Preface

The period between 2018 and 2022 showed us that the problem of wildfires at a global scale is not abating, rather on the contrary. It seems that the consequences of climatic change are already affecting the occurrence of wildfires in various parts of the World in a form that we would expect to happen only several years later. In many countries of Southern Europe, as well in some regions of the USA, Canada and Australia, where we are used to face the presence of very large and devastating fires, we continued to have record breaking events. Some countries, like those of Central and Northern Europe that were not used to having large fires, during these years experienced them.

The previous years were very demanding to the entire World also in other aspects that affected all of us. We refer to the restrictions imposed by the pandemic that limited our meetings and travel, affecting in many cases the health of members of the Wildfire Scientific Community. Fortunately, we were able to find new forms of communication, to overcome those limitations and keep in touch with each other. During weeks and months, for many of us, the personal meetings and group work were replaced by online connections. In spite of the economy of money and time, and the easiness of bringing together a great variety of persons that these meetings provided, we realized that they did not replace the face to face meetings, that bring with them other invaluable dimensions, that are part of personal communication and help to build a scientific community.

Aware of this and of the uncertainties that the various phases of the pandemic brought and of the possibility of having a localized or wide spread worsening of the situation, in the face of a reality that was completely out of our hands, we decided to maintain the organization of our International Conference on Forest Fire Research, now in its 9th Edition, in November 2022, in its traditional form of a face to face meeting.

The good reception of our initiative encouraged us to go ahead with the organization of the Conference, hoping that it will be a hospitable and friendly place where we can all meet and interact. This is our contribution to the common effort to better understand and manage wildfires, to make our Planet a safer and more sustainable place, for many centuries to come.

For the first time in its history, our Conference is partially sponsored by two significant research actions supported by the European Commission. The project FirEUrisk, a Research and Innovation Action of H2020 (Grant 101003890) that aims to propose an innovative framework for managing the risk of wildfires in Europe

by integrating the various phases and scales of the process while focusing on large fires and future climate conditions, will use the Conference to share several of its findings with the scientific and operational communities. The Firelogue Coordination and Support Action, funded by the EU Greendeal program under Grant 101036534, plans to further the dialogue and network among stakeholders within the Wildfire Risk Management community by organizing several networking actions, identifying synergies and conflicts between different interest groups. By bringing together experts from the community, Firelogue will foster mutual discussions and exchange that will lead to just and fair solution to the increasingly threatening wildfires across Europe and the world.

For the second time, the International Association of Wildland Fire honored our Conference by linking it to the 17th International Wildland Fire Safety Summit. The subject of fire safety has always been very dear to our Conference, since its first edition in 1990. This is expressed by the large number of keynotes and papers dedicated to the problem of safety of operational agents and citizens in the face of fire, but also by the Short Courses on Fire Safety that we have organized, since 2002 (the year of the first association to the Safety Summit), in parallel to the Conference, to promote a research culture on fire safety in all countries.

This eBook compiles the valuable contributions to this Conference, made by authors from the scientific community all around the world. Each one of the six major themes of the conference includes different topics in the entire range of fields related to the problem of wildfires management. They compose the six chapters of this eBook, as follows:

Chapter 1) Decision Support Systems and Tools

Topics covered: Fire Detection and Monitoring; Remote Sensing; Fire Behaviour Prediction Systems; Meteorology and other support information; New Technologies

Chapter 2) Fire at the Wildland Urban Interface

Topics covered: Fuel Management; Fire Management; Risk Assessment; Community protection; Fire modelling

Chapter 3) Risk Adaptation

Topics covered: Human and Institutional Factors; Economic Issues; Fire Impacts on Society; Fire Ecology; Fire Climate; Fire Prevention

Chapter 4) Risk Assessment

Topics covered: Fire Risk Assessment; Fire Risk Communication; Fire Effects; Cascading Effects; Evaluation and Management of Burned Areas; Fire History

Chapter 5) Risk Reduction

Topics covered: Fire Behaviour; Fire Prevention; Fuel Management; Fuel Modelling; Fire Preparedness; Climate Change

Chapter 6) Wildfire Management and safety

Topics covered: Fire Behaviour; Firefighting training; Fire Suppression; Large Fires; Fire Safety; Fire protection; Fire Management; Fire Weather

We are sure that this Conference and eBook may serve the purpose of keeping a record of the recent research in these fields and to illustrate the role that is played by the scientific community in the face of the challenges

that these new times bring to fire science. We are sure that it will inspire and trigger more investigation and collaboration.

This e-book, published by the Coimbra University Press, is considered as a publication *per se*, independent from the Conference, and each paper is considered to be part of a chapter.

In the name of the Organizing Committee we wish to thank all the authors for their valuable work and for participating in the Conference.

We wish to thank Dr. Mike Flannigan for having accepted, once more, the role of Head of the Scientific Committee, who with the help of a group of selected experts reviewed and revised the submitted abstracts. Their work was very important to keep the high level of quality that has been the standard of this Conference.

We wish to thank to the distinguished individuals that accepted to be members of the Honorary Committee and to all the entities that sponsored our Conference.

We would like to express our personal thanks to all the members of the Organizing Committee and in particular to our colleagues of the Local Committee and the Secretariat for all their support, work and dedication during the preparation of the Conference. They carried the largest part of the workload that included the performance of large and small tasks that are required to put this Conference together and therefore they deserve thanks from all of us.

Coimbra, 24 August 2022

Fuel moisture content; Landscape forecasting; Machine learning; Forest management; Weather forecasting

Abstract

Accurate and timely forecasting of forest fuel moisture is critical for decision making in the context of bushfire risk and prescribed burning. The moisture content in forest fuels is a driver of ignition probability and contributes to the success of fuel hazard reduction burns. Forecasting capacity is extremely limited because traditional modelling approaches have not kept pace with rapid technological developments of field sensors, weather forecasting and data-driven modelling approaches. This research aims to develop and test a 7-day-ahead forecasting system for forest fuel dryness that integrates an automated fuel sensor network, gridded weather, landscape attributes and machine learning models. The integrated system was established across a diverse range of 30 sites in south-eastern Australia. Fuel moisture was measured hourly using 10-hour automated fuel sticks. A subset of long-term sites (5 years of data) was used to evaluate the relative performance of a selection of machine learning (Light Gradient Boosting Machine (LightGBM) and Recurrent Neural Network (RNN) based Long-Short Term Memory (LSTM)), statistical (VARMAX) and process-based models. The best performing models were evaluated at all 30 sites where data availability was more limited, demonstrating the models' performance in a real-world scenario on operational sites prone to data limitations. The models were driven by daily 7-day continent-scale gridded weather forecasts, in-situ fuel moisture observation and site variables. The model performance was evaluated based on the capacity to successfully predict minimum daily fuel dryness within the burnable range for fuel reduction (11 – 16%) and bushfire risk (<11%). The sites with long-term data performed favourably using the LightGBM model. Producing average probability of detection (POD; probability of detecting an event in the specified range) prediction results 1-days out, 5-days out and the average across all seven days of 0.92, 0.81 and 0.80 (<11%), and 0.71, 0.54 and 0.53 (11 – 16%); with R2's of 0.77, 0.59 and 0.55. The machine learning models performed favourably compared to the statistical and process-based models. This demonstrates that accurate, real-time operational fuel moisture forecasting can be achieved by integrating sensor data, weather forecasts, landscape information, and data-driven modelling approaches. The proposed system has the potential to be applied in any wildland fire setting where weather forecasts are available, and the adaptation of this system will greatly enhance the decision-making capabilities of fire managers.

1. Introduction

Bushfires as a natural disaster are the cause of hundreds of fatalities in Australia and across the globe (Blanchi et al., 2014; Haynes et al., 2010, 2019). An important component of bushfire risk is the dead fuel moisture content (DFMC). This is partially due to the ignition probability of fuels having a non-linear relationship, with a significant increase in ignition risk once the fuels reach a threshold moisture content (Ellis, 2015). In

productive forests, fuel moisture is also an important variable which controls the risk of bushfire ignition and spread, with the fuel loads being high enough to maintain a fire once started (Cawson et al., 2018). Fuel moisture also makes planned burning extremely difficult (Slijepcevic et al., 2015). Due to this being able to predict the DFMC into the future would allow for better risk identification and fuel management planning.

Modelling of DFMC has been attempted using processes-based methods which input temperature, relative humidity, solar radiation, and precipitation. With the model proposed by Nelson (2000) being widely used. Recently this model has been surpassed by more mechanistic (Van Der Kamp, 2017) or data driven (Lee et al., 2020; Shmuel et al., 2022) approaches which improve the representation and accuracy of FMC predictions. These methods utilise a larger number of input variables which aim to improve the modelling accuracy by more detailed representation of the physical processes, or through determining the relationships through statistical, data driven techniques (e.g. random forest, neural networks). These methods have not been explored in predictive modelling under varying forest canopies (key driver of FMC (Brown et al., 2021)), forecasting fuel moisture multiple days in advance using forecast data. A forecasting system would be another valuable tool to assist fire managers in early warning risk detection systems or allow fuel reduction burn operations to be moved to a day which will optimise the likelihood of achieving a successful burn.

The overall aim of this study was to develop an automatic fuel moisture monitoring system, capable of forecasting 10-hour fuel moisture. This system is aimed at capturing the change in fuel moisture under varying forest types, located across a large spatial and climatic range. The system integrates advancements in the ability to forecast short-term climate conditions and utilise the ever-expanding, continuous dataset which the automatic fuelsticks provide. For this system to produce the highest accuracy predictions, two specific research questions arose, these being:

1. If you have a high quality and quantity of data how do machine learning models compare with statistical (VARMAX) and process-based models, and which model is likely to be the most reliable in a real-world scenario?
2. How well does the best performing methods in question forecast across a larger network with smaller datasets and varying data quality?

2. Methods

2.1. Overview - Fuel moisture monitoring forecasting system

The Forest Fuel Moisture Forecasting System (FFMFS) comprises four components that come together to allow fuel moisture to be forecast for up to seven days. The conceptual diagram shown in Figure 1 illustrates how these key components are integrated for a continuously retrained spatial/temporal forecast model (gridded weather forecast, gridded landscape attributes, live on ground sensor network, daily re-trained ML model). It integrates spatially forecast climate variables, with the significant advancements in continuous in-situ forest fuel moisture monitoring (Automated fuel moisture sticks), and in remote sensing datasets. These different streams of data and information were brought together in a machine learning algorithm which predicts the minimum, maximum and mean fuel moisture content across the landscape at a daily timescale, seven days in advance. The system was developed in consultation with the Department of Environments, Land, Water and Planning (DELWP, Victorian Government, Australia), this was to ensure that it could be replicated within the government organisation, with the potential to be used in risk and management planning.

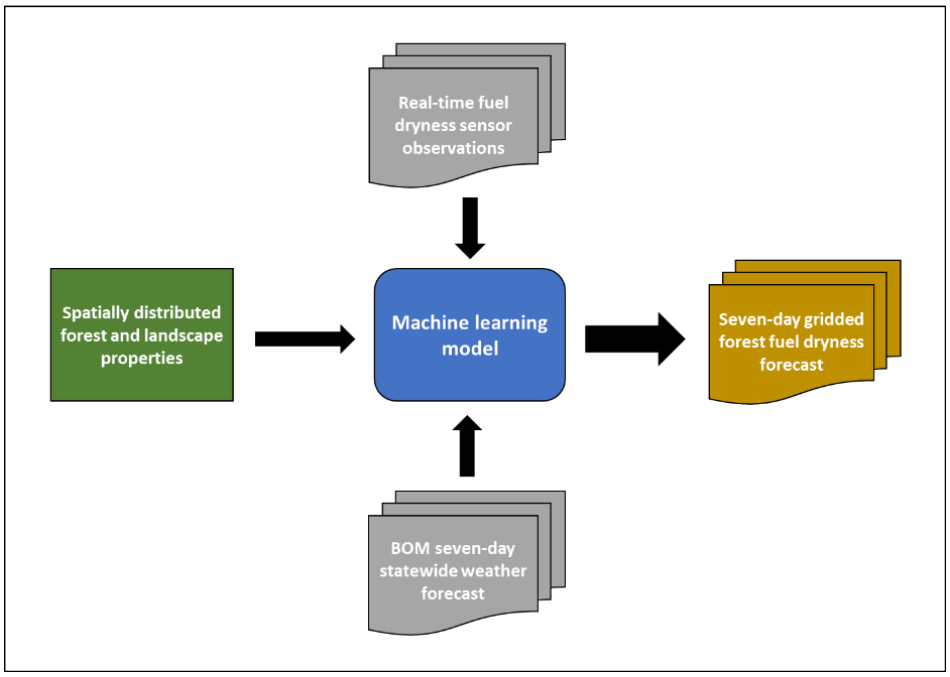

Figure 1- The components of the forest fuel moisture monitoring system

2.2. Study area

The study area was located across Victoria, Australia (Figure 2). On the traditional lands of the First Nations peoples (Victorian Aboriginal Heritage Council Victoria's Current Registered Aboriginal Parties (RAP), 2022). The study comprised of 30 field sites which captured a wide range of physical and environmental variables throughout the region. The long-term climatic conditions vary significantly across the sites, with aridity indexes from 1.13 to 5.90. The study area also covers a range of vegetation types and forest structures, from tall eucalyptus forests to sparse woodlands with shrubs and minimal vertical structural complexity. The sites aimed to capture both open and closed forest conditions.

