic-GLMs exhibited the most uniform probability distributions and the greatest overlap between the presence-absence probabilities. In turn, the logistic-GAMs shifted the probability distributions towards higher values for the presence locations and towards lower values for the absence locations, indicating better differentiation. Overall, the spatial-GAMs (with geographic coordinates and optimized k values) yielded the greatest separation between the probability distributions. For the spatial-GAMs, half of the locations with a natural and human ignition had a predicted probability >76% and >80%, respectively; and half of the locations without a natural and human ignition had a predicted probability <25% and <18%, respectively. Consequently the spatial-GAMs offered the best performance, with AUC = 0.84 (natural-cause) and AUC = 0.89 (human-cause).

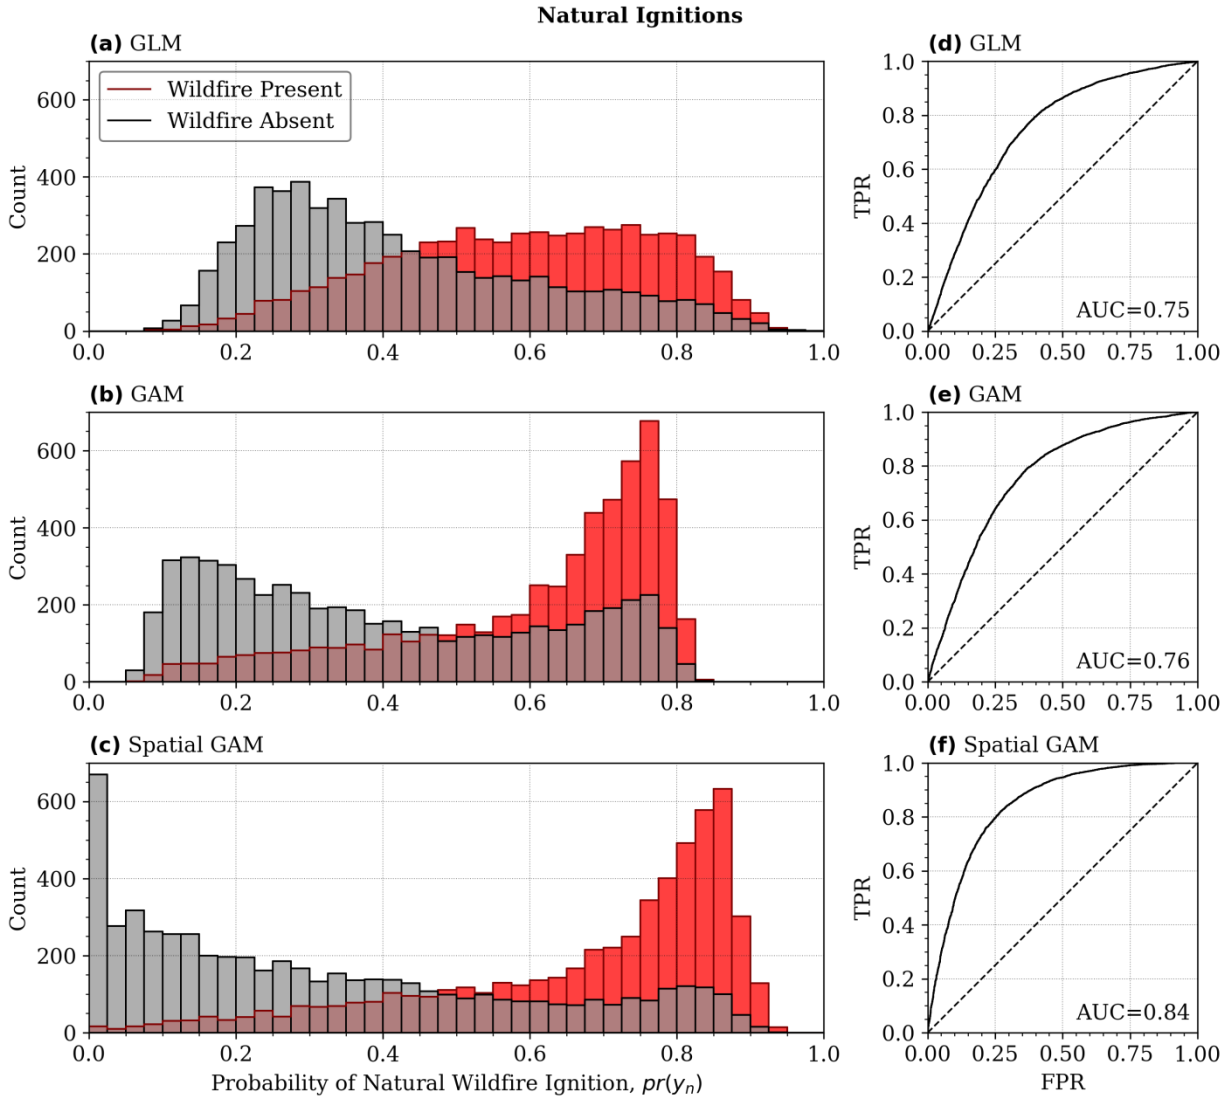

Figure 5. Evaluation of the General Linear Models (GLMs), General Additive Models (GAMs) and spatial-GAM used to model the probability of natural wildfire ignitions. Each model was applied to the held back testing datasets and the frequency distributions shown in (a)-(c) indicate the count of presence (red) and absence (black) grid cells according to their predicted probability.

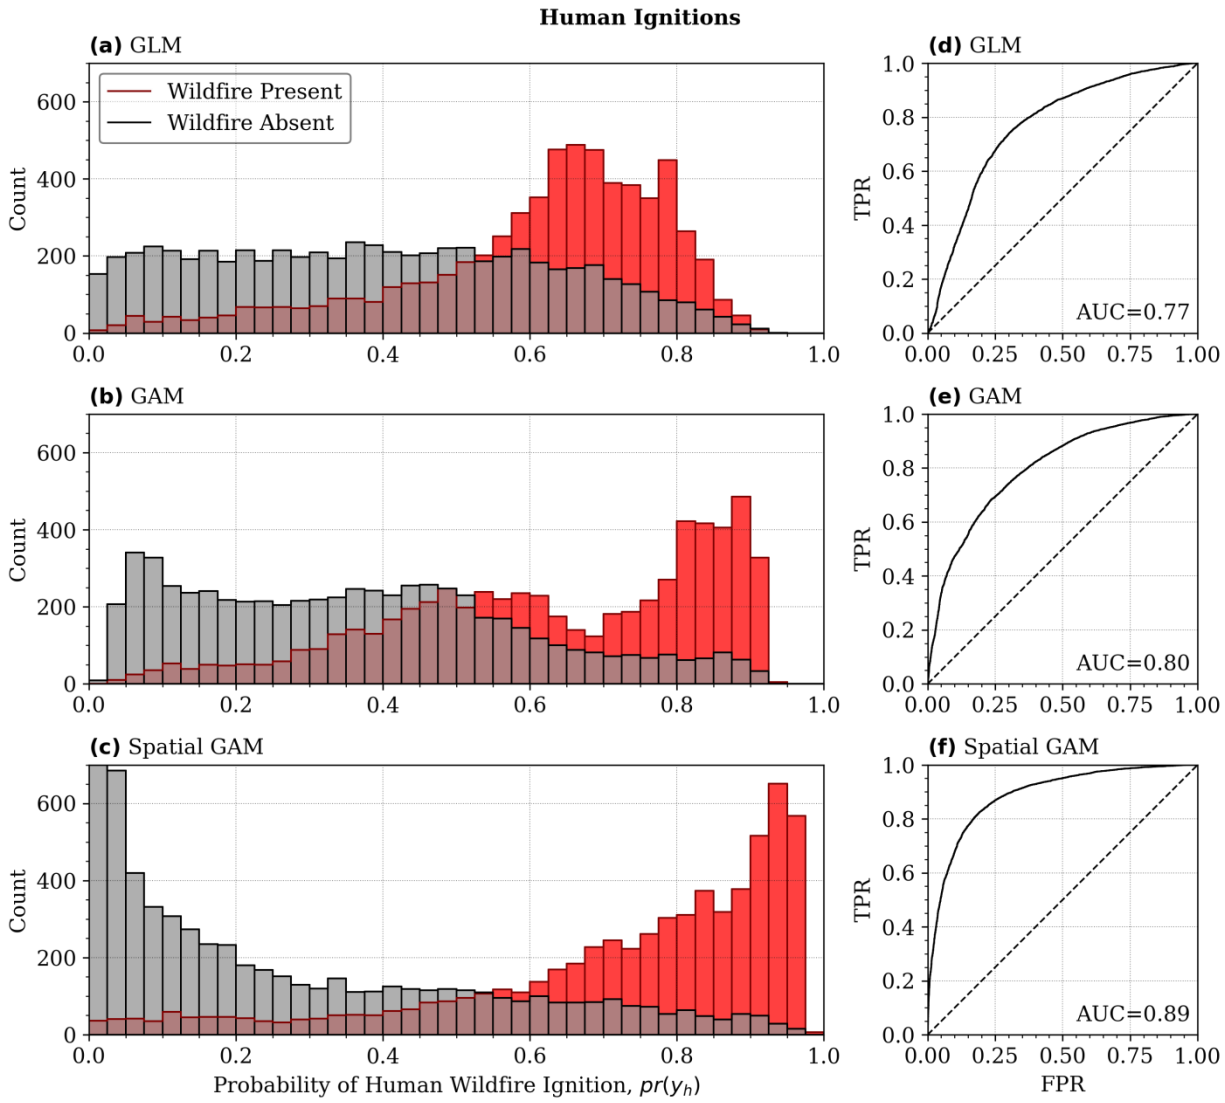

Figure 6. Same as Figure 5, but for human wildfire ignitions.

For natural ignitions, the response to slope (Figure 7a) shows a likelihood increase up to ~30º and decreasing thereafter with a greater predictive uncertainty due to fewer training data. In turn, the likelihood of a new wildfire was relatively insensitive to maximum-NDVI until a value of ~0.5 and then decreased. The geographic coordinates in the logistic-GAM imparted a spatial smoother, with locations in the Northern Rocky Mountains and south-eastern MT, exhibiting the highest probabilities. For human ignitions, the response of the spatial-GAMs to slope and distance to roads was similar to GAMs with the exception that, again, of maximum-NDVI. Here, distance to roads played a prominent role in the spatial-GAM of human-caused ignitions (50% of the grid cells containing a human caused wildfire located < 2,500 meters of a road). The spatial smoother revealed similar though slightly different patterns, most noticeably in northern MT along the Canadian border.

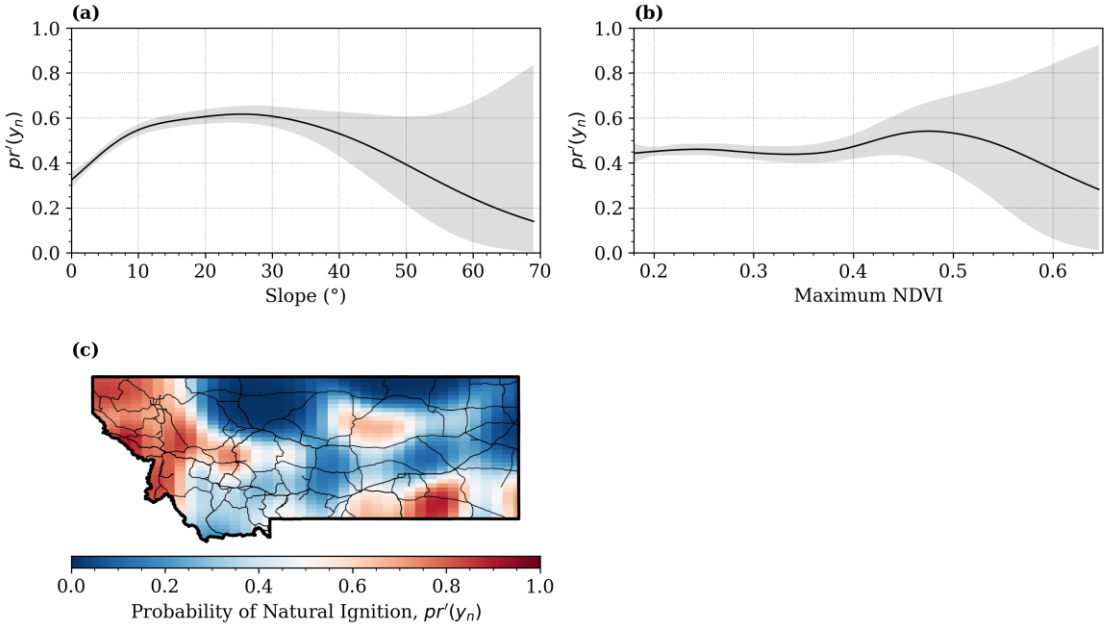

Figure 7. Partial effects plots for all smoothed variables in the spatial-GAM built to predict the probability of a natural wildfires.