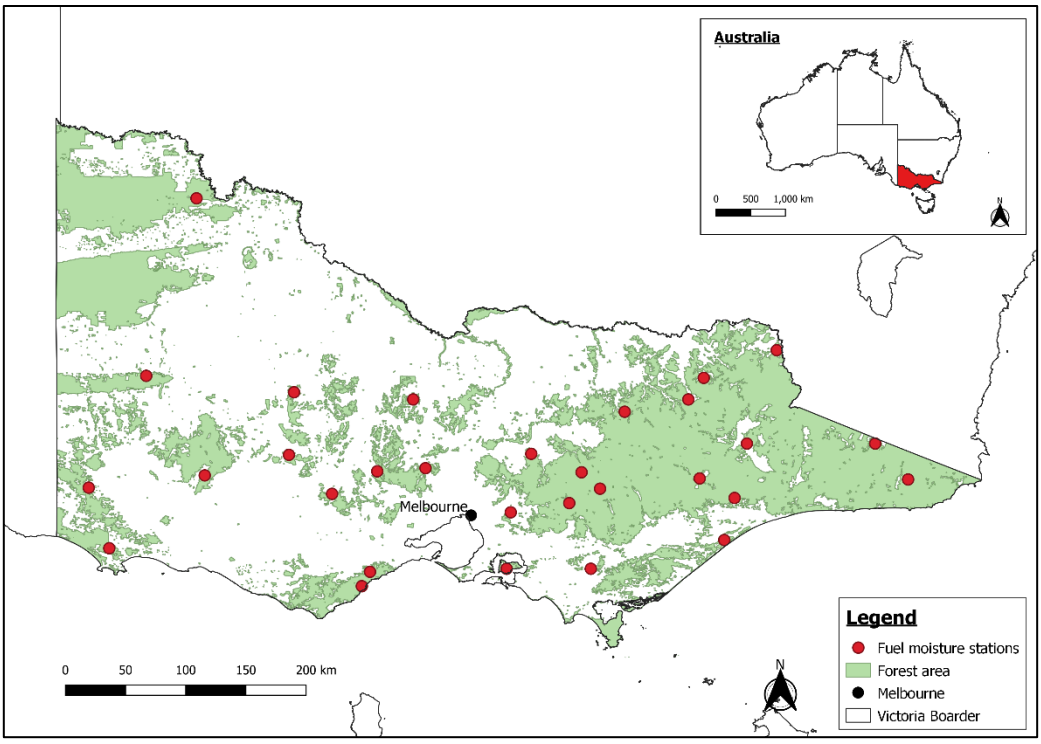

Figure 2- Study area spatial extent across Victoria, Australia.

2.3. Site instrumentation and data collection

The data collection period was from April 2014 to August 2021, with seven sites installed throughout 2014 and 23 in 2019. The sites had fuel moisture content readings collected half hourly using fuel sticks (CS506, Campbell Scientific, Inc., Logan, USA). The fuel moisture sticks were installed 10 - 30cm above the ground to represent elevated ground fuels. Site variables used to represent the vegetation and climate signature includes elevation, slope, aspect, aridity index, long term annual rainfall and vegetation cover fraction. The weather forecast variables were from the Australian Digital Forecast Database (Australian Bureau of Meteorology, 2022). This is a gridded seven day forecast across Victoria, producing daily to sub-daily predictions at ~3km resolution. The daily climate variables used in the model were: Temperature, precipitation, relative humidity, skyview factor, Keetch–Byram Drought Index (Keetch & Byram, 1968), wind direction (predominant) and wind speed (max).

2.4. Modelling

Time Series prediction models fall into three broad categories: Autoregressive, Statistical/machine learning, and process-based/mechanistic. In this study a comparison of these methods for DFMC forecasting is presented.

Autoregressive (AR) models are often the simplest to implement with time series predictions. These models attempt to forecast from the existing dataset using recent values as independent variables. They use linear models with previous values, or residuals from the rolling average of previous values. In addition to recent variables, they may also account for seasonal and long-term trends estimated from time series decomposition, and other independent variables. This study uses an Autoregressive integrated moving average (ARIMA) variation VARMAX as the baseline autoregressive model to determine whether fuel dryness can be predicted using past time series data alone.

The two machine learning methods used were, a boosted regression tree random forest (BRT-RF) model (Breiman, 1998; Elith et al., 2008) and a long short term memory recurrent neural network (LSTM-RNN) model. Boosted regression trees train an ensemble of models (i.e. Random Forest regression models), on subsets of data iteratively to create a decision tree algorithm to predict the response variable. We used the LightGBM python package (Ke et al., 2017) to build and train the random forest model. In addition to BRT's, Neural Networks have also been used effectively for time series forecasting (Fan & He, 2021). We used a Long Short Term Memory Recurrent Neural Networks (LSTM-RNN) to compare ML approaches.

The process–based (PB) model used as a comparison was the model proposed by Van Der Kamp (2017). The model only requires four inputs: temperature, relative humidity, precipitation and radiation. The fuelstick model proposed by Van Der Kamp is an improved version of the Nelson model (2000), representing the radiation loading on the fuelstick in more detail. The original Nelson model has been used operationally in the U.S. National Fire Danger Rating System (NFDRS 2016 version; US National Wildfire Coordinating Group, 2021), as well as in fire behaviour models such as FARSITE and FlamMap.

2.4.1. Long-term climate trends

Time Series Forecasting of environmental systems is a problem in that it typically needs to account for long term trends, seasonal cyclicity, antecedent conditions and lag response to controlling processes (Cheng et al., 2015). Time series data often contain patterns of trend and seasonality that can be extracted to improve predictive capability. To do this, Time Series Decomposition (TSD) is used to split a time series dataset into long term trends, seasonal cycles, and residual error. We use the Facebook prophet python package (Taylor & Letham, 2018), which uses an additive method to decompose the time series. This was used to create a seasonal term for input into the BRT-RF and LSTM-RNN models.

2.5. Model validation and performance metrics

All models were evaluated on the seven original sites installed in 2014. To determine which method performed best with the most high-quality data available. The training dataset was from 2014 to September 2020. The validation dataset was from May 2020 – May 2021. The BRT-RF and PB models were then assessed across the entire range of sites, with the additional sites installed in 2019 having a lesser quality of data. These real-world operational sites, which are centrally managed do not always have the same data quality as research-based sites. Each daily forecast had R^2, RMSE, NSE and MAE calculated, as well as the event-based metrics of the probability of detection (POD) and false alarm ratio (FAR). These event-based metrics predict how the model

performs predicting specific fuel moisture ranges (events), within levels relevant to planned burning (Slijepcevic et al., 2015).

3. Results

The RBT-RF results from the seven long-term sites are presented in Table 1. These results show an overall decrease in the accuracy across the seven days. There was high variability between the sites, with Dimboola, Bendigo and St. Arnaud performing well across all the metrics, while Alexandra and Daylesford performed poorly. The event-based metrics (Figure 3) showed the models performed best at low FMC (<11%), while as the higher two ranges performing worse. The "Patchy Burn" range had the highest FAR, making this range the most unreliable in predictions.

Table 1 – BRT-RF model performance across the seven long term sites from 2014 – 2021.

	R^2				NSE				MAE				RMSE			
Site	**1-D**	**3-D**	**5-D**	**7-D**	**1-D**	**3-D**	**5-D**	**7-D**	**1-D**	**3-D**	**5-D**	**7-D**	**1-D**	**3-D**	**5-D**	**7-D**

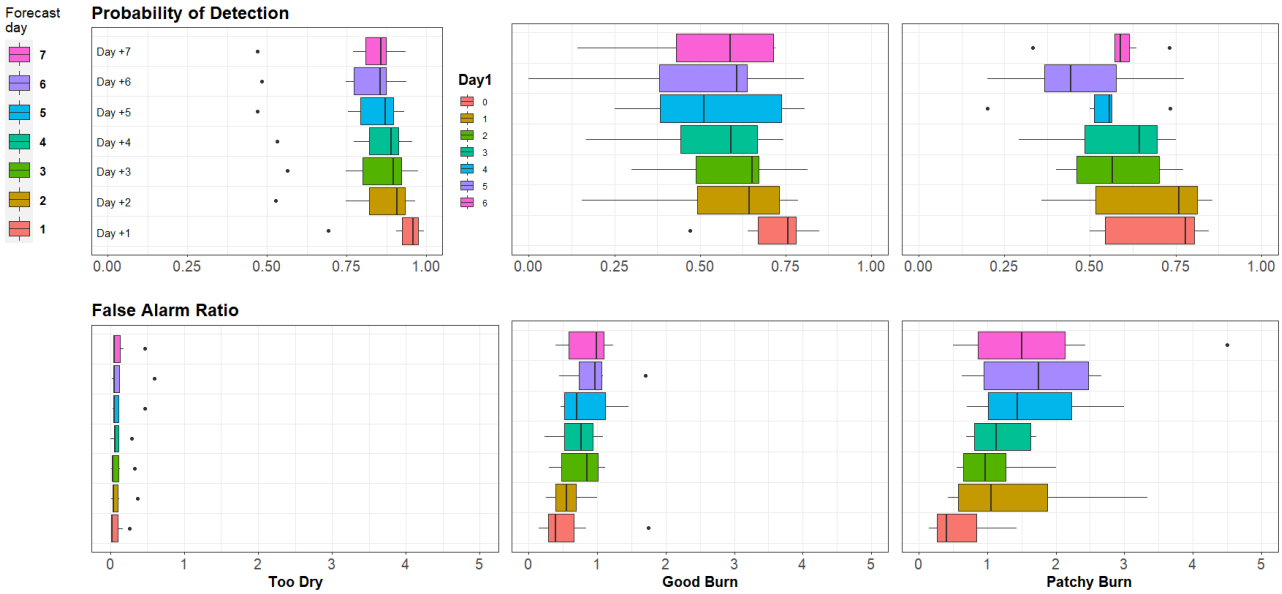

Figure 3 – Event based performance of the BRT-RF model for the daily minimum DFMC forecasts within the range of 11 – 16%, for the seven long term sites. (Top) Probability of detection, (Bottom) false alarm ratios. Left, middle and right columns representing planned burn outcoms proposed in Slijepcevic et al (2015) based on FMC ranges.(left) Too dry and higher risk of burn escaping (0 – 11% FMC); (middle) Good burn representing the FMC range that will sustain a burn but less likely to escape (11 – 16% FMC); and, a Patchy burn due to the FMC being too high and the burn not self sustaining (16 – 21% FMC)

4. Discussion

The BRT-RF managed to incorporate information traditional processed-based modelling cannot, determining how this information relates to the DFMC. The decay in the accuracy, decreasing POD and increasing FAR

across the seven days highlights the increased uncertainty associated with the weather forecast. However, the use of event-based performance metrics showed that although the model decreased in accuracy, it remained within the ranges to predict critical DFMC relevant to planned burning (Slijepcevic et al., 2015). This is critical as while traditional statistics highlight the accuracy in models, they don't reflect the important range for land and fire managers. The results demonstrated that a fuel moisture monitoring forecast system could effectively predict 10-h DFMC up to seven days in advance. Linking ground-based fuel moisture monitoring stations spatially across forested terrain with gridded forecasts allows the complex sub-canopy climate variability to be accounted for in predictions. Grounding the starting DFMC in observations also proved important due to the decay rate across the seven days. If the starting DFMC was incorrect, then adding this uncertainty to the decay rate would decrease the reliability of the forecasts. Lastly, incorporating site variables assisted in the model's ability to account for the transfer of climate relationships from above the canopy to below. The ability to incorporate canopy and landscape variables also has the potential to expand the point-based forecasts into a spatial forecast.

The proposed system differs from previous DFMC forecasting as it incorporates live continuous below canopy measurements with above canopy weather, machine learning techniques and a seasonal rolling term. The assembled dataset represents the largest below canopy comparison of continuous DFMC forecasting using machine learning to our knowledge, across the largest range of forest types. The performance of the model validates the use of ML for predicting DFMC below canopy in closed forests, this being highlighted as an area of limited research by Shmuel et al. (2022). Early results from the other traditional models indicate that the machine learning model performed favourably in comparison, highlighting the value of ML techniques for below canopy moisture forecasting.

5. Conclusion

The proposed Forest Fuel Moisture Forecasting System has demonstrated the ability to incorporate advancements in ML techniques, weather forecasting, ground-based sensors, and remote sensing into a theoretically operational system for land managers. The ability to predict forest fuel moisture multiple days in advance with known levels of uncertainty within relevant DFMC ranges will allow for more informed decisions and planning around fuel reduction burns and bushfire risk. While more work needs to be done on validating the effectiveness of using DFMC forecasting for decision making in bushfire risk and planned burning, the proposed system provides a tool and framework with which this research can be conducted.

Burned Area Mapping; Time Series Analysis; Boreal Forest; LTDR.

Abstract

Burned Area (BA) is an essential variable for studying the Earth's climate evolution. The boreal forest is one of the largest biomes in the world, spanning North America and Eurasia. For North America, two record fire occurrence databases since the 1950s are available: Alaska Fire Service (AFS) database and the Canadian National Fire Database (CNFDB). However, there are currently no reliable burned area data for the boreal region of Eurasia, mainly Siberia, for the 1980s and 1990s. In this work, a Bayesian network algorithm was applied to the Long-Term Data Record (Version 5) to generate a burned area product at a resolution of 0.05 degrees for the entire boreal region above 60°N from 1982 to 2020. An assessment of burnt area estimates was carried out using high-resolution satellite images, official reference data and the MCD64A1 MODIS global burned area product (when were available). The results showed a high correlation with all the reference burned area datasets (95% with AFS-CNFDB, 93% and 95% with MCD64A1 in North America and Eurasia, respectively). The derived database constitutes unique long-term burned area information for studies of fire and carbon dynamics in the Northern Boreal Region, as well as their effects on the climate system.

1. Introduction

Forest fires contribute to greenhouse gas emissions and are responsible for changes in carbon dynamics and their implications for global climate change (Chuvieco *et al.* 2019). One of the regions of the planet where this global change is expected to have the highest impact is the northern boreal region. Boreal forests represent one of the largest sources of carbon storage on our planet (Schuur *et al.* 2015; Young *et al.* 2017).

Images derived from sensors aboard quasi-polar orbiting satellites have in recent years allowed the construction of time series of burned area (BA), providing the scientific community with essential information that could be correlated with other variables involved in global change. Among the main BA products developed are MCD64A1 (Giglio *et al.* 2018) and Fire_CCI (Chuvieco *et al.* 2018), both derived from the MODIS (Moderate Resolution Imaging Spectroradiometer) sensor. However, these products have only been available since 2000, so they do not allow the construction of time series of more than two decades, limiting their application in medium- and long-term fire trend studies.

In this paper, we present and validate a unique database containing annual BA estimates for the northern boreal forest from 1982 to 2020 with a spatial resolution of 0.05°. It is derived from a new BA product, generated by applying a Bayesian network-based classification algorithm to the LTDR (Land Long Term Data Record) v5 dataset (Pedelty *et al.* 2007).

2. Materials and Methods

2.1. Study area

The study area covers all northern boreal regions bounded by 60ºN and 72.5ºN parallels. It was divided into two sub-regions: North America (Alaska and boreal Canada), limited by the 168.5ºW and 43.5ºW meridians and Eurasia (from Scandinavia to the Pacific coast of Siberia), bounded by the 5ºE and 180ºE meridians. The North

American sub-region contains one-third of the boreal ecosystem and the Eurasian sub-region the other two thirds.

2.2. LTDR data set. Pre-processing

The Long-Term Data Record (LTDR) from NASA is a consistent long-term dataset at a spatial resolution of 0.05° (~5 km) based on daily data from the Advanced Very High-Resolution Radiometer (AVHRR) on-board the National Oceanic and Atmospheric Administration (NOAA) satellites and daily data acquired by MODIS on-board NASA's Terra and Aqua satellites (Pedelty *et al.* 2007). Daily global LTDR version 5, download from NASA server (https://ltdr.nascom.nasa.gov/cgi-bin/ltdr/ltdrPage.cgi), was used in this study. The original daily images in HDF (Hierarchical Data Format) format were transformed to BSQ (Band Sequential) format and cropped to the boundaries of the study region. Then, 10-day composites were constructed with the maximum brightness temperature criterion to eliminate atmospheric effects. Simultaneously, vegetation indices derived from the original radiometric bands were calculated for burned area discrimination: NDVI (Normalized Difference Vegetation Index) (Rouse et al. 1973), GEMI (Global Environmental Monitoring Index) (Pinty and Verstraete, 1992) and BBFI (Burned Boreal Forest Index) (Moreno-Ruiz *et al.* 2012).

2.3. Burned area detection

The BA-LTDR classifier initially developed for the NE Siberia region (García-Lázaro *et al.* 2018) was used to generate the corresponding annual BA maps. This classifier is based on the Bayes-Net algorithm of the WEKA (Waikato Environment for Knowledge Analysis) software package (Frank *et al.* 2016).

To assess the accuracy of the BA-LTDR time series for the Northern boreal region, we considered splitting the time series for both sub-regions (Eurasia and North America) into two parts: pre- and post-2000. Since 2000, accuracy assessments for the Eurasian sub-region have been evaluated using only MCD64A1 C6 burned area product with 500 m spatial resolution, according to CEOS validation protocol (Morisette *et al.* 2006). MCD64A1 Collection 6 is currently the product with the highest reliability compared to the other BA products (Padilla *et al.* 2015), and it has the lowest commission and omission errors in the boreal forest region (Boschetti *et al.* 2019). Before 2000, accuracy assessments could not be evaluated in this way because other BA products with a higher spatial resolution for this study sub-region were not available. For the North America boreal sub-region, the BA-LTDR burned area maps obtained (and also BA maps of the MCD64A1 C6 product) were compared with reference data from the Alaska Fire Service (AFS) database (https://afsmaps.blm.gov/imf/imf.jsp?site=firehistory) and Canadian National Fire Database (CNFDB) (http://cwfis.cfs.nrcan.gc.ca/ha/nfdb) (García-Lázaro *et al.* 2018).

The temporal accuracy of the BA-LTDR product in each sub-region was assessed considering the total calculated annual BA. A timing distribution of BA-LTDR product was represented on a chart together with the time series of reference BA and a correlation analysis was carried out. The relative percentages of the annual BA of the BA-LTDR product were calculated concerning the reference data for the common years when available.

3. Results

3.1. Annual burned area maps

The BA-LTDR database contains annually burned area maps for the Northern boreal forest (above 60°N) for the 1982-2020 period in 0.05° (~5 km) resolution Climate Modelling Grid (CMG) cells. Figure 1 presents a decade-by-decade grouping of the annually BA maps for both sub-regions. Burned pixels have been plotted in a dark colour on the green land.

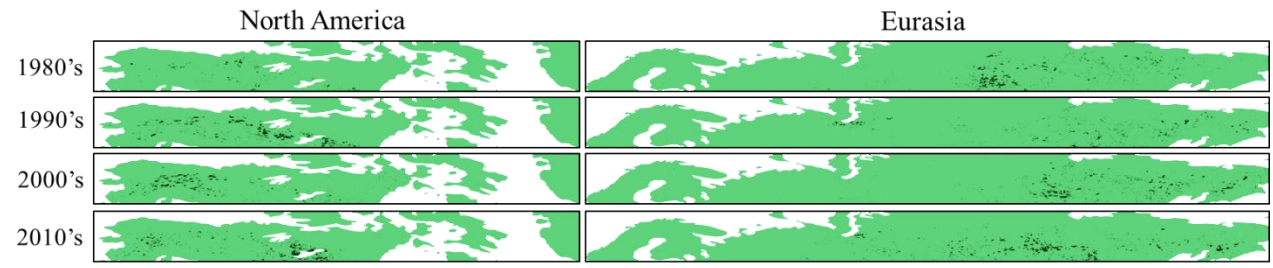

Figure 1- Maps of area burned by decades for the sub-regions of North America and Eurasia. Black: burned area, white: water, green: unburned.

3.1. Temporal Accuracy

Figure 2 shows the annual distribution of the total BA estimated for 1982-2020 in the North America sub-region. BA-LTDR detected 61% of the reference burned area, underestimating the BA in all years of the time series. There was a strong correlation (0.95) between the LTDR-BA data and the reference AFS-CNFDB data. If we divide the time series into two parts (pre-MODIS: 1982-1999, MODIS: 2000-2020), the BA-LTDR algorithm shows a practically homogeneous behaviour both in percentage of burnt area estimation (64% vs 59%) and correlation coefficient (0.98 vs 0.95), concerning the reference data. Making an intercomparison of BA-LTDR with the MCD64A1 C6 product in the common period (2000-2020) in North America, LTDR-BA detected approximately 86% of the area burned, with a correlation coefficient of 0.93.

In the Eurasia sub-region, the assessment of the temporal accuracy of the BA-LTDR burnt area was calculated using the MCD64A1 C6 product as a reference. MCD64A1 C6 estimated an annual BA of around 47.10 millions ha for the period 2000-2020. While BA-LTDR estimated around 66%. BA-LTDR underestimates the BA in all common years except for 2000, but its temporal pattern matches the reference, with a correlation coefficient of 0.95.

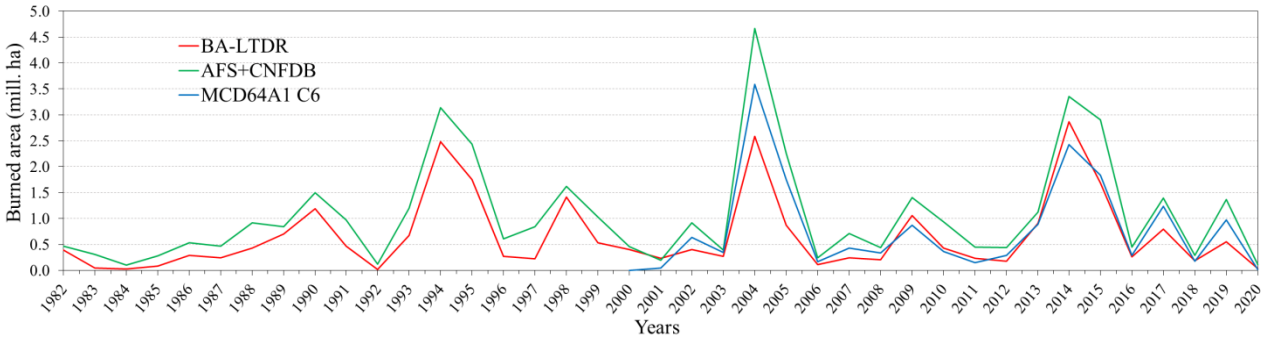

Figure 2- Annual distribution of the burned area estimate (mill. ha) in the North America boreal sub-region from the Alaska Fire Service/Canadian National Fire Database (AFS + CNFDB), BA-LTDR and MCD64A1 C6.

4. Conclusion

A comprehensive burned area database (1982–2020) for the Northern boreal region using a Bayesian network algorithm from the LTDR v5 dataset at 0.05° spatial resolution has been built. This time series is the longest developed for this region at this spatial resolution. It constitutes a unique data source for studies of fire and carbon dynamics in the Northern Boreal Region, as well as their effects on the climate system.

5. Acknowledgments

This research was funded by the Spanish Ministry of Science, Innovation and Universities (MCIU), the State Research Agency (AEI) and the European Regional Development Fund (ERDF) through the project RTI2018-099171-B-I00. The University of Almeria and the Andalusia ERDF Operational Program partially funded this work through projects 2019/006 and UAL18-TIC-A023-B1. The authors would like to thank the LTDR project and its team for the processing and free distribution of the data used in this work.