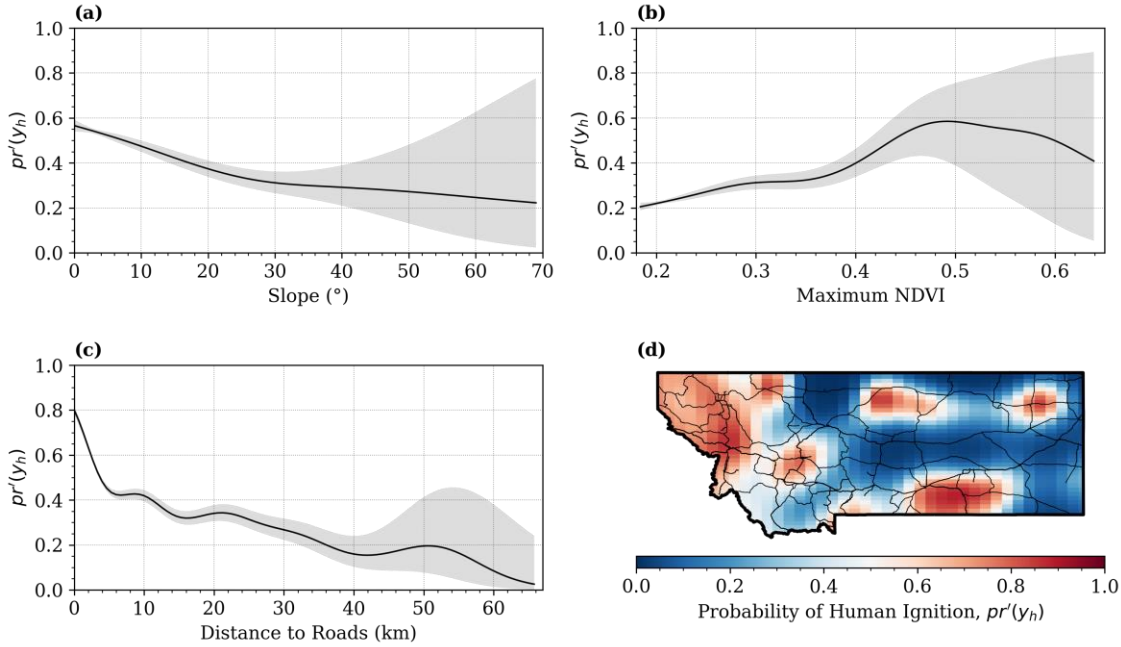

Figure 8. Same as Figure 7, but for human-caused wildfires.

Generally, the 30m static probability maps were broadly influenced by the spatial smoothers (Figures 9a and 9c versus Figures 7c and 8d) and locally modulated by slope, maximum-NDVI and distance to roads. This is most evident in the spatial-GAM of natural ignitions where probabilities are lower in the valley bottoms and nearby shallower slopes, and in the spatial-GAM of human-caused ignitions where probabilities are highest along the road network. In fact, both spatial-GAMs predicted large areas with low probabilities of wildfire ignition (50% of the territory have <23% and <15% chances of a natural and human-caused ignition, respectively). Conversely, locations with a high predicted probability of a new wildfire are rare (~2% of the state had >90% of ignition chance).

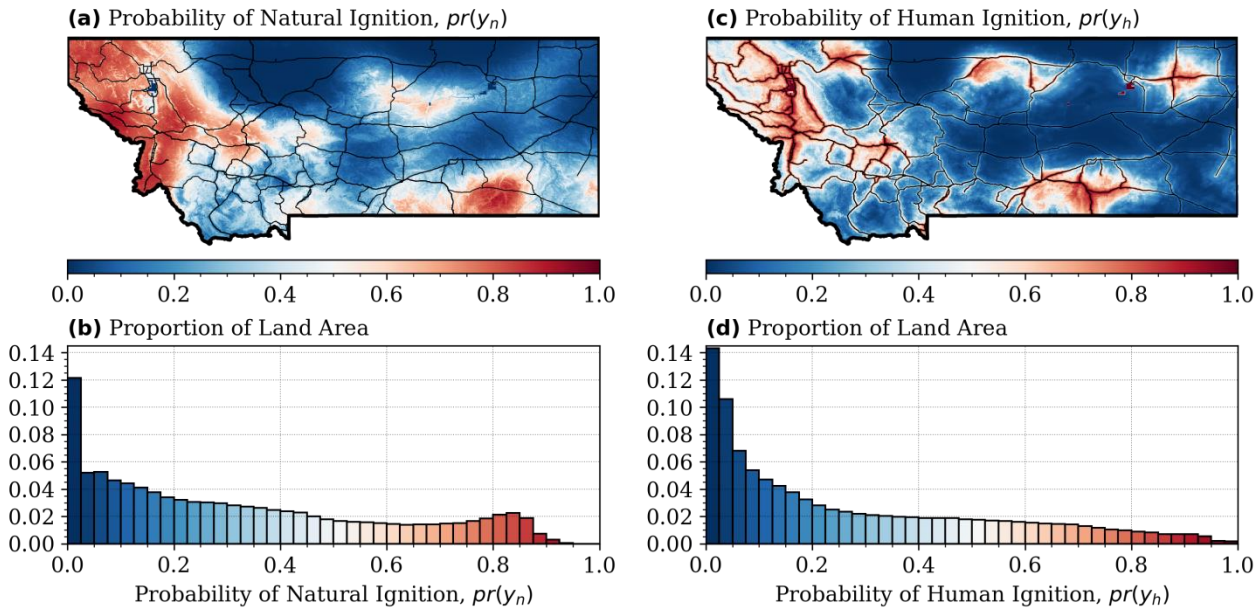

Figure 9. Maps of (a) the probability of a natural wildfire, and (b) the probability of a human wildfire obtained from the spatial-GAMs. Distributions of the land area proportion as functions of both causes are shown in (b) and (d), respectively.

4. Conclusions

In this study we have tested two different spatial-GAMs models using a daily wildfire database and drivers through a 25-year time span. Spatially, human model produced the highest wildfire probabilities, although the homogeneity of its greatest values were very clustered in particular areas. The inclusion of environment-human variables allowed us to forecast static wildfire probability in areas with a high wildfire activity and, thus, a future danger is expected. In addition to the advantage of easily updating the models as new available wildfire data, we find the selection of these basic variables to be practical.

Hazard Mapping – Susceptibility mapping – Risk Management - Machine Learning

Abstract

Wildfires are a menace which is growing in intensity and spreading in range across all planet's ecosystems causing devastation on the environment, wildlife, human health, and infrastructure. Most of the damage caused by forest fires is related to extreme wildfire events (EWEs). To foster prevention activities, a thorough understanding of territorial features determining EWEs is crucial in Civil Protection and fire management activities. An approach which learns from past wildfire events providing susceptibility, intensity and hazard maps is presented. This mapping approach leads to the individuation of the main drivers of EWEs and in the zonation of the areas more prone to hazardous and impactful wildfire events. The case study where the mapping approach is applied encompasses thirteen countries of the Eastern Mediterranean and Southern Black Sea basins. The presented results focus on wildfire susceptibility. A Machine Learning approach is pursued, by adopting open data layers as both predisposing factors and past wildfire events.

1. Introduction

Fire trends from the '70s up to now show on the average a decrease in burned area and number of fires, after the large impacts of the '80s wildfire seasons, in most of the Southern European countries, as demonstrated by (Turco et al. 2016). This can be mainly considered as the results of increasing firefighting capacities and awareness thanks to improved forecasting. However, impacts of climate change, coupled with the drastic modifications in land use and socio-economic conditions, occurred in the same period, have triggered a potential increase in frequency, extent and severity of wildfires worldwide (Doerr and Santín, 2016). Wildfires are growing in intensity and spreading in range across all planet's ecosystems, causing devastation on the environment, wildlife, human health, and infrastructures (UNEP, 2022). In highly densely populated areas, recent studies indicate that most of the damage caused by forest fires is related to extreme wildfire events (EWEs) which represent less than 2% of the total number of fires (Catry et al., 2009; Tedim et al., 2013). Despite huge investments in fire suppression, firefighting activities cannot effectively cope with EWEs, even in cases of massive resource deployment (Fernandes et al., 2016).

The impacts of the recent and recurrent EWEs in the Mediterranean highlight that societies are facing an increasing fire risk due to the combination of climate conditions and landscape-scale accumulation of fuel because of the almost complete abandon of rural activities.

Recently, EWEs characterized the 2021 wildfire summer season, where Greece, Italy, Algeria and Turkey experienced a large number of severe wildfire events burning more than 630,000 ha (San-Miguel-Ayanz, 2022). The 2021 Algerian wildfires killed at least 90 people (ReliefWeb, 2021) resulting in the deadliest fires of the recent times after the EWEs in Portugal (2017) and in Mathi, Greece (2018).

It is evident that there is an urgent need to shift from suppression to prevention and risk mitigation in order to reduce such impacts. A limitation to this shift is represented by the absence of a collective and pervasive understanding of the conditions related with EWEs beyond both the sole cause of ignition and the effect of weather, which are the main uncontrollable aspects of EWEs. The fatalist approach which blames only ignition patterns and weather effects neglects that there is still plenty of room for knowledge improvement leading to the identification of priorities for effective wildfire prevention. Such knowledge begins with susceptibility, hazard and risk mapping, including the characterization of the exposed elements in terms of their value and vulnerability, and ultimately leads to the identification of the areas where EWEs can happen with more severe impacts.

To foster prevention activities, a thorough understanding of the features of the territory determining EWEs is of crucial help in Civil Protection and fire management activities. From a technological point of view, there is plenty of data, tools and models which can be applied to this issue.

A harmonized mapping methodology is needed to be applied at different scales. Synoptic time series of burned area a significant help to learn from the past, bringing useful knowledge to present wildfire management, determining the principal drivers of catastrophic wildfires. However, those time series may be not long enough locally to reach these goals. To circumvent this problem, a more vast and diverse area can be studied, to infer wildfire drivers in different climates, topographic and anthropogenic conditions. This is achieved using wildfire susceptibility, hazard, and risk maps, which can help decision makers and practitioners in wildfire management and long-term landscape management, strengthening proactive prevention activities adapted to local environmental and socio-economic contexts. The objective of such maps may range from the static assessment (hazard) to the dynamic one (danger).

This is in line with the recent IPAFF European program, which targets Western Balkans (Albania, Kosovo*[1], Montenegro, Serbia, North Macedonia, Bosnia-Herzegovina) and Turkey to empower capacities in forest fire risk assessment and mapping, considering static hazard and risk mapping across boundaries.

The Authors with the presented work continue a research framework started at the local level (Tonini et al., 2020) and recently expanded at the national scale (Trucchia et al., 2022). The described work is one of the first attempts (up to the Authors' knowledge), to model wildfire hazard at the supernational scale, where useful information can be drawn in view of cross-border wildfire management, supporting also the European Civil Protection Mechanism.

1.1. The proposed framework to wildfire hazard assessment and mapping

The proposed approach combines multi-source data gathering, model / expert-based processes and Machine Learning (ML) analyses.

This preliminary work, undertaken for a large set of countries in the Eastern Mediterranean and Southern Black Sea region, tries to get the most from the available global data sets, using only open data. The main steps are summarised below:

1. Susceptibility mapping - wildfire susceptibility is defined as the static probability of experiencing wildfire in a certain area, depending on the intrinsic characteristics of the terrain. This can be achieved with several approaches, ranging from the statistical hierarchical ones to the ML driven ones.
2. Intensity mapping - wildfire intensity is defined as the rate of heat energy released by the fire. At this stage, the areas where severe wildfires can develop owing to the fuel cover and other features of the terrain are detected. This can be done with expert-based classification of fuel cover or via empirical models.
3. Hazard mapping – wildfire hazard is the spatial distribution of the areas where a severe wildfire is likely to occur. This can be done merging the outputs of the two previous steps.

In this short abstract, the results obtained for Steps 1-2-3 are described.

[1] This designation is without prejudice to positions on status, and is in line with UNSCR 1244 and the ICJ Opinion on the Kosovo declaration of independence.

2. Materials and Methods

2.1. Study Area

The considered countries are the following: Italy, Slovenia, Croatia, Western Balkans (Albania, Bosnia and Herzegovina, North Macedonia, Montenegro, Kosovo* and Serbia), Greece, Cyprus, Bulgaria, and Turkey. They constitute a vast area (more than 1,600,000 km2) characterized by a high number of biogeographical regions: Mediterranean, Continental, Alpine, Anatolian, Pannonian, and Black Sea biogeographical region (European Environment Agency, 2002).

2.2. Methodology

The proposed methodology for susceptibility mapping is based on a ML model (Trucchia et al., 2022), structured as a classification task. It uses a Random Forest Classifier (RF) as an algorithm, to find a functional relation between the dependent variable (the label, that is, wildfire occurrences) and the independent variables (that is, the predisposing factors). As per the predisposing factors, geographic data (elevation, slope, aspect, land cover/fuel cover), climatic data (Köppen-Geiger climate classes, mean precipitation, mean temperature) and anthropogenic data (distance from settlements and crops) are considered. The input layers are summarised in Table 3. The main data source used for computing vegetation cover variables is CORINE Land Cover 2018 (CLC2018). The obtained raster, containing the CORINE code for the pixels, then has been processed to obtain the neighbouring vegetation variables, which express the vegetation continuity over the analysed landscape. Those extra variables are used to associate with any pixel information on the surrounding vegetation. This is useful to identify homogeneity in vegetation, or to spot the interface between two main vegetation covers. For any pixel, a Moore neighbourhood of order 2 (the 24 surrounding pixels) has been evaluated (see Figure 1). The frequency of appearance of the several vegetation types has been computed. For instance, in case of a pixel is totally surrounded by CLC2018 code “311”, that is, broadleaves, the variable “neighbouring_311” will be set to 1 while all the other "neighbouring_XXX" variables will be set to 0.