Live fuel moisture, density, model

Abstract

Wildland fires are a common global disturbance and many of these fires burn through mixtures of living and dead vegetation. Live fuels are unique because they regulate biomass and water content actively through processes such as photosynthesis or transpiration. The main goal of these processes is to maintain the growth and maintenance demands of the plants while minimising water loss. Historically, live fuel dynamics were assumed to be only driven by evaporative or drying processes and little attention was paid to the interplay between carbon and water dynamics. Here we present a mechanistic model of live fuel moisture (LFM) which is a critical component of live fuel flammability. The model decouples LFM into physical and chemical metrics that are easy to. Each metric serves as a proxy for important components of the seasonal water and carbon cycle or to capture inter-species variations in physical properties. We evaluate this model using field measurements of physical and chemical characteristics for a Douglas Fir (*Pseudotsuga menziesii*), a common intermountain US tree species that commonly burns in crown fires. This simple, mechanistic model was effective at characterising the seasonal variations in LFM across both new and old foliage as a simple function of specific leaf area, surface-area-to-volume ratio, relative water content and a species-specific scalar ($r2=0.995$, $p < 0.05$). Finally, we suggest how this decoupled model can be used to more appropriately parameterize a 3-dimensional computational fluid dynamics-based fire behaviour model to represent an appropriate live fuel moisture as the combined effects of biomass and moisture variations on canopy flammability.

1. Introduction

Wildland fires are a common global disturbance and many of these fires burn through mixtures of living and dead vegetation. While there have been extensive studies exploring the factors that control dead fuel flammability, there have been considerably fewer studies that focus on live fuels. In part, this is due to the difficulty of controlling live fuel characteristics in the lab and considerable variation both seasonally and spatially of those characteristics in the field. These studies are further complicated by historical assumptions that attempt to link live fuel flammability variations to indicators of drought but many studies have found that drought indicators alone are insufficient to capture seasonal live fuel moisture variations (Pellizzaro et al., 2007,, Ruffault et al., 2018). While this is partially accurate, live fuel flammability variations are driven by several interacting factors such as changes in absolute moisture content, variations in needle biomass and structural differences in physical factors such as their surface-area-to-volume ratio. A more complete, mechanistic model of the drivers that influence live fuel moisture variations is needed (Pellizzaro et al., 2007).

2. Methods

We collected new and old live foliar samples bi-weekly from Douglas Fir for the 2021 growing seasons (Apr to October). For each sample we measured live fuel moisture content by weighing samples fresh, drying in a 95 degrees Celsius oven for at least 48 hours and re-weighing samples after drying. After initial fresh weights were taken, a sub-sample of the bulk foliar sample was separated to determine density, surface-area-to-volume ratio and leaf mass area. Foliar volume using an Ohaus density kit on a high precision balance and those samples were retained and dried to compute density. Surface area was measured by scanning the planar surface area and computing the planar surface area using ImageJ. Total surface area was assumed to be 2 time the planar area.

3. The mechanistic live fuel moisture model

We developed and tested a simple, mechanistic model of live fuel moisture. The model decouples factors that are known to influence season variations in live fuel moisture content by varying either their water status / hydration or their dry weight. The model was defined as follows:

$$Live\ Fuel\ Moisture\ (\%\ dry\ wt) = \frac{SLA*RWC*\kappa}{SAV} \qquad \text{Equation 1}$$

SLA is the Specific Leaf Area on a dry weight basis ($m^2\ kg^{-1}$), RWC is the Relative Water Content or a metric of the amount of water in the particle compared to how much water the particle can hold at saturation, *k* is a scalar that represents the amount of water a fuel particle can contain relative to its volume (kg H_20 m-3), SAV is the surface-area-to-volume (SAV) ratio of the particle (m^{-1}). The scalar is a measure of the amount of water a particle can hold relative to its volume and should be species specific but could also be influenced by particle elasticity. When combined, these individual metrics of foliar physical and chemical properties will yield an appropriate metric of live fuel moisture in percent of dry weight.

$$\frac{LFM}{100} = \frac{SLA*RWC*k}{SAV} = \frac{\frac{m^2}{g_{Dry\ Matter}} \times \frac{g_{H_2O}}{g_{H20Sat}} \times \frac{g_{H_2OSat}}{m^3}}{\frac{m^2}{m3}} = \frac{g_{H_2O}}{g_{Dry\ Matter}} \qquad \text{Equation 2}$$

Equation 2 shows that the dimensional analysis of the model will yield a metric with the same units as live fuel moisture content in grams of water per unit gram of dry matter / weight. *k* values were computed from measurements and averaged across needle ages.

4. Results

Seasonal variations in live fuel moisture were most pronounced when comparing new and old growth. During green-up, live fuel moisture contents were over 300% for new foliage, while previous year's foliage had moisture contents near 100% (Figure 1). On average, new foliage moisture content was significantly higher than old foliage moisture content (Figure 2). New foliage had a very low foliar density and very high relative water content while old foliage had a higher density and lower relative water content. Density variations were strongly related to live fuel moisture content variations (Figure 3). Final model predictions showed strong agreement between modelled and predicted live fuel moisture content (rho=0.984, $p < 0.05$) (Figure 4). Mean k values were 736.98 kg H_20 m^{-3} for new growth and 560.17 kg H_20 m^{-3}. Assuming k as fixed for needle ages, we computed the live fuel moisture content using Equation 1 and compared to the final measured live fuel moistures. The model accurately predicted live fuel moisture content $r^2 = 0.995$ across the range of new and old foliage.

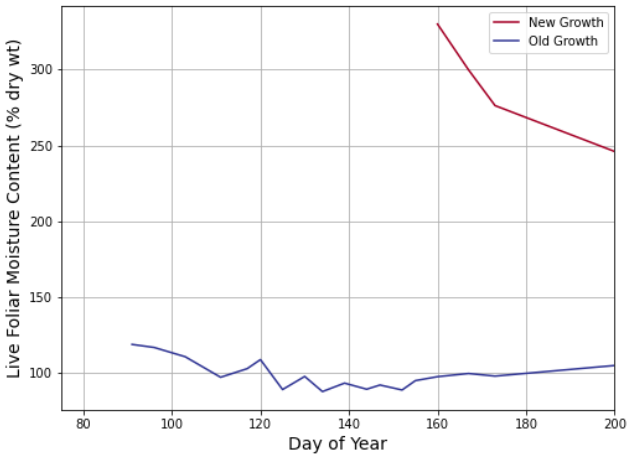

Figure 1 - Seasonal variations in live fuel moisture over the 2021 growing season. New foliage moisture content is shown in Red and previous year's growth in Blue. New growth moisture content was nearly 3 times higher than previous year's growth. Old growth showed a pronounced 'dip' during spring, consistent with other species.

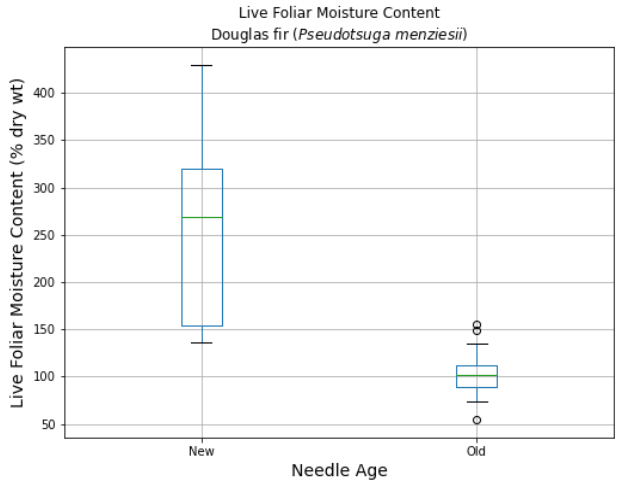

Figure 2 - Difference in live fuel moisture between current year (New) and previous year's growth (Old) for the 2021 growing season of Douglas fir.

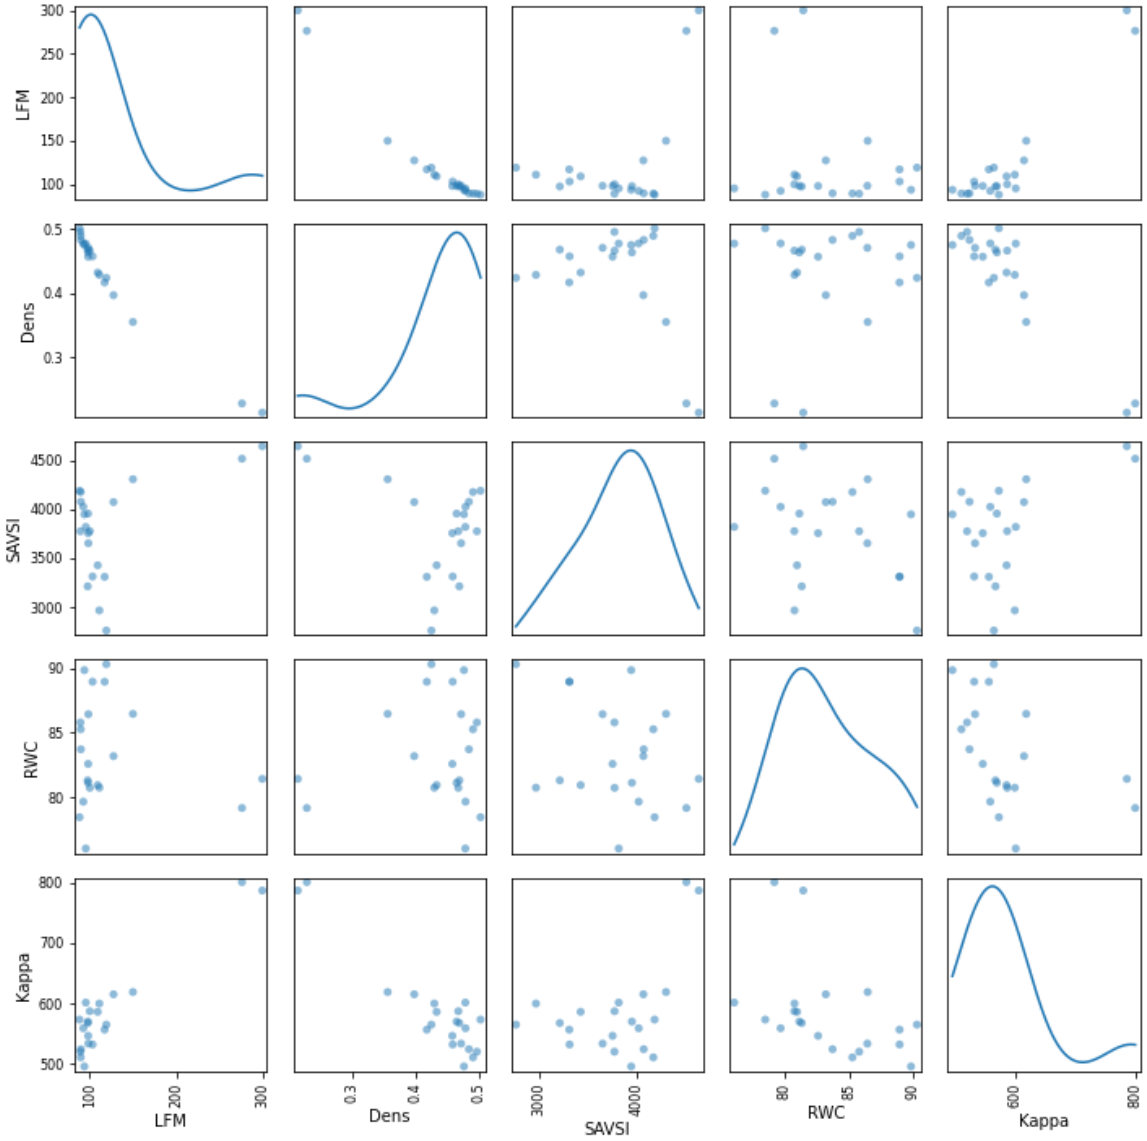

Figure 3 – Cross-scatter plots of input variables to mechanistic live fuel moisture model. LFM is strongly related to density variations and other variables have direct relationships with Live Fuel Moisture (LFM).