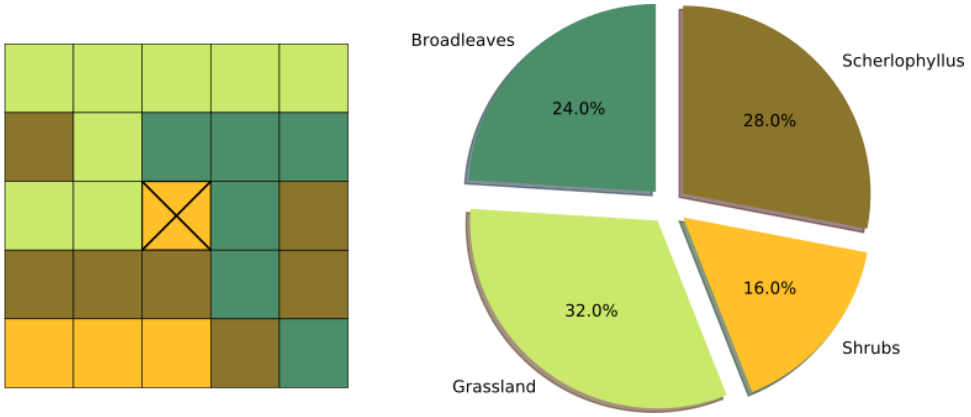

Figure 1- A representation of a Moore Neighbourhood and the obtained “neighbourhood percentages” of vegetation classes (vegetation continuity) is portrayed. Any other neighbour vegetation type not represented in the image is set to 0%.

As per the observed data, the EFFIS database of 10,118 burned polygons (more than 2,922,500 burned hectares), retrieved from 2008 to 2019 is considered.

All inputs and outputs are rescaled to the working resolution of 500m.

For any of the considered countries, 10% of their burned pixels is retrieved and their predisposing factors collected, as well as an equal number of non-burned pixels with their geoclimatic and anthropogenic factors. This allowed building a balanced dataset. The contribution of each country is merged in the total dataset. Such database was split between the training ones (75 percent of the entries) and the test ones (the remaining 25% of the database). The RF model has been trained on the training dataset and evaluated over the test pixel, to compute performance indicators. In this work, the Area under the ROC Curve (AUC) and the Mean Square Error (MSE) are considered and reported in Table 4.

The input features then are ranked by their relevance using the measure given by the Gini impurity to spot the main drivers of wildfire occurrence in the study area.

While the susceptibility layer raw values ranging from 0 to 1 have been used to compute the performance indicators, the values have been also aggregated into percentile classes (see Figure 2).

In order to have a layer accounting for wildfire intensity, the CLC2018 land cover has been processed aggregating the CLC2018 classes into four different intensity classes, as reported in Table 1.

Having for every pixel of the study area a class for potential intensity and a class for wildfire susceptibility, a simple expert-based contingency matrix for hazard assessment has been developed. Such matrix is reported in Table 2.

Table 1- Fire behaviour / fire intensity classification. Thanks to this classification a land cover map can be converted to a fire intensity map, to be used as input for the hazard mapping.

Intensity classes	Description	Vegetation cover
1	Surface fire – low intensity	crops, grasslands
2	Surface fire – medium intensity	broadleaves, agroforest
3	Surface fire – high intensity	Sclerophyllus, shrubs
4	Crown fires – very high intensity	Conifers, mixed forest

Table 2- The contingency matrix for the Hazard is portrayed. It combines the input classes of susceptibility (rows) and intensity (columns). Every entry of the matrix is the hazard level (from one to six: very low, low, medium, high, very high, extreme hazard) related to a specific combination of susceptibility and intensity levels.

Susceptibility / Fire Intensity	Low Intensity	Medium Int.	High Int.	Very High Int.
Low Susceptibility	1	2	3	4
Medium Susc.	2	3	4	5
High Susc.	3	4	5	6

3. Results

The first results for the susceptibility mapping of the study area are here listed. In Figure 2, the susceptibility distribution is portrayed after aggregating via percentile classes. In Figure 3, the Hazard Map for the reported area is portrayed.

The performance indicators are resumed in Table 4, with promising and consistent results for the AUC score.

Interesting insights are also given by the ranking of the predisposing factors in Table 5: the importance of vegetation continuity when compared to single pixel vegetation is an evident result of the analysis, with climatic and topographic classes which cannot be neglected for a good classification of the study area. This is in line with the more consolidated results from the recent work at the national scale in Italy (Trucchia et al., 2022).

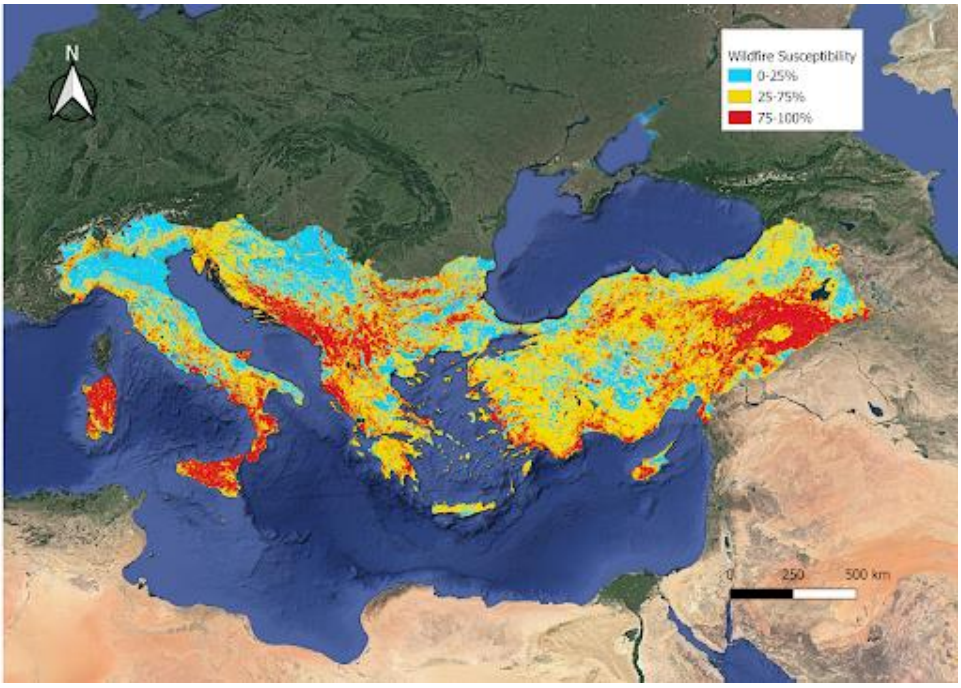

Figure 2: Susceptibility map of the study area, coloured by percentiles: 0-25% (low susceptibility), 25-75% (medium susceptibility), 75-100% (high susceptibility).

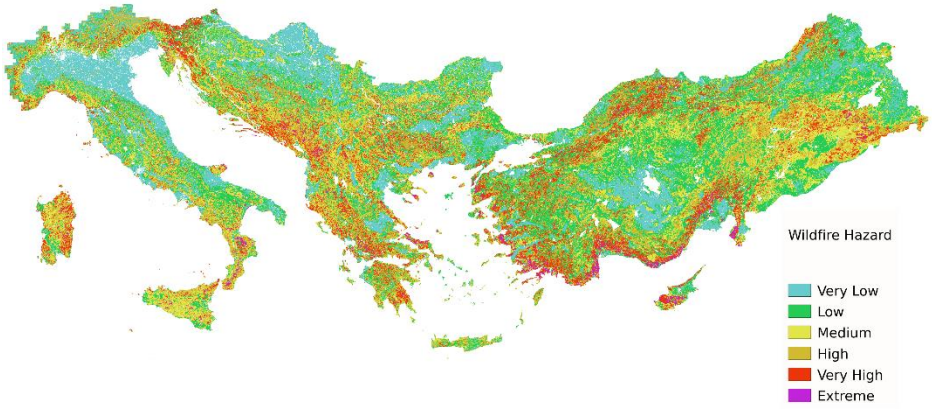

Figure 3: Wildfire Hazard map of the study area, coloured by the hazard classes of Table 2, taking as inputs the susceptibility classes (Figure 2) and the fire intensity category (Table 1)

4. Discussion and Conclusions

Promising results showing the most wildfire prone areas achieved through ML in step 1 supported the work in step 2 and 3 of the proposed approach. The susceptibility map produced at this stage of the implementation evidenced the importance of vegetation continuity in susceptibility assessment. At the scale of the presented analysis of course climatic information is a good asset for discriminating between different species of vegetation that belong to the same CORINE class. On the other hand, vegetation continuity covers at least two roles: firstly, high flammability fuels continuity is the main responsible of EWEs; secondly, continuity of native broadleaved forests may limit the propagation of EWEs. The adopted strategy for fire behaviour/intensity mapping and Hazard mapping are an example of how to make use of open data and informed decisions to perform hazard mapping at the supernational level. There exist of course plenty of different modelling choices, but the Authors tried to stick to the most straightforward one to highlight the solidity of the proposed framework. For instance, a modelling approach relying to worst-case scenarios for wind and moisture conditions could have been employed for intensity mapping (Trucchia et al. 2022 b). These preliminary results open the right path to

restoration and adaptation strategies, fostering the objectives of EU Biodiversity Strategy for 2030. This initial susceptibility mapping is currently under refinement by implementing ad-hoc spatial validation procedures, and a more thorough factor importance analysis, with a special focus on the impact of the different vegetation types.

Table 3- Input data for the susceptibility mapping

Input data	**Source**	**Description**
CORINE land cover	Copernicus[2]	Land cover raster file of the Corine 2018 at 100 m resolution
Copernicus tree cover density (TCD)	Copernicus[3]	Density of the forestry areas at European level at100 m resolution

Abstract

Understanding and predicting fuel moisture content (FMC) is a crucial prerequisite to increase our knowledge of forest's vulnerability to fires in a changing climate. While live fuel moisture content (LFMC) is a main driver of fire behavior and activity in crown fires in forests and shrublands, it remains poorly understood and predicted, especially under extreme drought. A major reason for that is that LFMC sensitivity to climate is mediated by a range of location-specific factors, including soil characteristics and plant response to drought. Another reason is that LFMC is often simulated at the leaf scale while, from a fire danger perspective, canopy scale fuel moisture content (CFMC) is more relevant.

Here we introduced a FMC module in the plant-hydraulic SurEau-Ecos model to simulate the dynamics of both LFMC and CFMC as a function of leaf water potential (ψ_{Leaf}). CFMC integrates the impacts on moisture content of foliage mortality that can occur under extreme drought because of leaf embolism. SurEau-Ecos-FMC relies on two main mechanisms. The relationship between ψ_{Leaf} and leaf relative water content of the symplasm is modeled through pressure volume curves. Percent loss of leaf conductance (PLC) is derived from ψ_{Leaf} through vulnerability curves to cavitation and affects the dynamics of fuel moisture content in two different ways. At the leaf level, PLC dictates the dynamics of the leaf apoplasmic reservoir. At the canopy level, PLC drives the proportion of dead fuel within the canopy.

SurEau-Ecos-FMC accurately reproduced the temporal dynamics of LFMC in a Quercus ilex stand at the Puéchabon site over a three-years period. The model explained 69 % (RMSE = 4.27) and 74 % (RMSE = 4.92) of the variance in the minimum and maximum daily observed LFMC, respectively. The model was also able to capture the dynamics in CFMC resulting from leaf mortality during the summer drought. The years when SurEau-Ecos-FMC predicted leaf mortality were also the ones with the highest anomaly in NDVI. Multi-model projections of fire danger indices based on CFMC showed a general increase of fire danger over the next century. Under RCP8.5, the averaged minimum CFMC reached during the year is expected to decrease from 65 % to 32 % and the fire season length (number of day when CFMC<67%) is expected to increase from 15 to 120 days per year.

SurEau-Ecos-FMC offer new opportunities to improve our comprehension of LFMC's sensitivity to climate and we show that plant embolism might be a growing cause of FMC decrease in a drier climate. We also encourage the use of SurEau-Ecos-FMC to inform fire models in order to increase our understanding of the FMC's effect on fire behavior and activity.

1. Introduction

Fuel moisture content (*FMC*), the ratio of water mass to dry mass of vegetation, governs the amount of time and energy needed to vaporize fuel moisture before ignition can occur. *FMC* is usually separated into dead (*DFMC*) and live (*LFMC*). Declining *LFMC* was associated with an increase in area burned (Pimont *et al.* 2019a), extreme wildfires (Ruffault *et al.* 2018a) and increased fire behavior (Pimont *et al.* 2019b).

Despite its importance, LFMC remains poorly understood and predicted for two main reasons. First, unlike DFMC, the effect of climate on LFMC is regulated by a range of location-specific factors, including plant traits

and soil characteristics (Ruffault et al. 2018b, Nolan et al. 2020). As a result, models based on meteorological drought indices do not accurately predict LFMC (Ruffault *et al.* 2018b). Second, canopy level moisture content (CFMC) is more relevant for wildfire danger (Rossa and Fernandes 2018) but predicting CFMC requires to take into account the mechanisms that lead to leaf mortality under severe to extreme drought.

Recent advances in our physiological understanding of plant response to drought have led new opportunities to improve our comprehension of leaf-level and canopy-scale FMC sensitivity to climate (see Figure 1). A first theoretical framework, derived from pressure volume (p-v) curves, states that the response of symplasmic water content to leaf water potential essentially depends on cell wall elasticity (ε) and leaf osmotic potential (π_0). Such relationships have recently been adapted to model leaf-level LFMC (Nolan *et al.* 2020). A second framework, inherited from plant hydraulic, allow to derive the water content of the apoplasmic tissue and the ratio of dead to live fuels within the canopy from the percent loss of conductance (PLC).

Understanding and anticipating fire hazard requires to improve our current knowledge of fuel moisture response to climate. As compound dry and hot events become more frequent and intense (Ruffault et al. 2020), drought-induced plant defoliation and mortality that affect CFMC are likely to increase in many ecosystems (Allen et al., 2015). Here we developed a FMC module in the plant-hydraulic SurEau-Ecos model (Ruffault et al., 2022) to simulate the dynamics of LFMC and CFMC and compared them with field measurements. We then explored the impact on future climate changes on wildfire danger.