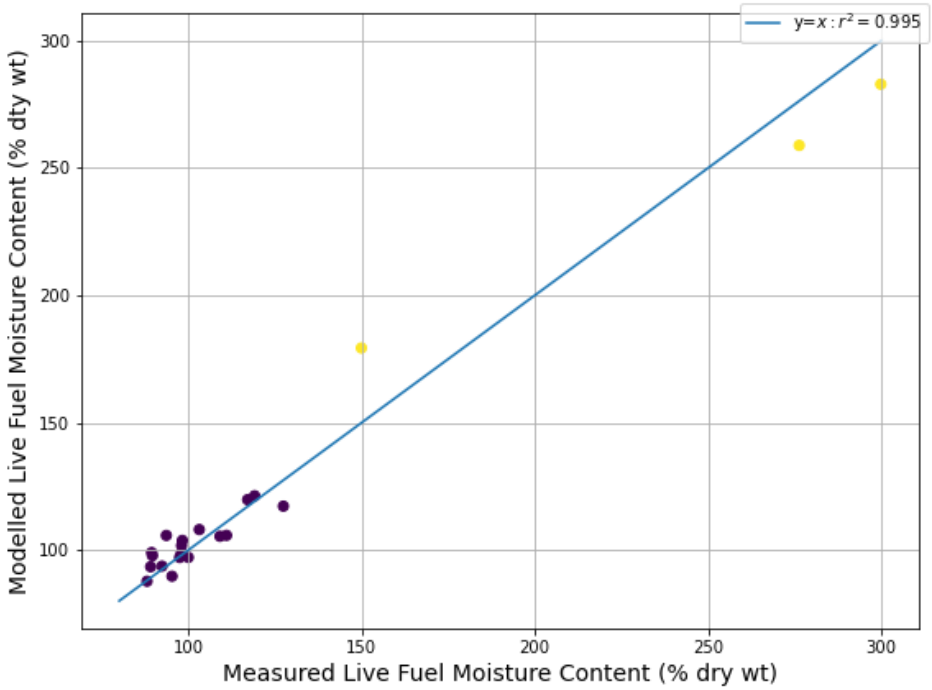

Figure 4 – Preliminary model predictions of live fuel moisture as a function of specific leaf area, relative water content and surface-area-to-volume ratio using a fixed k parameter for new and old foliage.

5. Discussion

This model is the first of its kind to allow the decomposition of live fuel moisture content into components that are easily measured in the field and that allow the decomposition of LFM into components that are important for fire behaviour models. SAV is a critical input to most 2-d and 3-d fire behaviour models because it is primary driver in heat transfer through both radiation and convection. Further, SLA and SAV combine to yield the particle density, which is another very important physical property for heat transfer and subsequent fire behaviour modelling. Finally, RWC is the preferred metric to measure the water status of plants and it dominates plant physiology literature. For example, RWC is strongly linked to soil water potential in Douglas Fir (Barnard et al., 2011) and both metrics correlate well with periods of water stress. Collectively, these variables all yield a framework for better understanding live fuel moisture. As fires grow larger and more intense, understanding the factors that drive live fuel flammability and contribution to overall fire intensity is critical. This mechanistic model of live fuel moisture is one step towards that goal.

Thermal Images, Image Segmentation, Airborne Sensors, Wildfire Monitoring, Level Set Segmentation

Abstract

The infrared (IR) thermal images of a propagating wildfire taken by manned or unmanned aerial vehicles can help the firefighting authorities on the ground. The segmentation of such images in regions of fire vs non-fire is a necessary step to measure the fire perimeter and determine the location of the fire front. This work proposes a segmentation method based on level sets, which have the property of handling topology, which makes them suitable to segment wildfire images since the fire areas may be spread out across the image. The results were compared against other common unsupervised segmentation methods, including Otsu, K-means and Mean Shift. The Level Set method was optimized to ensure contour smoothness and reliability, as well as reduce the computation time. Although falling out of use in relation to Deep Learning methods, unsupervised segmentation can still be very useful when annotated datasets are unavailable. The experimental results were compared using hand-drawn labels over a set of images provided by the Portuguese Air Force (FAP) as a ground truth. These labels were carefully drawn by the author to ensure they complied with the requirements indicated by the Portuguese National Authority for Emergency and Civil Protection (ANEPC).

1. Motivation and Objectives

The development of UAVs equipped with cameras and reliable communication and navigation systems enabled a powerful tool in the observation of forest areas, both in the early detection of fires, during the active wildfire combat and the aftermath stage. For early detection, it is important to accurately identify images containing wildfires, while avoiding false positives, for example, with similar color patterns, such as sunsets of dry foliage. During the active stage, it is important to have a tool that allows the authorities to geo-localize the fire front, measure the fire extension, and realize any external effects that can affect the wildfire evolution, such as strong winds. Understanding the evolution of the wildfire and its potential spread areas can help minimize damages and contribute to a more effective combat. When the wildfire is eventually declared as controlled, it is still important to detect if and where reburns occur to quickly extinguish them, preventing a new critical situation.

This work aims at finding the best method for segmenting aerial wildfire thermal images. The thermal cameras can prove extremely useful in situations where smoke and vegetation obscure the field of vision of the aircraft. The algorithms implemented should be able to systematically receive the thermal images and perform multiple segmentations over the same image. Specifically, they should be capable of dividing the image in different areas, sorted according to the fire intensities in each area. The contour lines will then resemble level curves, to eventually construct a thermal map of the image. The contours will also be used to obtain the perimeter of the wildfire and the extension of the fire front in future work.

The layout of this paper is as follows: Section 2 presents the state of the art in thermal image segmentation, Section 3 presents an overview of the theory behind the models used, Section 4 refers some aspects of the implementation, Section 5 presents the datasets used and results obtained. Finally, Section 6 concludes this paper and presents suggestions for future work.

2. Related work

Segmentation of IR images has been done in the past mainly applied to medical images, using watershed (Grau *et al.* 2004), K-means (Ng *et al.* 2006) and level set methods (Banerjee *et al.* 2010). The segmentation of aerial

IR wildfire images for tracking of the active front was attempted using, for example, a combination of Otsu and optical flow (Yuan *et al.* 2017) and Canny edge detectors (Valero *et al.* 2018). However, these methods only present a division of the image in 2 classes.

Multilayer level set methods, like the ones used in Huang and Wu (2010), Huang *et al.* (2013) and Wen *et al.* (2020) were applied to construct thermal mapping of materials. This work applies a similar algorithm but instead to thermal images of wildfires, using only one level set function, which makes the algorithm faster, and adding an edge stopping term.

3. Active Contours

3.1. Level Set Segmentation

The segmentation methods that are based on level sets make use of the idea of implicitly representing a propagating front (or a contour) C through the evolution of a higher dimensional, continuous differentiable function ϕ (dubbed the level set function). In the case of image segmentation, the 2D contour is represented by the level curve of a 3D surface represented by function $\phi: \mathbb{R}^2 \rightarrow \mathbb{R}$. To ensure curve smoothness, the evolution of this function depends on the contour curvature k along its normal direction N which are given by (see Osher and Sethian 1988 for proof)

$$N = \frac{\nabla\phi}{|\nabla\phi|}$$

$$k = \mathrm{div}\left(\frac{\nabla\phi}{|\nabla\phi|}\right)$$

where $\nabla\phi$ represents the gradient of ϕ and $|\nabla\phi|$ the respective norm, while $\mathrm{div}()$ is the divergence operator. The evolution of the level set function is given, according to Osher and Sethian (1988) and Malladi and Sethian (1996), by

$$\frac{\partial\phi}{\partial t} = |\nabla\phi|\mathrm{div}\left(\frac{\nabla\phi}{|\nabla\phi|}\right)$$

For a given open region $\Omega(x, y)$ with smooth boundary, ϕ satisfies

$$\begin{cases} \phi(x,y) > 0, (x,y) \in \Omega \\ \phi(x,y) = 0, (x,y) \in \partial\Omega \\ \phi(x,y) < 0, (x,y) \in \bar{\Omega} \end{cases}$$

where $\partial\Omega$ represents the contour of Ω, which is the contour that is to be obtained. In image processing, all the curve derivatives are taken in a discrete rectangular grid instead of a continuous curve (Malladi and Sethian 1996), which simplifies their calculation.

3.2. Edge-based ACM

Edge-based active contour models use gradient information to stop the contour evolution near strong edges. This can be achieved through the usage of an edge stopping function g that has the property of being positive and decreasing with gradient magnitude, becoming near zero at the edges and neutral when there are no differences in gradient. An example chosen in Caselles *et al.* (1993) is

$$g(\nabla I) = \frac{1}{1 + |\nabla[G_\sigma(x,y) * I(x,y)]|^2} \quad \textbf{(1)}$$

where the image I is convolved with a gaussian kernel G_σ with standard deviation σ.

Edge based methods, such as the Geodesic Active Contour (GAC) model (Caselles *et al.* 1997) are sensible to the placement of the initial contour. If it is initialized away from the object, it may never reach it and instead detect another strong edge, since it has no information about the whole image. This is especially critical if the

image is very noisy, since then the smoothing Gaussian will have to be strong and thus will smooth the edges too.

3.3. Area-based ACM

Area based active contour models use global image information, attempting to divide an image in regions by associating the pixels that share common properties, such as similar intensities. One of the most famous examples is the method introduced by Chan and Vese (Chan and Vese 2001), which is based on the Mumford-Shah functional (Mumford and Shah 1989). The Mumford-Shah formulation for image segmentation comprises the decomposition of an image in *n* regions, such that the intensities vary slowly within each region and briskly across the borders between them.

The Chan-Vese method, initially developed for a two-class segmentation which was achieved by cutting the level set function at level set zero, was generalized to multi-class segmentation (Vese and Chan 2002; Chung and Vese 2005, 2009; He and Osher 2007). For n=m+1 regions, the multi-layer Chan-Vese model determines the evolution of the level set function according to

$$\frac{\partial \phi}{\partial t} = \mu \sum_{i=1}^{m} \left[\delta_\varepsilon(\phi - l_i) div\left(\frac{\nabla \phi}{|\nabla \phi|}\right)\right] + \delta_\varepsilon(l_1 - \phi)|I - c_1|^2 - \delta_\varepsilon(\phi - l_m)|I - c_{m+1}|^2 + \sum_{i=2}^{m} [-\delta_\varepsilon(\phi - l_{i-1}) H_\varepsilon(l_1 - \phi)|I - c_i|^2 + \delta_\varepsilon(l_i - \phi) H_\varepsilon(\phi - l_{i-1})|I - c_i|^2] \quad (2)$$

where δ_ε and H_ε represent the regularized Dirac and Heaviside functions (Chung and Vese 2005), respectively, μ is a weight term, $l_1, \dots, l_m$ are the defined level set positions and $c_1, \dots, c_n$ are the intensity means in each region. The first term in (2) is a regulation term, the rest acts as a 'balloon force' that expands or shrinks the contour to minimize, for each region, the differences between the pixel intensities in the image I and the mean intensity calculated for that region.

4. Implementation

4.1. Multigrid implementation

The calculations required to apply the law in (2) may have an extremely high computational cost if the input image has a high resolution. Even at a resolution of 768x576, which is the most common resolution of the IR images supplied by the FAP, the time needed to achieve convergence on the level set function can be over one minute. To address this issue, we compute several lower resolution images, each one with half the pixels of the previous one in each direction. The level set function is initialized over the coarser grid, evolved until convergence, and extrapolated to the next finer grid. This process is repeated until convergence is reached on the grid with the original image resolution, as explained in Figure 1.

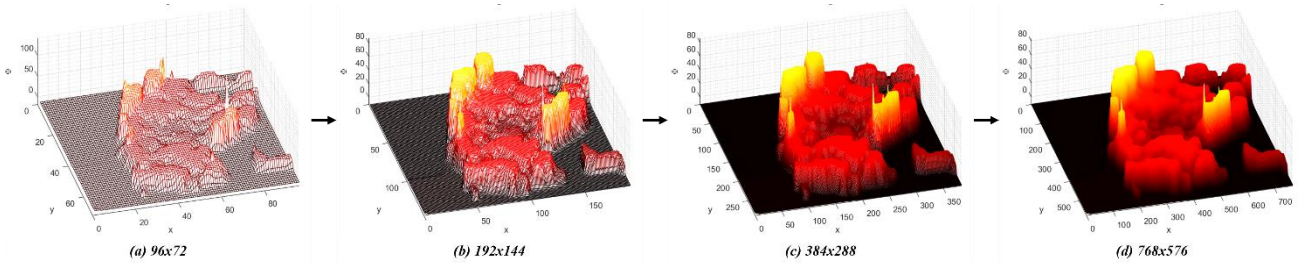

Figure 1 - State of ϕ at the end of the evolution for each resolution. The evolution is processed from the coarser grid (a) to the finer grid (d). Parameters: 6 contours, μ=0.008, α=10000, ε=1, σ=1

4.2. Inclusion of an edge-stopping term

It was verified that with the inclusion of more contours, the outer contours were detecting non-relevant edges or no edges at all, and inner contours were not "sticking" with the borders of the inner-most areas. To correct

this issue, it was decided to add an edge stopping term, like the one in (1), directly to the evolution rule (2), like what was done in Li *et al.* (2010). This term is given by

$$\text{EST} = \alpha g(\nabla I)[\delta_\varepsilon(\phi - l_1) + \delta_\varepsilon(\phi - l_m)] \quad (3)$$

where α is a weight term, $g(\nabla I)$ is given by (1) and $\delta_\varepsilon(\phi - l_i)$ allows for selective application of this term to the i^{th} level set, which is performed since the inclusion of this term has a destabilizing effect on ϕ. The term in (3) approximates the inner contour, given by the level set l_m, to the boundary of the brightest areas and keeps the outermost contour (corresponding to l_1) from propagating outside of the wildfire area.