2. Methods

2.1. SurEau-Ecos-FMC

We implemented a fuel moisture content (*FMC*) module into *SurEau-Ecos* to simulate *FMC* dynamics of fine canopy fuels (shoot and leaves), both at the leaf and canopy levels. *SurEau-Ecos* is a plant-hydraulic model that simulates plant water status and fluxes between the soil, plant and the atmosphere. *SurEau-Ecos* draws on the mechanisms developed in *SurEau* (Cochard *et al.* 2021) and an ecosystem-level water balance model (Ruffault *et al.* 2013). It predicts hourly plant water potentials as function of soil properties, plant hydraulic traits, stand structure and daily climatic variables (see a full description in Ruffault *et al.* 2022).

SurEau-Ecos-FMC relies on two main mechanisms (Figure 1). The relationship between ψ_{Leaf} and leaf relative water content of the symplasm is modeled through pressure volume curves. Percent loss of leaf conductance (PLC) is derived from ψ_{Leaf} through vulnerability curves to cavitation and affects the dynamics of fuel moisture content in two different ways. At the leaf level, PLC dictates the dynamics of the leaf apoplasmic reservoir. At the canopy level, PLC drives the proportion of dead fuel within the canopy (α_{Dead}). Dead leaves are assumed to stay on plant until the end of the year.

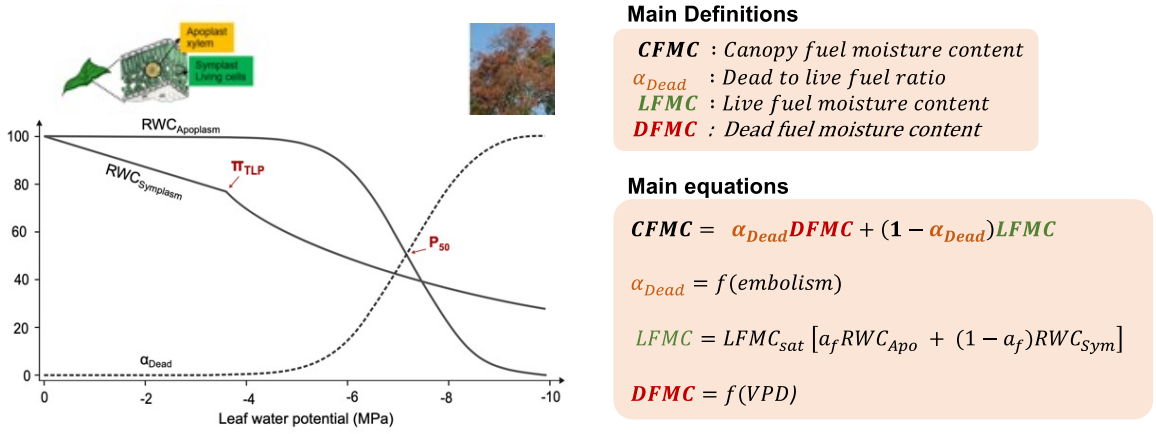

Figure 1- Schematic representation of the main processes and equations involved in the dynamics of live fuel moisture content (LFMC) and canopy moisture content (CFMC) in the plant-hydraulic model SurEau-Ecos-FMC.

2.2. Validation datasets

SurEau-Ecos-FMC estimations of ψ_{Leaf}, LFMC and *CFMC* were compared to measurements made on a *Quercus ilex* Mediterranean forest for the period 2016-2018. The study site is located at the Puéchabon forest at 35 *km* north-west of Montpellier (southern France; 270 m ASL). ψ_{Leaf} and *LFMC* were measured at predawn and at midday for five trees during the summer drought (May to October) approximatively once per 3 weeks each year. As a proxy of leaf mortality, we used the Normalized Difference Vegetation Index (NDVI). Continuous NDVI measurements were made using a sensor positioned above the canopy. We computed an index of foliage change during the summer drought as the relative variation in NDVI between leaf maturity (around early July) and the end of the summer.

2.3. Projections of fuel moisture content

Projections of climate variables for the future climate period (2005-2100) and historical periods used as input in FMC projections (section 2.3.5) were obtained from the climate simulation program involved in the 5th phase of the Coupled Model Intercomparison Project (CMIP5) produced as part of the EURO-CORDEX initiative. 13 GCM-RCM couples were selected and extracted for the historical (1990–2005) and future (2006–2099) periods for the RCP4.5 and RCP8.5 scenarios. Model outputs were bias-corrected by a multivariate correction approach (*MBCn*, Cannon, 2018).

3. Results and Discussion

SurEau-Ecos-FMC captured well the variations in predawn (ψ_{pd}) and midday (ψ_{md}) leaf water potentials measured at the Puéchabon site over the three studied years (Figure 2A), explaining 98 % (RMSE = 0.27) and 87 % (RMSE = 0.45) of their variance, respectively. *SurEau-Ecos-FMC* also captured relatively well the temporal dynamics of leaf level LFMC (Figure 2B). The model explained 69 % (RMSE = 4.27) and 74 % (RMSE = 4.92) of the variance in the minimum and maximum daily observed LFMC, respectively. This provides further evidence of the relevancy of p-v curves to estimate LFMC from leaf water potential. However, model performance was lower than that obtained for ψ_{pd} and ψ_{md}. A potential gain of performance in LFMC predictions could be attained by taking into account year-to year osmotic adjustments.

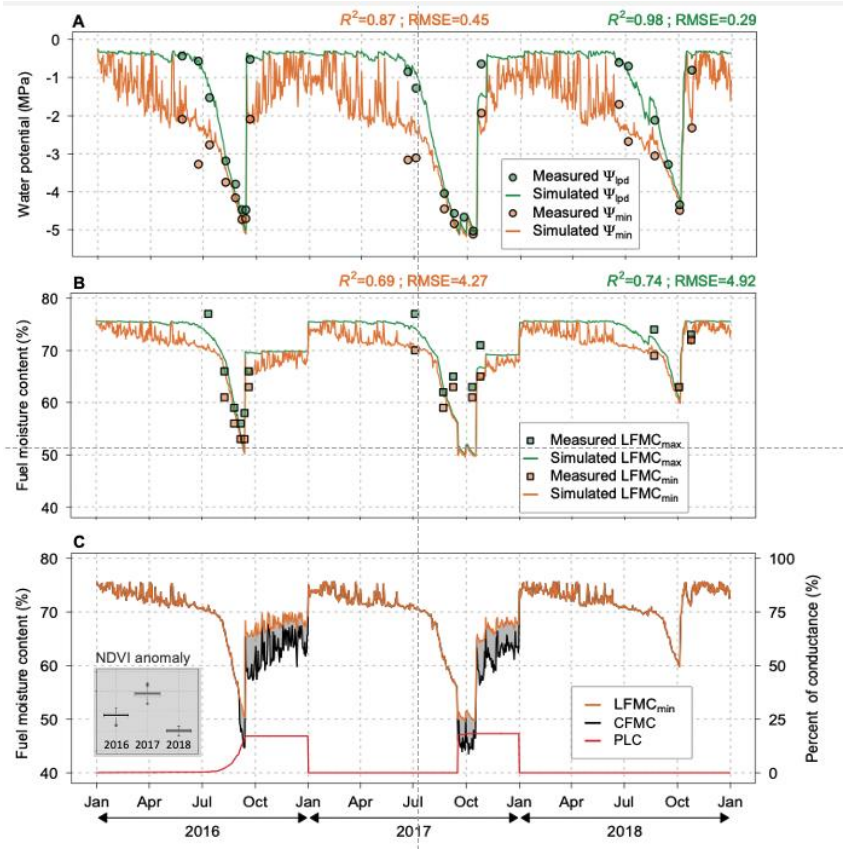

Figure 2- Dynamics of simulated and observed (A) leaf water potential, (B) live fuel moisture content (LFMC) and (C) canopy fuel moisture content (CFMC) for the three studied years. The insert panel in (C) shows the standardized anomaly in NDVI

Our model showed that the conditions observed during the 2016 and 2017 summer droughts (Figure 2C) led to a 20% rate of leaf embolism. This in turn led to a decrease in *CFMC* compared to what was observed at the leaf level. These results are consistent with a higher relative change in NDVI during the year 2016 and 2017 compared to 2018 (insert panel in Figure 2C).

Our projections of fire danger indices based on *CFMC* showed a general increase of fire danger over the next century but with major differences according to the emission scenario (Figure 3A and 3B). $CFMC_{min}$ decreased from 65% to the 62% for end of the century under RCP4.5 but down to 32% under RCP8.5. Similarly, FSL increased from 15 to 20 days per year under RCP4.5 but up to 120 day per year under RCP8.5. A significant part of these trends was due to the increase in drought-induced leaf embolism (Figure 3C) that contribute to decrease LFMC and increase dead to live ratio of foliage in the canopy. More research is need to assess how long do dead leaves might stay on the trees. Plants are also likely to adapt to drier conditions by a series of mechanisms, including long-term reductions in leaf are index, that were not included in the present simulations, but might be explored in future work.

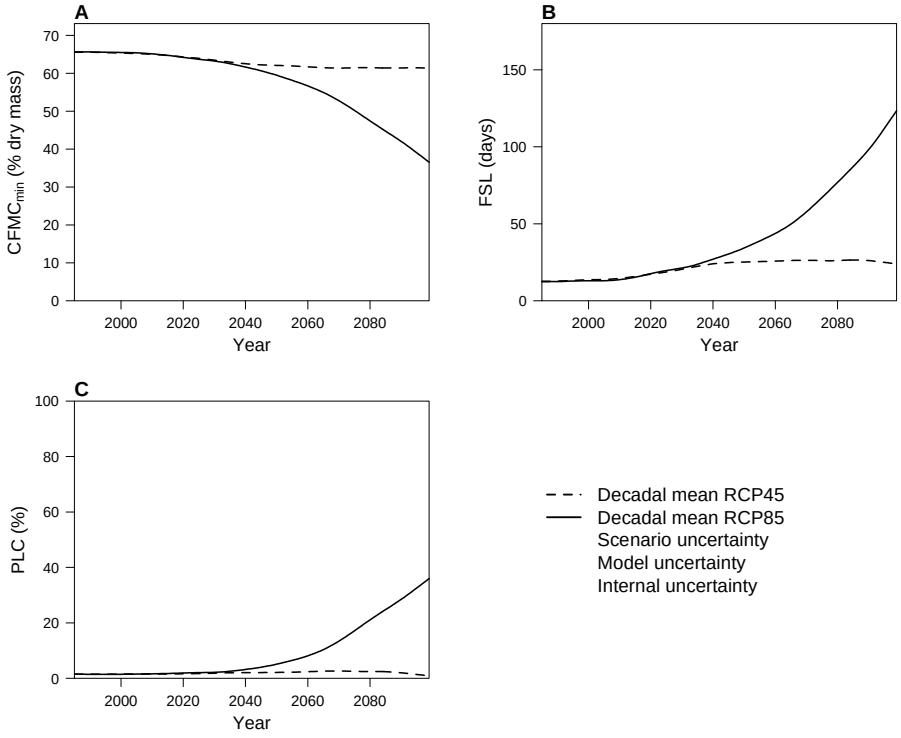

Figure 3- Multi-model projections of fire danger indices and plant cavitation for Quercus ilex at the Puéchabon study site for two emission scenarios (RCP4.5 and RCP8.5). $CFMC_{min}$ is the minimum canopy moisture content reached during the year; FSL is the fire season length, defined as the number of days when CFMC is below the 67% critical threshold.

4. Conclusion

Understanding and predicting FMC is an important prerequisite to increase our knowledge of forest's vulnerability to fires in a changing climate. Here, we developed and validated *SurEau-Ecos-FMC* a mechanistic model predicting *LFMC* and *CFMC* based on plant-hydraulics. We show that leaf embolism might be a growing cause of FMC decrease in a drier climate. We encourage the use of *SurEau-Ecos-FMC* to inform fire models and increase our understanding of the FMC's effect on fire behavior and activity.

Heathlands, Fire spread, Fuel moisture content, Energy release, Heat flux, Fuel structure

Abstract

Shrubs are the dominant fuel for wildfires which occur in heathland systems however, there are relatively few studies which explore the processes of flame spread in shrub fuels. A series of laboratory flame spread experiments are used to identify the relationships between the fuel moisture content of the fuel components of heather (Calluna vulgaris) shrubs and the resulting fire spread dynamics. Measurements of energy release, flame spread rate and mass loss are made to characterise the burning of 2 m × 0.75 m fuel beds, and heat flux measurements are made to record the magnitude of the propagating fluxes. Fuel moisture thresholds for fine and coarse fuel elements required for fire spread are identified, and the magnitude of the in-bed heat fluxes are reported. From the observations, it is suggested that the leading edge of the flame front is driven by the moisture content of the fine dead material suspended in the heather canopy while the trailing edge is dominated by the burning of coarser fuels which supports the burning of fine green fuels. These findings allow further targeted experimental study and can be used to aid determination of fire effects.

1. Introduction

Heathlands represent a major fire hazard in many parts of the world. For example, in the UK, 94% of wildfires fires occurred on heathlands (Taylor et al., 2021). The primary vegetation structures on UK heathlands are shrubs (e.g., *Calluna vulgaris, Ulex minor*), mosses and litter. There are also significant areas of upland heaths in the UK with underlying organic peat soils which, if ignited, can result in large release of carbon dioxide to the atmosphere. Despite the significance of these systems globally, there remains relatively little understanding of the drivers of fire spread in these systems. Fires are common in these systems through natural ignitions or through traditional land management practices (Davies et al., 2008). However, climate and land use changes are predicted to alter the intensity, and frequency of fires in these systems and therefore it is necessary to develop a detailed understanding of the mechanisms of fire spread in shrub fuels. This will allow improved fire risk prediction in these systems.

This work seeks to develop a process-based understanding of the fire spread in shrub fuels. Laboratory experiments are used to study the burning of *Calluna vulgaris*-dominated systems under quiescent conditions to identify the drivers of fire spread.