5. Results

5.1. Datasets

The datasets used for segmentation were provided by the Portuguese Air Force. They consisted of images and videos taken both during real occurrences and during contained tests.

The main video is dubbed FOGO_1. It consists of different points of view of a wildfire, with nearly a minute of IR footage in total between RGB segments. To evaluate the segmentation quantitively, 55 images were selected, 1 second apart from each other, from the total 1342 frames. The ground truth masks were created by hand using MATLAB® Image Labeller App, following the indications given by the ANEPC. These requirements demanded a division of the images in three classes:

- Class 1 (outer): outside of the fire
- Class 2 (middle): region inside the fire that does not belong to the propagating front
- Class 3 (inner): the hottest (brightest) regions, which represent the propagating front

The contours should be smooth to later calculate the perimeter of the burning areas. Additionally, small high intensity 'dots' within the fire are to be classified as class 2, given that they most likely correspond to trees or other objects that are still burning actively but do not represent the fire front that is desired to track.

All the frames of FOGO_1 dataset were subjected to a 6-class segmentation (5 contours) using the level set method in (2) with the addition of the term in (3), with later selection and grouping of the 6 classes in the desired 3 classes (2 contours). The division in 6 classes is also useful to construct thermal maps of the fire. Performing a segmentation with more contours with further reduction, as was done in this case, allows for more reliable results without the need for heavy tuning of parameters. Figure 2 present some of the results obtained.

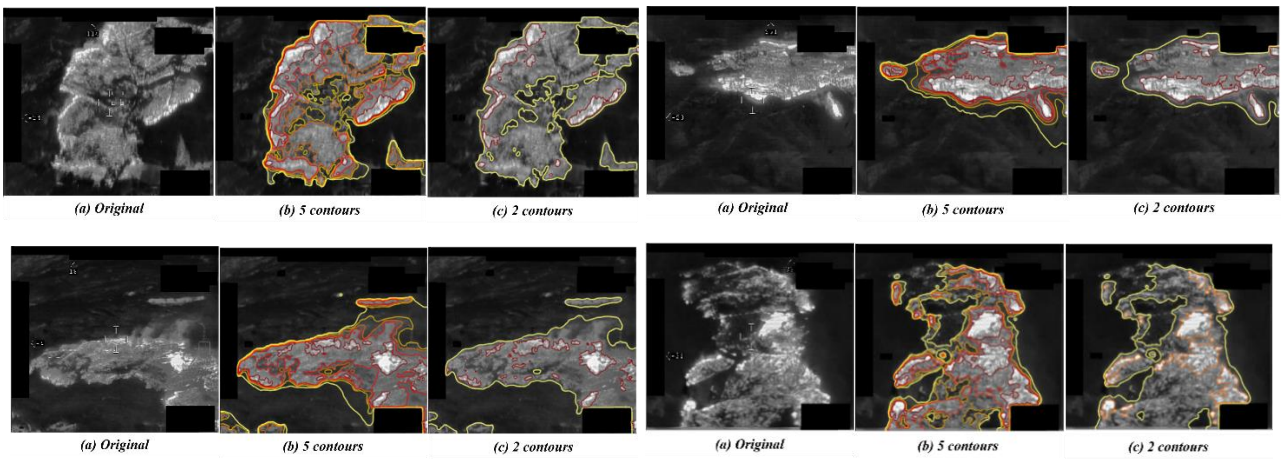

Figure 2 – Segmentation examples of FOGO_1 images using 5 contours with further reduction to 2 contours

To test the algorithm over the whole video sequence, all the frames in FOGO_1 were segmented and compiled in a video that was made available in the following link: https://youtu.be/kD9TEFOaHxw.

5.2. Comparison with other methods

With the objective of finding the best set of parameters for the level set method a grid search of parameters was conducted using the selected 55 frames, and to further compare its performance against other common unsupervised methods, they were also subjected to the application of the multi-layer Otsu (Otsu 1979; Liu and Yu 2009), K-means (Liu and Yu 2009, Sinaga and Yang 2020) and Mean Shift (Fukunaga and Hostetler 1975; Comaniciu and Meer 1999) algorithms. Class grouping was also applied when using these methods.

Experimental results, present in Table 1, were conducted in MATLAB 2020a, using a computer running in Windows 10 64-bit with an Intel® Core™ i7-6700HQ microprocessor and 8 GB of RAM. All metric values displayed correspond to the average of values for the three referred classes. For Mean Shift two types of inputs were tested, a 1-D input corresponding to the pixel intensity (i) and the 3-D input consisting of the pixel intensity (i) and position (x,y), with respective weights 0.8 and 0.2. Since Mean Shift calculates the number of classes automatically, we combine it with Otsu thresholding to aggregate classes. It is important to refer that the ground truths have compromised reliability, since they were not made by the authorities.

Table 1 – Comparison of results using FOGO_1 55 image labelled dataset

Method	Precision	Recall	Accuracy	IoU[1]	WEoS[2]	Time [s]
Proposed	**0.871**	**0.859**	**0.962**	**0.775**	**0.035**	2.86
Otsu	0.812	0.832	0.916	0.688	0.066	**0.15**
K-means	0.803	0.838	0.909	0.682	0.069	1.24
Mean Shift + Otsu (1D input)	0.862	0.741	0.926	0.646	0.056	1.65
Mean Shift + Otsu (3D input)	0.852	0.675	0.902	0.571	0.071	17.3

In terms of computational time, Otsu vastly outperforms by far all the other methods which allows for real-time segmentation. However, to obtain curve regularization, one need to increase the intensity of pre-process blurring, which leads to less reliable contours. Level sets allow for a highly customizable contour regularization therefore they present the best segmentation results.

6. Conclusions and Future Work

This work presented a method based on level sets that can detect the wildfire area and the burning fire front in wildfire thermal images which will enable the calculation and location of the fire perimeter and the most critical areas in future work. It outperforms other common unsupervised methods in terms of segmentation quality, albeit at a cost of computational time.

The lack of a labelled database dictated the non-usage of supervised learning. The hand labels created throughout the development of this work can be used to start such database. It would be interesting to apply state-of-the-art deep-learning methods to these images and compare the results with the ones obtained in this research.

7. Acknowledgements

This work was supported by FCT projects FIREFRONT (PCIF/SSI/0096/2017) and VOAMAIS (PTDC/EEI-AUT/31172/2017, 02/SAICT/2017/31172). The authors would like to thank everyone involved in these projects for the fruitful discussions and collaborations. Furthermore, we would like to express our gratitude to the

[1] Intersection over Union
[2] Weighted Error of Segmentation (same as EoS but a misclassification by just one class counts as a ‘half’ error)

Portuguese Air Force for providing the surveillance images and videos used throughout this work and to the ANEPC for the support and the many suggestions.

Abstract

Spatial modelling and machine learning are powerful techniques that can be used to identify patterns within data and build complex relationships between response and predictor variables. While powerful, many of these techniques are computationally intensive and are not designed to fully leverage high performance computing resources, especially when used within a geospatial context. To fully leverage system resources, while facilitating various spatial, machine-learning, and statistical modelling workflows, we developed a Python-based processing library called *raster-tools*. The *raster-tools* library automates delayed reading and parallel processing using Dask and integrates seamlessly into popular spatial, machine learning, and visualisation libraries such as geopandas, rasterio, xarray, scikit-learn, xgboost, pygeos, shapely, matplotlib, plotly, folium, and many more. Combined, these open-source libraries provide users with free and powerful analytical capabilities that can be used at scale and can dynamically display textual, tabular, spatial and graphical data. In this paper, we will provide a brief overview of the *raster-tools* library and demonstrate how the described open-source stack can be used to perform GIS analyses in both a web and desktop environment.

1. Introduction

Our environment is constantly being monitored. Today, satellite and airborne sensors on programs and platforms such as MODIS (MODIS, n.d.), Landsat (USGS, n.d.), Sentinel (EOS, n.d.), and NAIP (NAIP, n.d.) are acquiring data at spatial, spectral, and temporal resolutions that were, until recently, hard to imagine. Similarly, with advancements in drone technology and sensor hardware, the amount of remotely sensed data that is constantly being acquired and used to quantify aspects of natural resources is staggering. The recognition that large volumes of data are not being fully leveraged to inform decision making has led to an increased awareness in the fields of data (Gibert et al, 2018) and decision (Elshawi et al, 2018) science and the potential of what has become known as “Big Data” (Markwo et al, 2017). While there is great potential and promise attributed to “Big Data”, the practical use of data to drive decision making within the natural resource community has not been fully realised (Gibert et al, 2018).

In large part the discrepancy between the potential and use of “Big Data" to aid in natural resource decision making stems from two primary deficiencies: 1) a lack of analysts and technicians trained in the tenets of data science within the natural resources community and 2) software libraries that fully leverage computer resources and integrate tabular, geospatial, and machine learning (ML) domains. Within the first deficiency, common obstacles to implementation include: a lack of education and skills associated with integrating the various mathematical, statistical, ML techniques, computer programming languages, data formats, and the size of the data (Gibert et al, 2018). Less understood issues include leveraging data processing results (e.g. modelled outputs) for efficient decisions, the impact of applying models to new domains, the propagation of errors, and model misspecification. Issues of scale, domain, error, and relevance can have additional meanings within a complex natural resource setting. These issues often prevent studies that convert data into pertinent forest and fire related information from being used to their potential for planning and management decisions.

Within the second identified deficiency (integrated software libraries), geospatial analysis is core to natural resource management and planning. To facilitate geospatial analyses, geographic information systems (GISs) and remote sensing software such as ESRI's software suite (ESRI, n.d.), ERDAS (Hexagon, n.d.), ENVI (L3Harris, n.d.), IDRISI (Clark Labs, n.d.), QGIS (QGIS Dev. Team, n.d.), GRASS (GRASS Dev. Team, n.d.), and Whitebox (Whitebox Geospatial Inc., n.d.) have been developed to support spatial analytics and visualisation. However, commercial software platforms are expensive, typically have only a subset of commonly used routines, have a proprietary code base, do not necessarily integrate well with other processing libraries, and are only partially designed to fully leverage computer hardware, making it challenging to use those systems within a Big Data context. Open-source projects such as QGIS, GRASS, and Whitebox address cost issues but also tend to be plagued by issues similar to their commercial counterparts and typically are less intuitive to use, have stability issues, and often lack documentation.

These obstacles have led some to develop open-source data processing libraries such as gdal (GDAL Contributors., 2022), geopandas (Jordahl et al, 2020), rasterio (Gillies et al, 2013), xarray (Hoyer & Harmon, 2017), scikit-learn (Pedregosa et al, 2011), xgboost (Chen & Guestrin, 2016), shapely (Gillies, 2007), matplotlib (Hunter, 2007), plotly (Plotly Tech. Inc., 2015), and folium (python-visualization, 2020) that build upon common processing frameworks such as numpy (Harris et al, 2020), scipy (Virtman et al, 2020), and pandas (McKinneyl, 2010). However, these libraries alone do not natively address issues of parallel processing, memory management, or excessive use of input and output (Hogland & Anderson, 2017). To address these issues, Dask (Dask Dev. Team, 2016) has built a newer processing framework that builds upon the core processing frameworks of numpy and pandas that can be leveraged to facilitate and integrate tabular, geospatial, and ML analyses through lazy processing and parallelization. Two relatively recent coding projects that have successfully leveraged Dask to facilitate lazy processing, parallelization, and geospatial analyses from a vector and raster perspective include dask-geopandas (Geopandas Dev. Team, n.d.) and xarray-spatial (Makepath, n.d.), respectively. To further address the need for geospatial libraries that fully leverage computer resources and integrate tabular, geospatial, and ML analyses we have developed a new open-source project called *raster-tools*.

Our open-source package leverages the extensive data science, data processing and geospatial ecosystems of Python to provide a platform for developing data-driven decision making tools. Through the use of Python's Dask library (Dask Dev. Team, 2016), *raster-tools* allows users to easily scale their workflow from small laptops up to servers or high-performance computing (HPC) clusters, while fully utilising available resources. It contains a subset of the processing functions offered by ESRI software but can be used to implement many others. *raster-tools* also integrates easily with popular spatial, ML, and visualisation libraries such as geopandas, xarray, scikit-learn, xgboost, shapely, matplotlib, jupyter-lab, folium, and more.

Here, we highlight the use of our *raster_tools* package, in conjunction with an open-source stack, to inform decision making at scale through multiple use cases. Moreover, we demonstrate how this newly developed technology can be easily integrated with other spatial and statistical modelling workflows to realise the potential of Big Data. Finally we discuss the benefits of using *raster-tools* to perform geospatial analyses.

2. Methods

The *raster-tools* project is roughly based on the Rocky Mountain Research Station (RMRS) Raster Utility project (Hogland & Anderson, 2017). While similar in concept, *raster-tools* furthers the intent of the RMRS Raster Utilities project by improving processing efficiencies, increasing the size of datasets that could be processed, expanding possible compute platforms, and providing an open-source set of efficient geospatial, remote sensing, and ML procedures. The *raster-tools* package provides the same lazy processing and execution functionality as RMRS Raster Utility but can easily scale to larger datasets and hardware configurations, run on a wider range of platforms, and directly integrates with Python's wider ecosystem, making it a significant improvement over RMRS Raster Utility project.

The *raster-tools* package is built on the open-source python library Dask (Dask Dev. Team, 2016). Dask is a general-purpose library that embraces lazy operations and data partitioning for parallel data processing. At its core, Dask breaks data into smaller chunks of data, similar to pixel blocks within ESRI's ArcObjects [34], and allows users to apply lazy operations to those data subsets. An operation on the whole dataset is applied as lazy

tasks on the constituent chunks and only takes place when requested by the user. In this way, Dask allows for extensive, lazy data pipelines to be built. For execution, Dask provides robust task scheduling that can distribute per-chunk tasks across available compute resources. This approach to processing automates the parallel aspect of Dask procedures and allows for easy scaling from a single CPU core on a small laptop to distributed HPC clusters. Moreover, processing is performed "out-of-core", making it possible to process large datasets that exceed available memory by only loading chunks into memory at any given time. When chunks are kept small, computation can occur in memory constrained environments, making it feasible to process extremely large datasets quickly and efficiently in a parallel fashion.

To illustrate the benefits of chunking and lazy processing within a geospatial context, we use the *raster-tools* package (Raster-Tools Dev. Team, n.d.) and highlight common and not so common functionality through two use-cases. These are 21st century planning for fire resilient landscapes (Hogland et al, 2021) and burn severity prediction. These use vector and raster based datasets to demonstrate data acquisition, spatial and ML modelling, and visualisation. The rest of the article is separated into Use Case, Discussion, and Conclusion sections that describe the use cases, discuss how *raster-tools* facilitated the analyses within the use cases, and provide concluding remarks, respectively.

3. Use Cases.

3.1. 21st century planning for fire resilient landscapes

The 21st century planning for fire resilient landscapes use case, uses *raster_tools* to perform various spatial analyses to aid in planning forest treatments and quantify the costs and impact of those treatments at scale across a broad landscape. Spatial analyses used in this example include: arithmetic, logical, data format transformations, surface distance, surface allocation, and surface traceback, region grouping, and zonal summaries. Spatial data outputs created in this example include: multiple raster surfaces that quantify desired future conditions (DFCs), actual tonne removal, potential and actual cost, revenue, and profit of treatment implementation for 1.2 million ha in north central Oregon, USA at spatial resolution of 30 m. Primary datasets used within the use case include basal area per ha (BAH: m^2 ha^{-1}), and a most likely classification raster surfaces (Hogland et al, 2021), potential operational delineations (Dunn et al, 2020), United States Census Bureau Tiger/Line files (USCBl, n.d.), the National Hydrography Dataset (NHD) Flowline and Waterbody line and polygon features (NHD, n.d.), and the location of the Malheur Lumber company. All datasets used within the analyses are available for download at Hogland, n.d.a and are explained in further detail in (Hogland et al, 2021).

We provide a Jupyter notebook (Hogland, n.d.b) with an in-depth, dynamic example of the analyses performed within (Hogland et al, 2021) using *raster-tools*. The notebook is meant as a companion piece with (Hogland et al, 2021) and demonstrates everything from installation to final analysis. It is free to download and can be used with Google's Colab for research and educational purposes (Google Research Colab, n.d.).

Key results from the analyses performed in the notebook include spatial surfaces describing estimated treatment cost, revenue, and profit, and the amount of material removed to meet DFCs at 30 m resolution, along with summary reports based on POD boundaries and management priority (Figure 1). Moreover, outputs can be displayed as an interactive map and saved as a HTML file and further embedded within any website. From start to finish the analyses performed within the notebook takes approximately 16 minutes to complete using Colab and represent a substantial improvement in both processing time (minutes vs hours) and storage space (no intermittent datasets were created) over the delivered cost processing technique described in (Hogland et al, 2021).

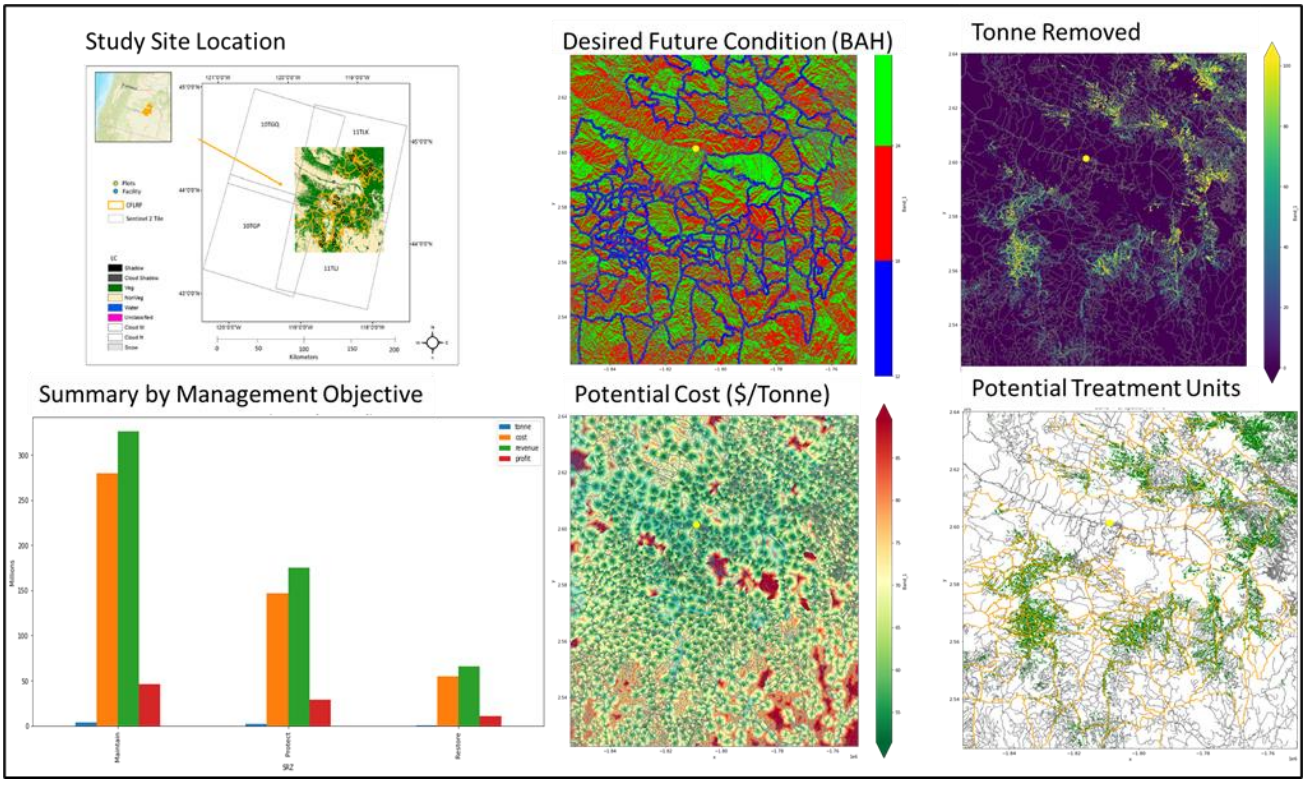

Figure 1- Study site location, Desired Future Condition (DFC), Potential Cost, Removals, Potential Treatment Units, and summarised tonne removed (blue), cost (orange), revenue (green), and profit (red) derived from the 21st century planning notebook.

3.2. Burn Severity Prediction

Our second use case was the development of a burn severity classifier similar to (Parks et al, 2018). For this, we created a training dataset consisting of 29.4 million burn severity labels and predictor values for the state of Montana from 1984–2020. Like (Parks et al, 2018), we used MTBS (Eidenshink et al, 2007) for the severity labels, but increased the number of severity classes used. For the predictors, we used 30 m CONUS EDNA elevation and derivative products (USGS, 2005) and 4 km CONUS gridMET reanalysis products (Abatzoglou, 2013). The training dataset was assembled using *raster-tools* to take MTBS data and pull the corresponding collocated data values from the predictor datasets. Using *raster-tools* allowed us to assemble the training dataset efficiently and in parallel in only a few hours on a desktop computer with limited memory. Figure 2 shows results for a single fire.

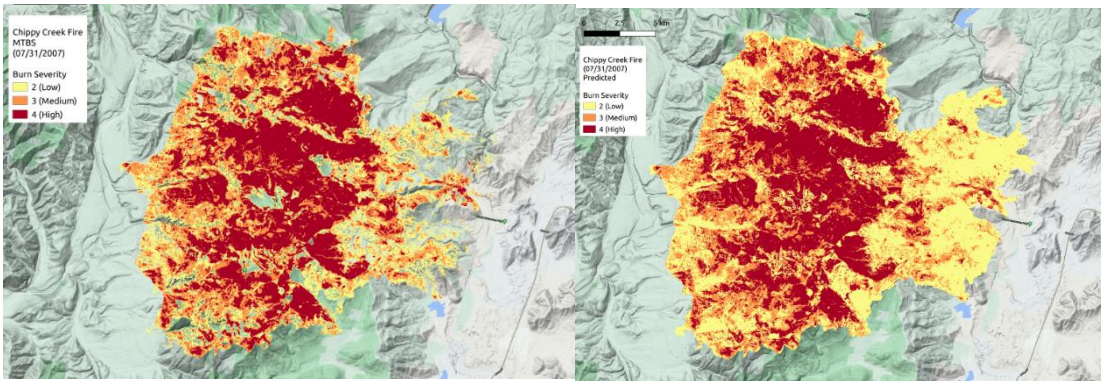

Figure 2- Comparison of MTBS (left) and model predicted (right) burn severity for the 2007 Chippy Creek fire in Montana.

4. Discussion

In both of the above use cases, large, high-resolution rasters and vectors were used as input data. Traditional methods for handling the processing of such data (e.g. ESRI) requires significant investment in computing resources, licensing, and time. With *raster-tools*, we were able to get meaningful, actionable results quickly using relatively small compute platforms. In the first use case, *raster-tools* allowed us to work with large rasters and vectors seamlessly and to carry out a very large number of computations quickly. It eliminated the need to write intermediate results to disk and also allowed us to carry out data analysis on the results with Python's wider data ecosystem.

In the second use case, *raster-tools* allowed us to pull together and work together with nearly 2000 large, high-resolution rasters, simultaneously to produce 29.4 million data points. This would not normally be possible without large investments in computing power, time, and extensive optimization work. Because *raster-tools* uses Python, we were also able to automate this task so that, in the future, we can apply the same processing pipelines to the other parts of the U.S. with only minor changes.

5. Conclusions

Our *raster-tools* package is a free and open-source tool for processing geospatial data. It provides the ability to build automatically scaling processing pipelines that can be run across compute platforms. We think that it can be used as a platform for building data driven applications that produce timely and actionable results at scale.

Abstract

While the undesired effects of wildfire continue to increase in many regions, the fire science community continues to suffer from an important shortage of observational data of fire behaviour, especially at the landscape scale. Observations of landscape-scale fire spread have traditionally been incomplete, infrequent or qualitative. Airborne remote sensing technologies are changing this paradigm with the increasing adoption of infrared and multispectral optical sensors by fire management agencies. However, fire observations acquired during firefighting operations are designed with the goal of supporting tactical fire management decisions and they may not completely meet the needs of a rigorous scientific analysis. In this paper, we discuss tactical fire observations collected by CAL FIRE in 2020 in California (USA), specifically regarding their utility for fire behaviour studies. Generic data properties are summarized and example data is presented for two fire events. Our inspection of the data suggests that the collected imagery will be useful to study fire progression with varying temporal resolution between a few minutes and 24 hours. Imagery was successfully georeferenced and the geographic location of active fire lines could be estimated with a spatial resolution of O(10m). However, the temporal resolution of observations is inconsistent across flights and frequently not enough to study fire behaviour in detail. Furthermore, radiated energy could not be successfully characterized because the sensors utilized were not radiometrically calibrated and saturated at high irradiances. We expect that these observations will be useful to (i) approximate the response of fire behaviour to topographic features as well as changing weather and vegetation conditions, and (ii) validate fire spread simulators at the landscape scale. However, a detailed analysis of local fire rate of spread requires observations made at a higher frequency, while a complete fire behaviour characterization is impossible without accurate measurements of fire radiated energy. Similarly, ecological fire effects and fire emissions can hardly be estimated using such sparse observations.