2. Methods

Experiments were carried out in the Rushbrook Fire Laboratory at the University of Edinburgh. Experiments were performed by constructing fuel beds with a nominal area of 2 m × 0.75 m using vegetation harvested locally.

2.1. Fuels: collection and conditioning

The structure of the *Calluna vulgaris* (heather) plant is given in Figure 1. There are three parts of note in the heather plant, older leafy growth which typically comprises fine dead (brown) leaves; younger growth which is

characterised by green leafy growth and flowers; and coarse stems. In addition to the heather, heathlands have a moss and litter layer on the soils.

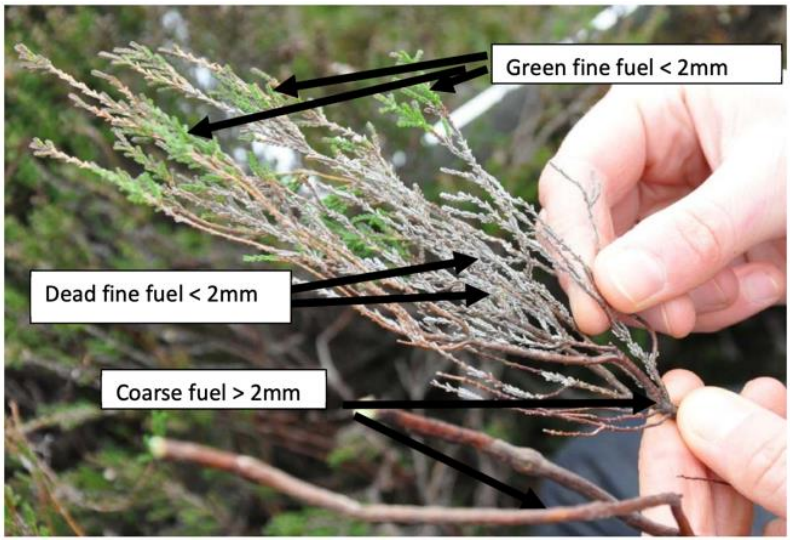

Figure 1 The different fuel types on heather (from Taylor et al., 2021)

Fuels were collected from the Pentland Hills Regional Park near Edinburgh, UK. Fuel samples comprised heather shrubs and the underlying moss and litter. Fuels were harvested in plots of approximate dimensions similar to those of the experimental fuel bed area (2 m × 0.75 m). After harvesting, fuels were stored under laboratory conditions until they were burnt. Prior to each experiment three samples of each of the fine green, fine brown, coarse stems and moss were collected. These were dried in an oven at 80°C for 48 hours to determine the fuel moisture content.

2.2. Experimental procedure

Immediately prior to burning, the fuel beds were assembled on a mineral wool substrate. The moss was distributed uniformly over the fuel bed area and the stems of the heather were pierced through the mineral wool. Care was taken to ensure consistent fuel bed heights and uniform distribution of stems across the area. A length of cotton rope (~0.8 m long) soaked in acetone and laid at the base of the heather was used as the ignition source. This is a strong, repeatable ignition source ensuring even ignition along the full 0.75 m short edge of the fuel bed. After ignition, the fire was allowed to spread (or not) and the test was terminated after flaming combustion had stopped or, if there was significant smouldering of course material, after this had stopped.

2.3. Measurements

Global and local fire behaviour measurements were made to characterise the flame spread and burning of the fuel bed. The whole fuel bed was supported on a load cell to obtain mass loss, total mass lost, and mass loss rate measurements. Heat release was measured by oxygen consumption calorimetry. Visual recordings of the flame spread were used to calculate the flame spread rate.

Local measurements of heat flux were made in three locations: at 2/3 fuel height facing the spreading flame; flush with the surface of the moss, and flush with the surface of the mineral wool substrate. Measurements were made using water cooled heat flux gauges (Huskeflux SBG01). These measurements allow analysis of the magnitude and duration of heating and help guide analysis of dominant heat transfer processes.

3. Results and discussion

An overview of the experimental conditions is given in Table 1. Sixteen experiments were conducted in total. These fall into two categories: experiments 2—7 with reduced measurement and instrumentation and variation in fuel loading and fuel moisture treatments. Experiments 8—17 were carried out with a more consistent fuel loading and fuel moisture treatment regime and also include the heat flux measurements. The fuel loadings are given on a wet basis.

Table 1 The experimental conditions, mass loss, and spread rate

Exp.	Fuel loading, kg/m^2				Fuel moisture content, %				Mass consumed, %	Spread rate, cm/s
	Moss	Heather	Total	Post burn	Fine green	Fine dead	Coarse	Moss/ Litter

Figure 2 shows a composite image of the 16 experiments taken 60 s after ignition to give an indication of the typical behaviours observed. The leading edge of the flame front in experiments 2, 3, 4, 7, 12, 15, 16 and 17 has propagated away from the ignition source and it is assumed that there is no longer an influence of this on the fire spread. Flame heights in these experiments are in excess of 2 m and the flame front has a depth approaching 1 m, indicating a significant degree of combustion behind the leading edge of the flame front. Experiments 5 and 6 remain in the location of the ignition source and flame heights in these cases are approximately 1.5 m. The flame in experiments 8, 9, and 14 are both discontinuous and less than 0.5 m in height. The flames in experiments 11 and 13 have quenched at this time with only residual burning near the ignition source apparent.

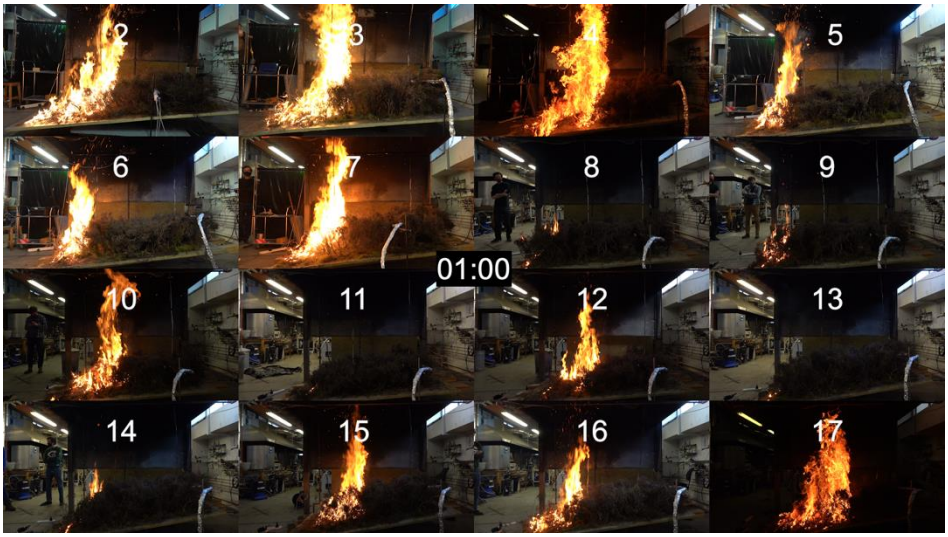

Figure 2 Composite image of laboratory flame spread experiments 60 s after ignition

3.1. Spread rate

The average rate of spread is measured by evaluating the time taken from ignition required for the flame to traverse the entire length of the fuel bed. Flame spread data are only reported when the flame traversed the entirety of the fuel bed. Flame spread rates ranging from 0.66 to 1.71 cm/s were recorded.

The spread rate is shown as a function of the fuel moisture content (FMC) of the different fuel elements in Figure 3. These data indicate that the flame spread rate has a strong dependence on the FMC of the fine dead fuels. The FMC of the fine green and coarse fuel elements also show an increasing trend in spread rate with decreasing FMC. The FMC of the moss does not appear to have a strong influence on the spread rate. It should be noted that in performing this analysis the assumption that the variations in fuel loading between experiments is not significant has to be made.

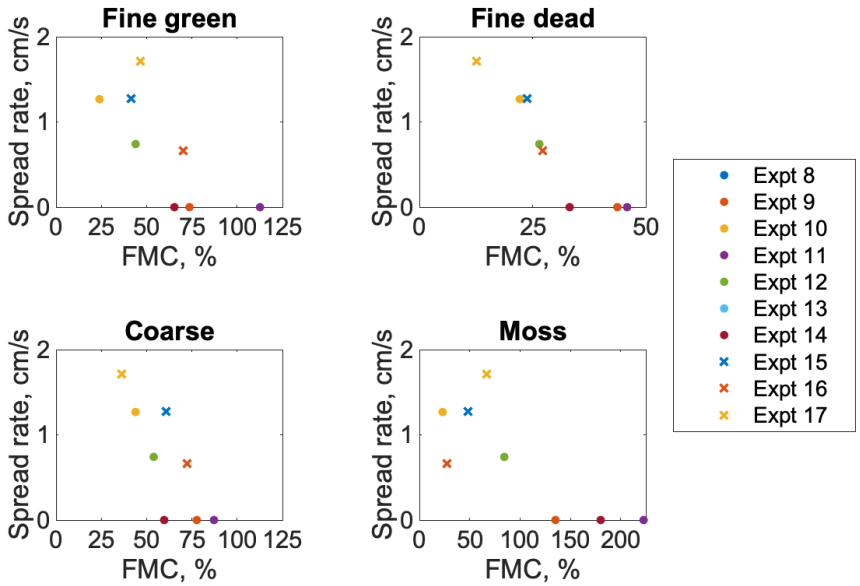

Figure 3 Flame spread rate as a function of the FMC of different fuel elements. Note the different ranges on the x axes.

These data also allow some thresholds for fire spread to be identified by evaluating the lowest FMC at which the fire did not spread and the highest FMC at which the fire did spread for each of the fuel classes to be identified. These are summarised in Table 2.

Table 2 Fuel element FMC thresholds for fire spread

Fuel element	**FMC threshold for spread, %**
Fine green	47—65
Fine dead	26—33
Coarse	54—60
Moss	84—135

3.2. Mass consumed

The total mass lost was recorded using measurements of the total mass of fuel in the fuel bed before ignition and at the end of the experiment. The mass loss ranged from 2 to 98%. Low mass losses were attributed to cases where the fire did not spread beyond the ignition source. For the cases which were identified as spreading through the whole fuel bed, the mass lost ranged from 51 to 98%.

The mass lost is shown as a function of the FMC of the different fuel elements in Figure 4. The total mass lost is again shown to be a function of the FMC for the different fuel elements. Again, there is a strong correlation with the FMC of the fine dead fuel. These data may suggest a stronger relationship between the FMC of the

coarse fuels and the total mass lost compared to the spread rate, however this should be treated with caution due to the interactions between spread rate and heat release rate.

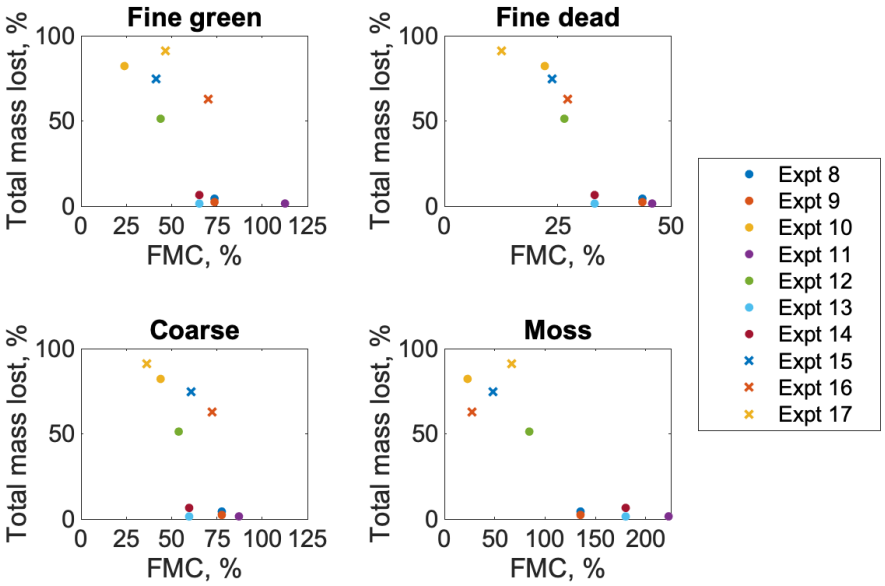

Figure 4 Total mass lost as a function of the FMC of different fuel elements. Note the different values on the x axes.

3.3. Energy release

The observations made until now can be subjected to independent verification using the energy release as measured by oxygen consumption calorimetry. This is shown for experiments 2—7 in Figure 5. The highest energy release exceeded 600 kW for experiment 4. This experiment also had the highest mass consumption (98%). This is due to these fuels having been dried for 3 days in the laboratory. Experiment 3 which also had a high mass consumption (85%) and had been dried for 2 days showed a lower peak energy release with a maximum in the range 400 kW. Similarly experiment 7 with 6 days conditioned dry heather and wetted moss, had a similar peak heat release rate (400 kW). However, this experiment took longer to reach the peak compared to experiment 3 indicating that the combustion of the moss layer, while not significant in determining the overall energy (due to the relatively small mass), may play a role in determining the total energy release under some conditions.

In experiments 2, 5 and 6, the flame did not spread on the full length of the fuel bed. In experiment 2 and 5, 43 and 31% of the mass was consumed indicating partial spread. No measurements of mass lost are available for experiment 6. Consequently, the measured energy release is low for these experiments. The peak in energy release in experiment 6 at around 120 s is attributed to uneven application of water while wetting the heather. These interpretations are confirmed by visual observations.

The energy release data for experiments 10, 12, 15, 16, 17 are shown in Figure 6 (data for experiments 8, 9, 11, 13 and 14 are omitted as no fire spread beyond the point of ignition was observed). These data indicate that there are two clusters: a high energy release cluster with experiments 10, 15 and 17 and a lower energy release grouping with experiments 12 and 16. This is reflected in the spread rate measurements where the spread rates in experiments 10, 15 and 17 were in excess of 1.20 cm/s but for experiments 12 and 16 the rates of spread were 0.74 and 0.66 cm/s, respectively. The higher spread rate in experiment 12 is attributed to the combination of lower moisture content of the coarse and fine green fuel elements compared to experiment 16. The coarse FMC was between 36 and 61% in experiments 10, 15 and 17 meanwhile for experiments 12 and 16 the coarse FMC was 54 and 72%. Likewise, the fine green FMC was between 24 and 47% for experiments 10, 15 and 17 and between 44 and 70% for experiments 12 and 16. For context, should be noted that in field experiments the FMC of the live coarse fuels was approximately 70—80% (Taylor et al., 2021).

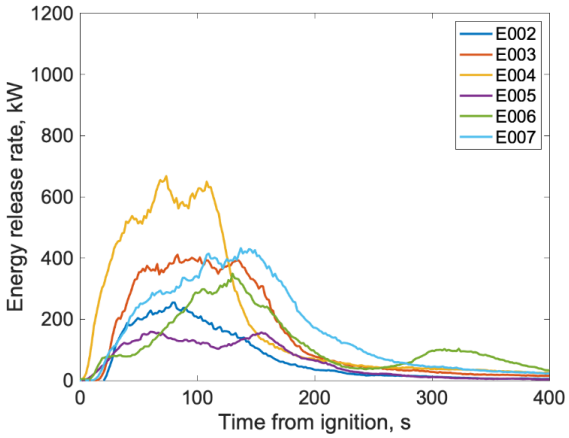

Figure 5 Energy release as a function of time for experiments 2—7.

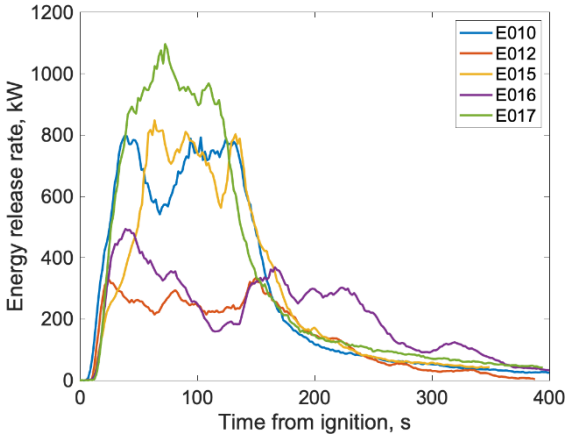

Figure 6 Energy release as a function of time for experiments 10, 12 15, 16, 17.

3.4. Heat fluxes.

The heat fluxes to the mid height of the heather canopy are shown in Figure 7. Only data for experiments in which flame spread was observed to occur on the whole length of the fuel bed are reported. The data show that the heat fluxes through the heather canopy exceed 100 kW/m^2 where there are large flames and significant burning behind the leading edge of the flame e.g., experiments 4, 10 and 17. For experiments with smaller flames with less burning behind the leading edge (e.g., experiment 16), lower heat fluxes are recorded but for extended durations. In cases where the flame thickness is lower (e.g., experiments 7 and 12), the heat flux was between 50 and 100 kW/m^2. Finally, in cases where the flame spread is characterised by a thin flame front, the heat fluxes is around 30kW/m^2. This highlights the importance of the burning behind the leading edge of the flame front in driving the fire spread processes.

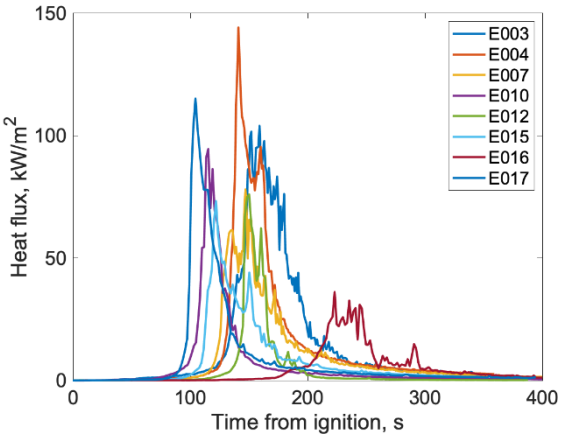

Figure 7 Heat fluxes to the heather canopy as a function of time from ignition.

4. Conclusions

Using laboratory scale experiments, we have observed the effects of different fuel elements on the likelihood for fire spread in *Calluna vulgaris*-dominated systems. These results apply only to laboratory conditions and should not be applied directly to fire danger assessments. The results indicate that the fire spread in heather under these conditions is a complex process in which the interaction between the different components of the fuel structure determines the fire spread characteristics. It seems that the fine brown fuels dominate the leading edge of the fire spread and that radiation from the trailing edge where the coarse fuels are burning supports combustion of fine green fuels. Heat fluxes greater than 100 kW/m^2 are measured from the combustion zone to the heather ahead however the heating lengths are very short. These insights will help develop models for flame spread in shrub fuels, in the development of fire danger systems and in the evaluation of fire impacts.

Abstract

The increased frequency and intensity of forest fires have been concerning populations particularly in countries typically affected by this natural disaster. Portugal has been harshly afflicted by wildfires specially in the north and central regions. In the frontline of forest fire combat there is one of the riskiest occupations in the world – firefighters. Firefighting involves high physical and psychological demanding activities typically performed in hostile environments. The proximity to fire exposes them not only to high temperatures but also to high concentrations of hazardous pollutants, most of which are listed as probable or known carcinogens. Given the above, IARC classified occupational firefighting activity as possibly carcinogenic to humans. However, it is still among the least studied occupations, existing very little information on exposure induced mechanisms that lead to health diseases. Thus, the general aim of Bio4FOX study is to identify a set of (bio)markers for the surveillance of Portuguese Wildland firefighters' occupational exposure during three phases, pre-, during and post- fire season. Here, we aim to describe the preliminary data on sociodemographic and occupational context of the Bio4Fox study population in the pre-fire season.

For the 1st phase of the study were enrolled around 175 wildland firefighters from 14 fire stations located in the northern region of Portugal. Information on sociodemographic data, health status, lifestyle and occupational exposure were obtained via a comprehensive questionnaire. The study group was composed by 143 men and 32 women; the mean age of the group was 37.46±10.85. Most of the firefighters reported to be voluntary (88%; n=155) beginning their activities at young ages; more than half (n=92) started within 17 - 22 years old and 15% (n=26) of the individuals attended firefighters' activities at earlier ages (12-16 years old). The average length of service as firefighter was 15.94±10.23 years. Around 45% (n=79) claimed to spend more than 10 hours in their duties, while 35% (n=62) and 13% (n=22) spend 8-9hours and < 8 hours, respectively. Concerning their risk perception related to exposure to occupational hazards, 80% (n=140) believed to be exposed to smoke, gases, and/or particles and 19% (n=33) to solvents (e.g., combustible). Self-reported symptoms (of last 30 days, not related with cold/flu) were: expectoration (14%; n=24), tiredness (13%; n=22), breath difficulty (9%; n=16), cough (7%; n=13) and wheezing (6%; n=10).

Our preliminary data describes the sociodemographic factors and occupational activities of a group of Portuguese firefighters before the fire-season. This data will be integrated together with the biological and environmental findings collected over different time points of a wildfire season. Bio4FOX will contribute to the establishment of recommendations/good practices to improve firefighters' working conditions, as well support the definition of better policies/prevention strategies highly needed in this sector.

1. Introduction

Portugal is a Mediterranean country extremely prone to forest fires (Schmuck et al., 2014). Unmanaged forest lands with extent fuel loads, high number of unwanted fire ignitions and the hot season periods characterized by dry weather contribute for the incidence and escalation of wildfires. Worryingly, the risk of fire is expected to worsen in the upcoming years and decades fuelled by climate changes through rising temperatures and low

humidity and precipitation levels (Flannigan et al., 2006). The frequency, extent and severity of wildfires, brings an urgent need to focus among a crucial human resource in fire management: wildland firefighters.

Firefighters are the backbone of any firefighting system. In Portugal the number of firefighters (both volunteer and professional) have been decreasing through the years requiring more efforts/longer periods of work from those on service. Firefighting is a physically and psychologically demanding activity and a potentially hazardous occupation (Naeher et al., 2007). During their activities wildland firefighters typically experience long work shifts (up to 24 hours), sleep deprivation, heat stress, exhausting hiking, and exposure to smoke via different routes of exposure (i.e., inhalation, dermal absorption and ingestion) (IARC, 2010). Smoke is a complex mixture that includes several hazardous combustion byproducts, including particulate matter, nitrogen dioxide, carbon monoxide, and volatile organic compounds (VOCs) such as polycyclic aromatic hydrocarbons (PAHs), formaldehyde, toluene, acrolein, xylene. But firefighters are not only exposed during wildfire combat. Their exposure continues long after a fire is extinguished, mainly from contaminated equipment/vehicles. Some of the symptoms reported include eye and respiratory irritation, shortness of breath, nausea, headaches, and dizziness (Reinhardt, 2000). It is known that many of the combustion by-products are associated to adverse health effects (Manisalidis et al., 2020) being some of these compounds classified as potentially/possibly carcinogenic to humans by the International Agency for Research on Cancer (IARC) (IARC, 2010). Several epidemiological studies have described an elevated risk of cardiorespiratory diseases/outcomes (Reinhardt, 2000; Gaughan et al., 2008; Navarro et al., 2019) as well as different types of cancers (e.g., prostate, testicular, non-Hodgkin's lymphoma) (LeMasters et al., 2006). Given the above, IARC has classified occupational firefighting activity as possibly carcinogenic to humans (IARC, 2010). However, firefighter is still among the least studied occupations concerning the exposure-induced mechanisms that lead to adverse health effects. The existing research gaps limits the ability to develop effective measures to protect the health of these workers. The timely occupational risk assessment is utmost importance for early interventions such the suggestion of preventive measures to mitigate the risk of possible adverse health outcomes in firefighters.

Different factors that may modify the relationship between health effects and pollutants exposure must be considered such individual characteristics (e.g., age, body mass index, health status, lifestyle) and other contextual factors such occupational-related variables (e.g., type/frequency of occupational exposures, use of personal protective equipment (PPE), tasks performed, etc.). The application of questionnaires is among the most used methods to collect relevant information in epidemiological studies. Questionnaires is a non-expensive tool that can provide useful information on the duration (past, recent or current) and frequency of certain exposures providing an overview of different risk factors. In combination with other exposure assessment methods such biological and environmental monitoring may provide a comprehensive characterization of firefighters' occupational risks.

Bio4FOX project is an ongoing study that aims to identify a set of appropriate biomarkers for the surveillance of Portuguese wildland firefighters' occupational exposure, evaluating the biological impact of different time-points of exposure through a longitudinal approach (pre-, during and post- fire season). Here, we aim to describe the preliminary data concerning the Bio4Fox study population characterization - sociodemographic and occupational related - in the pre-fire season. Preliminary data collected via self-administered questionnaires will be further used to perform a comprehensive assessment of firefighters' occupational exposure and related health impacts.

2. Methods

Around 175 wildland northern Portuguese firefighters, from 14 fire stations, were involved in this study. Participants were initially fully informed about the nature and the study – in a face-to-face approach - stressing the possibility of stop at any time. In case of acceptance, individuals were asked to sign an informed consent approved by the University of Porto Ethic Committee. The individual characteristics of the participants were collected through a comprehensive questionnaire that was applied in the first phase of the study (pre-exposure; 2021) comprising questions on sociodemographic factors, lifestyle, health status, occupational history (as firefighter or/and other profession) and environmental exposures.

Preliminary data related with the sociodemographic and occupational context are here described through means, standard deviation, percentages, and frequencies. Reported height and weight was used to calculate Body Mass Index (BMI - kg/m^2).

3. Results/Discussion

We present preliminary data collected from 175 professionally active firefighters - 143 males and 32 females. A greater proportion of men performing firefighting activities is part of the Portuguese reality; in 2016 there were about 28308 firefighters, being 5119 woman and 23189 men (INE, 2016). The mean age of participants was 37.88±11.03 and 35.62±9.99 for men and woman, respectively. BMI of this group of firefighters was 27.35±4.08kg/m2. According to World Health Organization criteria only 27% (n=48) were in the category of normal weight (range, 18.5–24.9 kg/m2) with the remainder, 41% (n=73) and 24% (n=43), being either pre-obese (range, 25.0–29.9 kg/m2) and obese (≥ 30.0 kg/m2) correspondingly. Previous studies also found higher rates of overweight levels (BMI ≥ 25 kg/m2) in firefighters when compared with the general population (Poston et al., 2011; Soteriades et al., 2011).

A total of 56% (n=98) reported to have accomplished the 12th grade, 24% (n=43) claimed to have the 9th grade or less and only 13% (n=23) declared to have completed university education. The majority of the participants (88%; n=155) reported to be voluntary firefighters, a common trend verified in the Portuguese firefighting system. The average length of service in firefighting activities was 15.94±10.23 years indicating a considerable life period of firefighting exposures. In fact, data shows that around 15% (n=26) of the individuals began their firefighters' activities (i.e., learning/training) between 12 – 16 years old, whereas more than a half (52%; n=92) started their activities within 17 and 22 years old. Around 26% (n=46) of individuals only started after turning 23 years old.

Regarding functions performed in firefighter activity, 30% (n=53) reported to have driver functions, 27% (n=47) indicated to provide support to emergency services, 26% (n=46) incorporate the permanent intervention team (EIP), 10% (n=18) mentioned to be telephone operator, 7% (n=12) to perform rescue activities, 7% (n=12) reported to have command activities and 1% (n=2) declared to have administrative functions. Concerning the mean time/day spend in some of the referred activities, long periods of work were reported: the most of firefighters (45%; n=79) spend more than 10 hours in their duties, while 35% (n=62) and 13% (n=22) spend 8-9hours and less than 8hours, respectively.

Firefighters are exposed to different hazards in their occupational context. Figure 1 presents an overview of the occupational exposures that were referred by the participants.

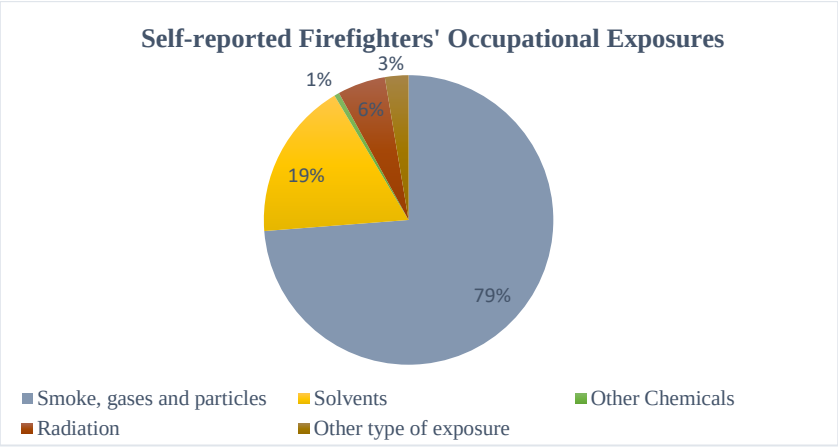

Figure 1 - Percentage of individuals that reported to be exposed to different hazards.

Data indicates that firefighters are mostly exposed (according to their risk perception) to smoke, gases and particles in their activities. Indeed, firefighters may be required to participate in firefighting activities (e.g., fire suppression, fuel management) with a certain regularity. As example, around 15% (n=27) of individuals reported to be exposed to fire in the week before, indicating a mean period of exposure of 2.08±6.66 hours/week.

Although in fewer proportions, firefighters also stated to be exposure to solvents (e.g., combustible), radiation and other type of exposures/chemicals.

When asked about the use of PPE during participation on firefighting activities, most individuals (97%; n=170) reported to use PPE, such protective clothes, boots, respiratory protection, gloves, protective glasses and helmet. PPE to be used by firefighters during their activities is regulated (Despacho nº3974, 2013) however, there is a general reluctance to wear protection since it adds physiological demands and heat stress upon the user (IARC, 2010) and the respiratory protection typically used is not ideal to effectively protect firefighters in wildfires context (Austin, 2008).

Concerning the health problems, 3% (n=6) of the individuals reported having diagnosed respiratory problems and 2% (n=3) heart disease. Figure 2 shows the felt symptomology in the last month (non-related with colds/flu).

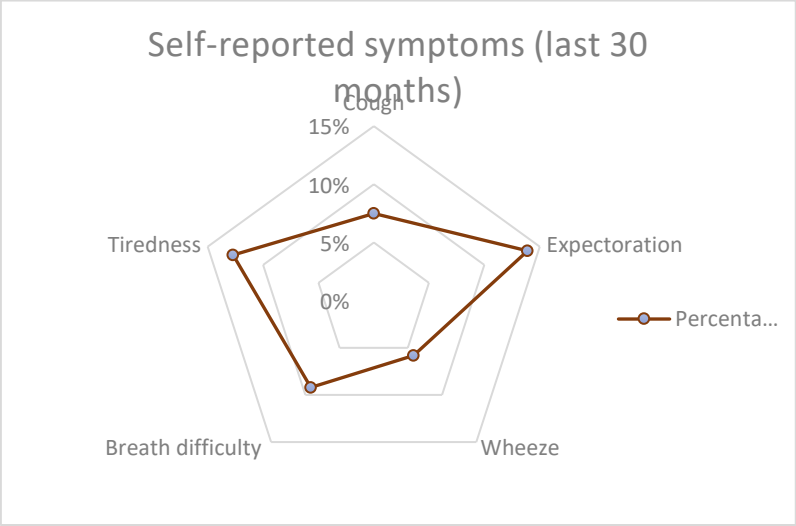

Figure 2 – Percentage of self-reported symptoms in the last 30 days among study group.

Expectoration (14%; n=24) and tiredness (13%; n=22) were the most common symptoms reported, followed by breath difficulty (9%; n=16), cough (7%; n=13) and wheezing (6%; n=10).

Regarding some aspects of their lifestyle, 31% (n=55) declared drinking alcohol regularly; 18% (n=31) have a daily consumption of wine whereas 23% (n=41) have a daily consumption of beer. In this group, thirty-eight percent (n=67) of individuals never smoked, 22% (n=38) were former smokers and 37% (n=65) current smokers (mean of 15 cigarettes/day).

4. Conclusions and future perspectives

There are no doubts that firefighters have one of the most dangerous and demanding occupations in the world being exposed to a variety of hazards. In the present study, we observed a high percentage of firefighters that indeed assumed to be exposed to particles, smoke and gases in their occupational context. This finding is particularly concerning due the long periods of work and the length of service that were described. Firefighters may have different physical and psychological demanding tasks that are many times accompanied by dangerous exposures. The stressful nature of this occupation may be related with some individual behaviours (e.g., smoking habits, alcohol consumption, high BMI) that were here observed.

Overall, present findings offer a glimpse of Bio4Fox study population. The characterization of population is a very important step to have a broad perspective of the relevant factors that must be considered in further analysis.

This ongoing study is expected to contribute for a comprehensive risk assessment of firefighting occupational exposure and for the establishment of recommendations/good practices to improve firefighters' working conditions as well as for the definition of policies and prevention strategies highly needed in this sector. The characterization of Portuguese firefighters' occupational exposure and potential health risks is particularly relevant because Portugal is one of the European countries more highly affected by forest fires. Finally, it is also essential to promote a wise fuel management in forests, because reducing the amount of fuel or changing

its arrangement before a wildfire can prevent or attenuate severe fire behaviors as well its impacts on human health.

5. Ackowlegments

This work received financial support by the project PCIF/SSO/0017/2018 by the Fundação para a Ciência e a Tecnologia (FCT), Ministério da Ciência, Tecnologia e Ensino Superior (MCTES) through national funds. Flame length; Flame angle; Fire safety

Abstract

Flames can be geometrically described from a simplified perspective by means of their length (or height), angle and depth. These parameters are key for fire safety calculations, to prevent injuries during entrapments or to design preventive infrastructures. Most methods to estimate flame geometry require information on fire behaviour (e.g. rate of spread or fireline intensity), which are not always available or straightforward. Within this context, we are developing a tool to estimate flame geometry only from environmental parameters (fuel, weather and terrain) and without the need of fire behaviour predictions beforehand. To achieve this, we have gathered data on field-scale fires and used them to fit binary logistic regressions, to obtain the probability of occurrence of a certain flame geometry for specific fuel structures. We have already modelled flame length probability from fine fuel load, moisture content and wind speed in different fuel structures and flame angle probability from fine fuel load and wind speed in grasslands. We are currently working to extend the dataset and cover a wider range of fuel structures and conditions.

1. Introduction

Wildfire flames are a complex and transient phenomenon, but can be geometrically described from a simplified perspective by means of their length (or height), angle, depth (Figure 1) and residence time.

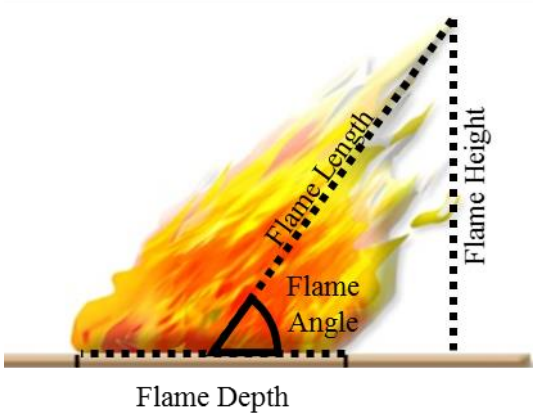

Figure 1- Flame geometry sketch.

Flame geometry is key for fire safety calculations involving radiative energy transfer, such as to estimate firefighter safety and survival zones (Page & Butler, 2017; Butler, 2014) or as input to solid flame models (*e.g.* Eisenberg *et al.*, 1975) to design preventive infrastructures by comparing the radiation profile with the resistance threshold of the elements to protect (*e.g.* Ricci *et al.*, 2021; Standards Australia, 2009). Several works attempted to estimate flame geometry from empirical and physical models (*e.g.* Alexander & Cruz, 2012; Nelson *et al.*,

2012; Anderson *et al.*, 2006), an approach that requires information on fire behaviour beforehand, namely rate of spread and intensity.

To overcome the need of *a-priori* fire behaviour predictions, our aim is to build a "Flames Catalogue" to estimate flame geometry for particular sets of environmental conditions (fuel, weather and terrain). The catalogue will consist on typical scenarios of interest for fire management linked to the range of expected flame geometries. In this short paper we present the current status of this tool and its potential to predict flame geometry in different fuel structures.

2. Methodology

2.1. Data gathering

We have gathered data from field-scale fires. These data consisted of environmental parameters (weather, terrain and fuel) and flame geometries (flame length and angle) from observations and measurements during wildfires and field experiments. We have excluded data from indoor experiments, wind-tunnel experiments and prescribed burnings, in which the aim of the burn constrains the free spread of the flame front. The sources of the data were the BONFIRE (Fernandes et al., 2020), Anderson et al. (2006) and CERTEC (unpublished) databases.

In this communication, environmental parameters refer to weather (wind speed) and fuel (Fine fuel load and moisture content of the dead fraction). We grouped the data in three fuel structures: open grasslands, open shrublands and undercanopy fuels (a mixture of litter, grasslands and shrublands). Flame geometries refer to flame length and flame angle, expressed in accordance with Figure 1.

2.2. Data modelling

We used these data to fit binary logistic regressions and estimate the likelihood of occurrence of certain flame length and flame angle at a given set of environmental parameters. Binary logistic regressions have the form of Eq. 1, with a logit of the form of Eq. 2:

$$P(Y = 1|X) = \frac{e^{f(x)}}{1 + e^{f(x)}} \quad \text{Eq. 1}$$

$$f(x) = \beta_0 + \sum_{i=1}^{i=n} \beta_i Var_i \quad \text{Eq. 2}$$

Where $P(Y = 1|X)$ is the probability of occurrence of an event under certain conditions (*e.g.* the probability of flames being smaller than 3 meters when fire burns dry grasslands with a fine fuel load of 1 kg/m^2 in still air). β_0 is a constant parameter and β_i are coefficients for the different independent variables (Var_i), namely fine fuel load (ffl), wind speed measured at a height of 2 (U_2) or 10 meters (U_{10}) and fuel moisture content of the dead fraction (FMC_d). The relation between an event and a predictor is expressed by means of its odds ratio; odds ratios greater than 1 indicate that the event is more likely to occur as the predictor increases, while odds ratios lower than 1 indicate that the event is less likely to occur as the predictor increases.

3. The Flames Catalogue

3.1. Flame length

Flame length results from the equilibrium between the release of pyrolysis gases, the diffusion of oxygen and the transmission of heat, among other factors involving combustion (Finney *et al.*, 2021). Generally, greater fuel loads (especially fine fuels) are a sign of a greater release of pyrolysis gases and hence larger flame lengths. Most models developed to predict flame length require fire behaviour predictions (*e.g.* Alexander & Cruz, 2012). Our approach dismisses fire behaviour predictions and relies exclusively on environmental parameters to predict flame length, which makes it easier to use for fire managers. To fit the binary logistic regressions, we used ffl for shrublands, ffl and U_2 for understory fuels and ffl, U_2 and FMC_d for grasslands. Table 1 shows the constant parameters and coefficients to fit Eq. 2 and Figure 2 computes Eqs. 1 and 2 to show the probability of having flames smaller than a certain length as a function of the expected variables. Data used to fit the model

covered up to 3 kg/m², 1.2 kg/m² and 1.5 kg/m² of fine fuels in shrublands, grasslands and understory fuels respectively, 25 % of moisture content in grasslands and 25 km/h of wind speed.

Table 1- Constant parameters and coefficients for logistic regressions to estimate flame length probability from fine fuel load (ffl), wind speed at 2 meters above the ground (U_2) and fuel moisture content of dead fuels (FMC_d). "FL" stands for Flame Length (m). Underlined values indicate p<0.05 in Pearson goodness of fit test.

		FL ≤ 0.5	FL ≤ 1	FL ≤ 2	FL ≤ 3	FL ≤ 4	FL ≤ 6	Odds ratio
Shrubland	β_0	3.10	3.88	3.68	4.79	4.57	4.91	-
(n = 117)	β_{ffl}	– 6.22	– 5.74	– 3.72	– 3.34	– 2.32	– 1.80	0.05±0.06
Grassland	β_0	0.96	2.10	2.78	4.06	5.64	-	-
(n = 173)	β_{ffl}	– 5.87	– 5.52	– 5.05	– 5.23	– 5.00	-	0.01±0.002
	β_{U_2}	0.08	0.06	0.05	0.08	0.07	-	1.07±0.01
	β_{FMC_d}	– 0.11	– 0.14	– 0.09	– 0.08	– 0.15	-	0.89±0.02
Understory	β_0	1.42	2.15	4.49	6.66	8.98	-	-
(n = 395)	β_{ffl}	– 1.94	– 0.99	– 1.51	– 2.11	– 2.51	-	0.18±0.11
	β_{U_2}	– 0.36	– 0.30	– 0.41	– 0.51	– 0.66	-	0.64±0.09

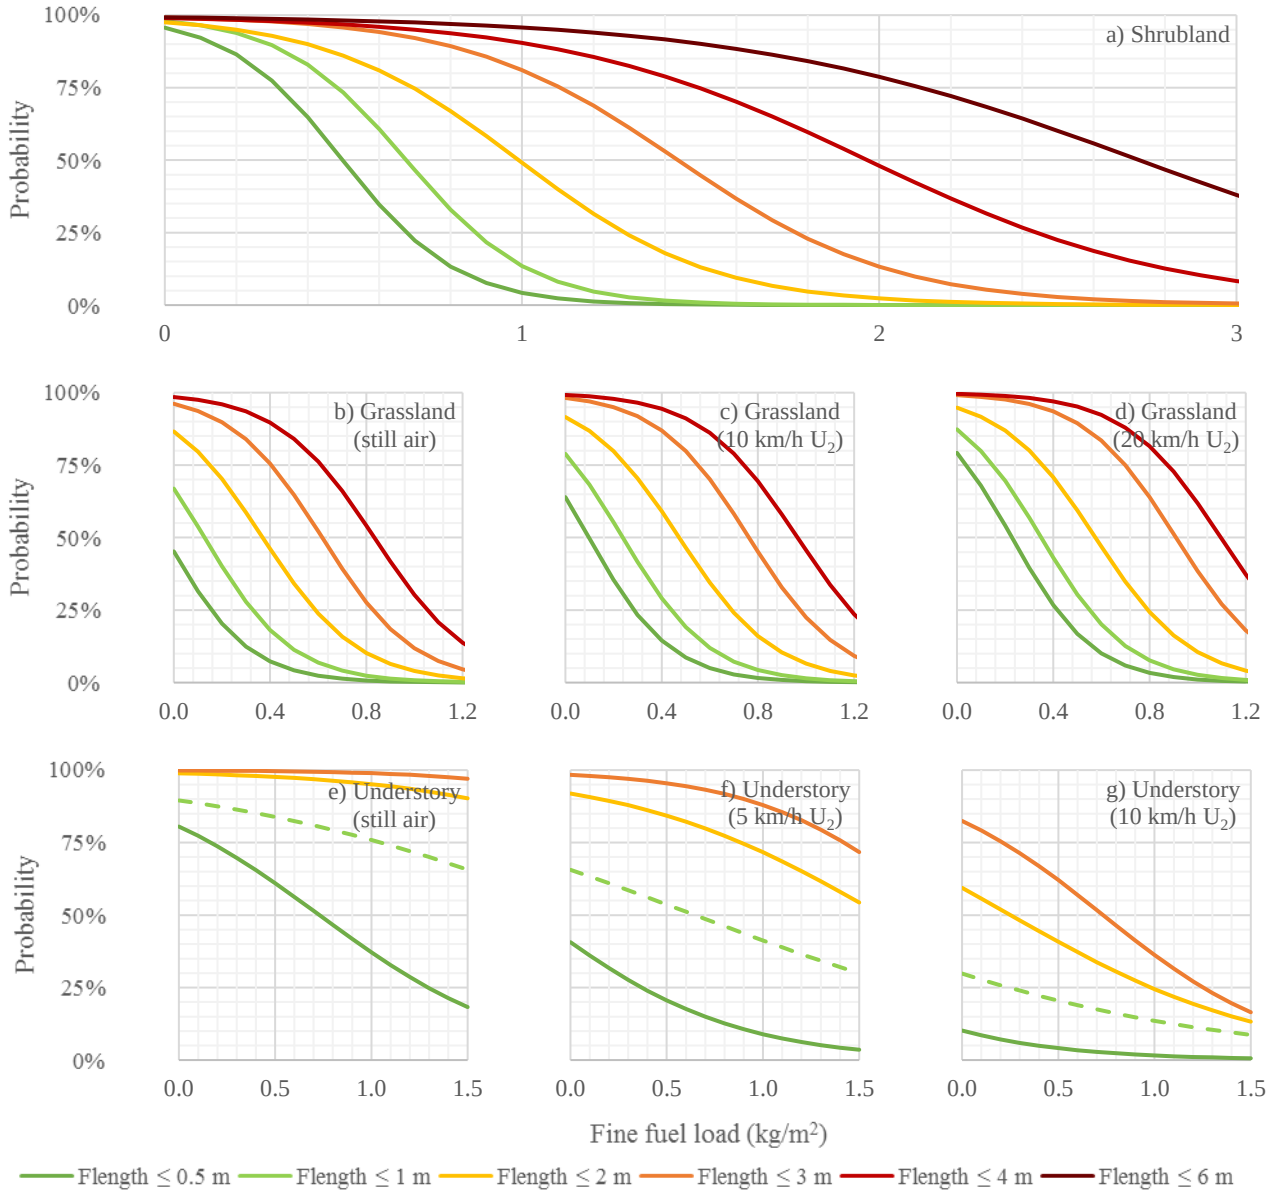

Figure 2- Logistic regressions to estimate flame length probability (y-axis) from the variables in Table 1. Dashed lines indicate p<0.05 in Pearson goodness of fit test.

3.2. Flame tilt angle

Flame tilt angle results from the equilibrium between buoyancy forces, that raise the fire plume, and wind, that pushes the flame forward (Finney *et al.*, 2021). Most models developed to predict flame angle require fire behaviour predictions (*e.g.* Nelson *et al.*, 2012). Our approach uses fine fuel load (ffl) as a proxy for buoyancy forces and wind speed at 10 meters above the ground (U_{10}), dismissing fire behaviour predictions and making it easier to use for fire managers.

Table 2 shows the constant parameters and coefficients to fit Eq. 2 and Figure 3 uses Eqs. 1 and 2 to show the probability of having flames with a certain angle from grassfires. Data used to fit the model covered up to 1 kg/m^2 of fine fuel load and 35 km/h of wind speed.

Table 2- Constant parameters and coefficients for logistic regressions of flame angle in grasslands.

		α < 80	**α < 60**	**α < 45**	**Odds ratio**
Grasslands	β_0	0.601	– 0.787	– 1.85	-
(n = 211)	β_{ffc}	– 2.311	–1.867	– 2.970	0.10±0.05
	$\beta_{U_{10}}$	0.235	0.152	0.105	1.18±0.08

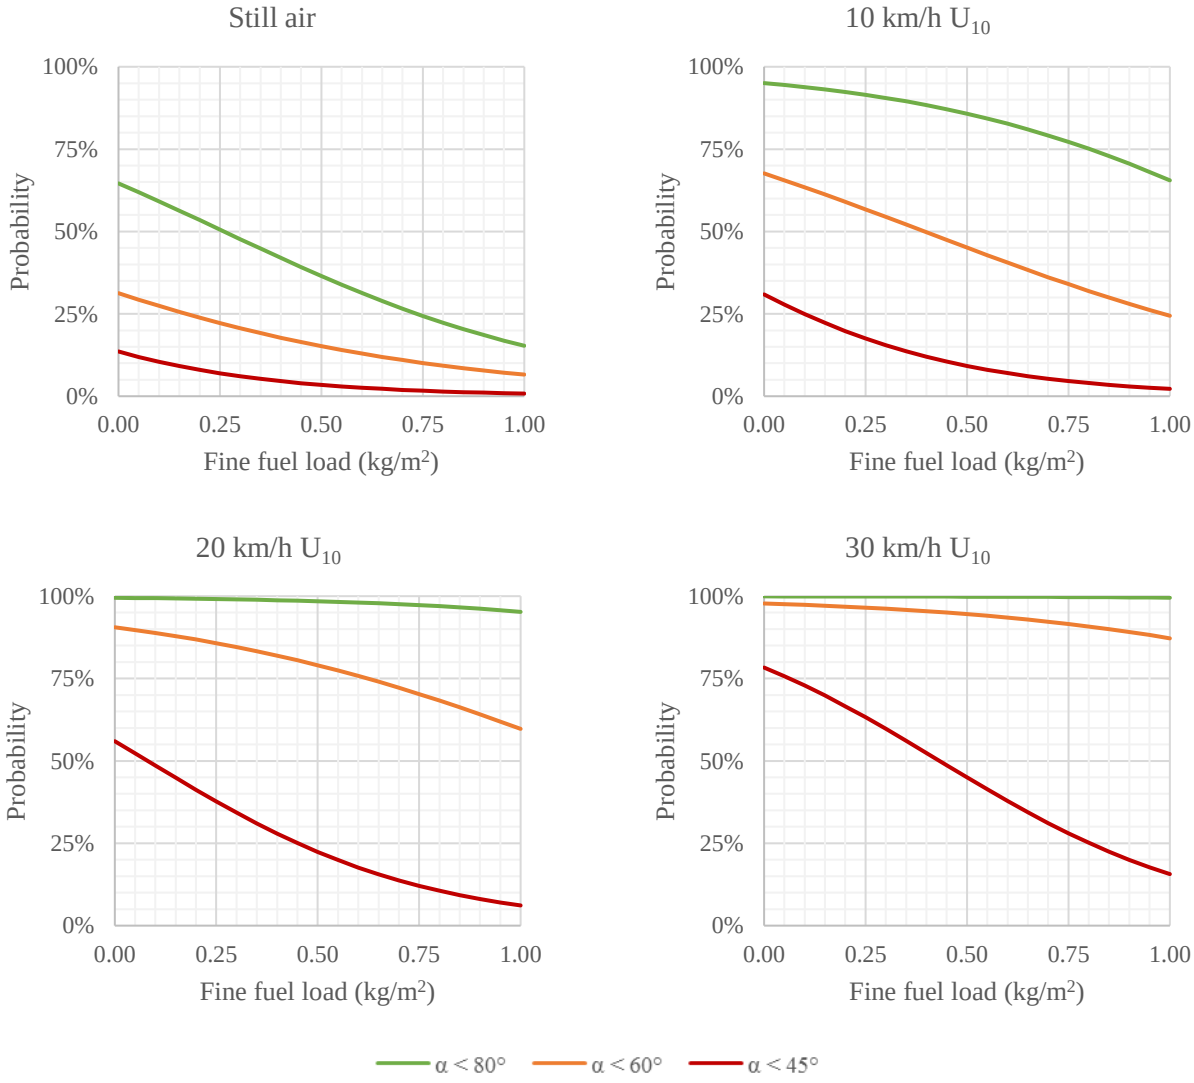

Figure 3- Logistic regressions to estimate flame angle in grasslands.

3.3. Study case

As part of the fire prevention program, the Fire Service is building safety areas for sheltering in a firebreak network. This firebreak network is surrounded by shrublands, with a fine fuel load of 1 kg/m^2. These safety

areas have been dimensioned for flames of 6 meters, at most. The Fire Service aims to outline their validity, with an acceptance threshold of 95% probability. Using Eqs. 1 and 2 and data in Table 1 for shrublands, the probability of flames equal or smaller than 6 meters is 96%, which is acceptable.

4. Conclusions

We have presented a novel approach to predict flame geometry from environmental parameters and fuel consumption, independent of *a priori* fire behaviour knowledge. With it, it is possible to manage fire prevention from a small number of inputs, easily measurable in the field. This Flames Catalogue does not intend to substitute empirical and physical approaches to estimate fire geometry, but to serve as a complementary tool for fire managers.

Prior to develop a definitive tool, the dataset should be extended to cover existing gaps, like the prediction of flame angles with fuel structures other than grasslands, or introducing slope values in the logit functions for flame length. Some obstacles to reach this goal are the lack of common criteria to measure flame geometry among the various existing studies and the difficulty to perform accurate measurements during large experiments and wildfires. The Flames Catalogue is aimed to include other important parameters such as flame depth or residence time.

Packing ratio, rate of spread, optical length, flame height, mass-loss rate.

Abstract

The influence of Pinus Pinaster needles packing ratio on fire spread at laboratory scale is investigated experimentally and compared to other wildland fuels. The packing ratio was varied from up to 10% by changing the fuel bed load and thickness. An optimum ratio of 5.5% is obtained corresponding to a maximum rate of spread. This optimum ratio is close to that found by Rothermel for crib fuels. However, the rate of spread increases again for higher porosity, which suggests the existence of a second optimum ratio. Two optimum ratios were also observed by Rothermel for excelsior fuels and recently by He et al for experiments using laser-cut cardboard. Recently, two optimum ratios corresponding to a minimum ignition time were observed using Pinus Halepensis needles. The minimum ignition time for spreading fuels correspond to a maximum rate of spread. These ratios have been attributed to a maximum heat flux absorption by the fuel. The heat flux absorption effect on the rate of spread is discussed by using the fuel optical length. The obtained optimum ratio corresponds to a small optical length ($12\ mm$), which means that the heat flux is absorbed by the surface of the fuel bed. The second optimum ratio may correspond to an optical length much larger than the fuel bed thickness (around $50\ mm$). This corresponds to a bulk absorption of the heat flux. Further analyses of the mass-loss rate are provided to discuss thermochemical effects.

1. Introduction

Forest fire behavior is still far to be understood, due to the large variety of wildland fuels and their complex structure and composition. Burning conditions may vary significantly from one region to another because of the fuel spatial distribution induced by their moisture, density, surface-to-volume ratio, and packing ratio. The packing ratio has been found to influence directly the fire propagation (Z. Campbell-Lochrie et al, 2021), and the observed optimum ratio has been attributed to thermochemical effects (Rothermel, 1972). Further investigations suggest that the packing ratio directly affects radiative heat transfer to the fuel bed surface (Simeoni et al, 2011). A recent experimental study on a discrete fuel bed composed of laser-cut cardboards found that internal heat transfer affects the rate of spread (ROS) in the case of dense fuel (He et al, 2021). Heat transfer has been found recently to be the main cause of the non-monotonic behavior of ignition time as a function of packing ratio (Boutchiche et al, submitted). This work aims to highlight the relation between ROS behavior and absorbed heat flux at different packing ratios.

2. Experimental setup