1. The 2020 California Fire Season

2020 was one of the worst years on record in the Western United States in terms of burned area, social impact and economic losses caused by fire. During the 2020 fire season, 8,648 fires burned over 4.3 million acres in California, more than 4% of the state's total land, making that year the largest wildfire season recorded in California's modern history. 11,116 structures were damaged or destroyed, 33 people died as a consequence of fires, and Emergency Fund expenditures exceeded USD $1B (CAL FIRE, 2020a; CAL FIRE, 2020b). Five fires occurred in 2020 are among the seven largest fires in California's history, and five are listed in the list of 20 most destructive California fires. Among them, the August Complex fire stands out as the first fire that has ever burnt an area larger than 1 million acres. Figure 1 shows the area burned in California during 2020.

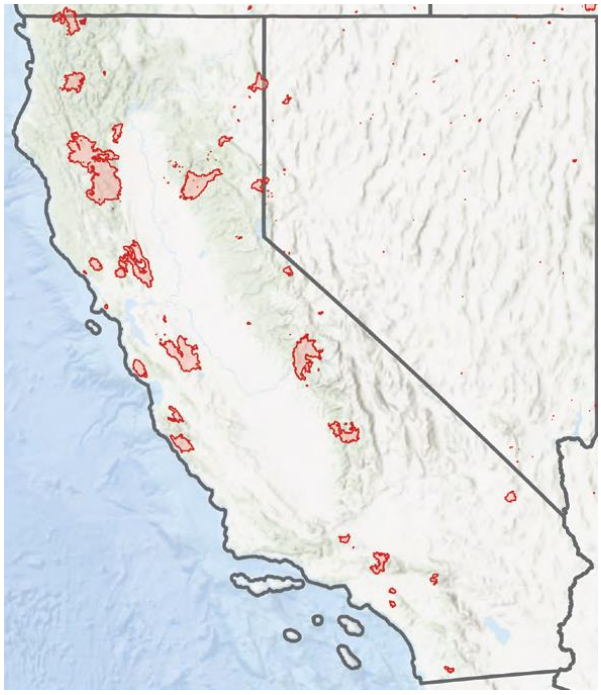

Figure 1- Area burned in California in 2020. Source: CAL FIRE.

2. Tactical Observations of Fire Spread

Fire management agencies deployed airborne imaging sensors during the largest and most impactful fires in 2020. In addition to using the imagery in real time, the data was stored for posterior analysis. This dataset is still being worked on by CAL FIRE. During our preliminary analysis of the dataset, we have identified a subset of the most impactful fires for which there is remote sensing information. The list of selected fires is summarized in Table 1. Two example fires were further selected from this list and are presented in Section 3.

Table 1- High-impact wildfires occurred in 2020 in California which have been selected for analysis based on the existence of fire spread remote sensing information.

Fire name	Location	Start Date	Containment Date	Area burned	Structures damaged	Casualties/Injuries
Creek	San Joaquin River near Mammoth Pool, Shaver Lake, Big Creek, Sierra National Forest	September 4, 2020	December 24, 2020	379,895 acres	71 structures damaged, 856 structures destroyed	26 injuries
North Complex (Clairmont, Bear)	Plumas National Forest	August 17, 2020	November 30, 2020	318,935 acres	2,455 structures destroyed	16 deaths
Glass	Napa county	September 27, 2020	October 20, 2020	67,484 acres	282 damaged, 1555 destroyed	None reported
Slater	Klamath, Six Rivers, and Rogue-Siskiyou National Forests in Siskiyou and Del Norte Counties in California and Josephine County in Oregon	September 8, 2020	November 16, 2020	157,229 acres	440 destroyed, 11 damaged	12 injured 2 dead
LNU	Napa, Sonoma, Lake, Yolo and Solano Counties	August 17, 2020	October 2, 2020	363,220 acres	1491 structures destroyed, 232 damaged	6 killed, 5 injured
Loyalton	Mount Ina Coolbrith, Sierra County, Tahoe National Forest	August 14, 2020	August 26, 2020	47,029 acres	None reported	None reported
Lake	Southwest Lake Hughs, Angeles National Forest	August 12, 2020	September 28, 2020	31,089 acres	33 structures destroyed, 6 damaged	4 injuries

Ranch 2	North San Gabriel Canyon Rd and Ranch Rd, San Gabriel Canyon	August 13, 20	October 2020	4,237 acres	None reported	None reported
CZU	San Mateo and Santa Cruz Counties	August 16, 2020	September 22, 2020	86,509 acres	1,490 Structures Destroyed, 140 Structures Damaged	1 injury, 1 fatality
Bond	Silverado Canyon, near Santa Ana (LA)	December 2, 2020	December 10, 2020	6,686 acres	21 structures damaged, 31 destroyed	None reported
Airport	Near Corona city (Riverside/LA)	December 1, 2020	December 12, 2020	1,087 acres	None reported	None reported
Crews	Crews Rd north of Gilroy	July 5, 2020	July 13, 2020	5,513 acres	1 structure destroyed	None reported
August Complex (Doe Fire - August south, Elkhorn Fire - August north)	Mendocino, Shasta-Trinity and Six Rivers National Forests	August 17, 2020	November 15, 2020	1,032,648 acres	995 structures destroyed	1 fatality
Red Salmon	14 miles northeast of Willow Creek	July 27, 2020	November 17, 2020	144,698 acres	None reported	None reported

3. Description of Remote Sensing Data

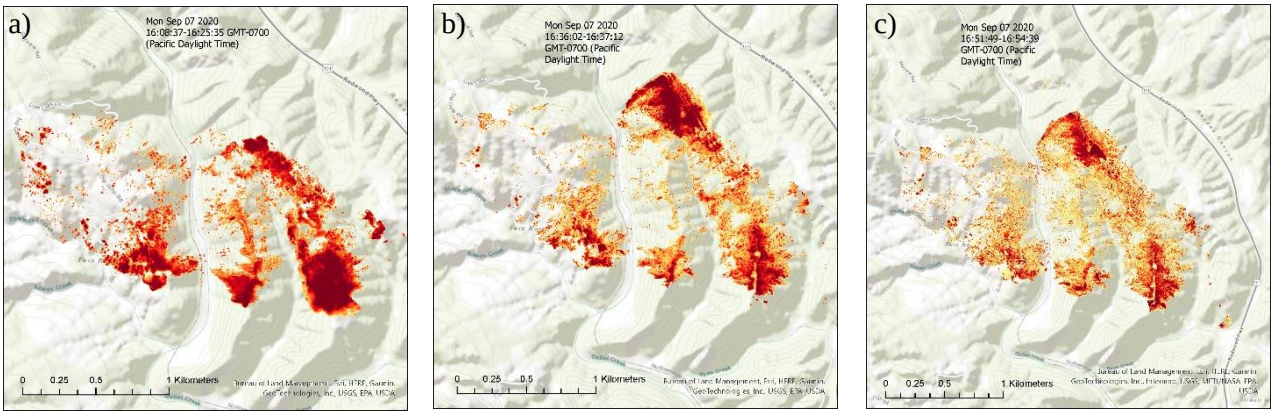
The primary source of data is aerial long-wave infrared (LWIR) imagery. Imagery was acquired on multiple flights for each fire. Time intervals between flights vary among fires and go from a few minutes to one day. Each video frame was timestamped and accompanied by camera position and attitude measurements, which allows for image georeferencing and accurate time referencing. The estimated spatial resolution of geocorrected images is in the order of 10m. However, LWIR images are non-radiometric and most of the them are saturated. This prevents retrieving fire radiative properties from this dataset.

4. Examples

This section showcases the available data in two example fire events with high temporal resolution data. In order to create the figures shown in this section, we applied georeferencing transformations to every video frame and stitched together all frames acquired during each flight. The resulting LWIR mosaics were then thresholded to identify active fire pixels. Because images are not radiometric, the optimum thresholding values were determined manually through inspection of image histograms.

4.1. Oak Fire

Fig. 2 shows a subset of the mosaics constructed from aerial LWIR frames captured during the 2020 Oak Fire. The time interval between observations is approximately 20 min. This frequency allows monitoring the fire progression and identifying significant events. For example, Fig. 2.c shows spotting on the south-east section of the fire perimeter. Such spotting significantly contributed to the advance of the fire as depicted in Fig. 2.d-e. Similarly, Fig. 2.f shows how the fire crossed a major highway through spotting.



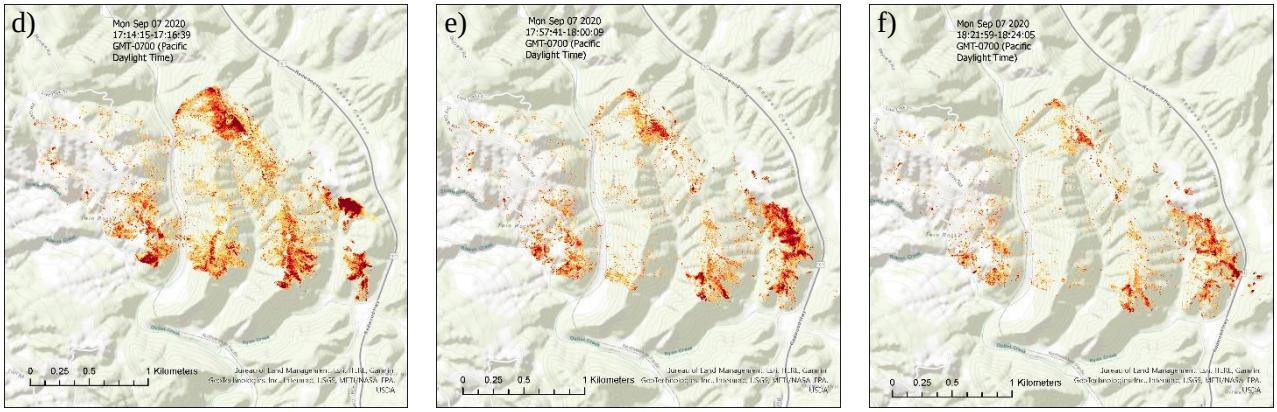


Figure 2. Observations of the 2020 Oak Fire progression. Darker colours represent a higher fire emittance, although images are not radiometric.

4.2. Glass Fire

Fig. 3 depicts the Glass Fire progression. In this case, only one LWIR mosaic is available per day. While the lower temporal resolution hinders the detailed analysis of fire behaviour, fire progression can still be observed in Fig. 3. Fire radiative properties could not be characterized due to the radiometric limitations of the deployed sensor.

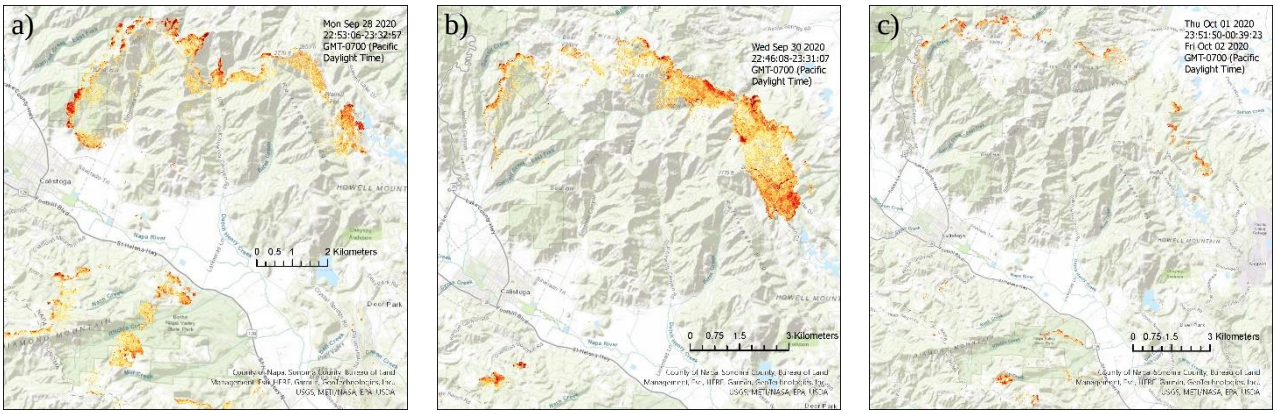

Figure 3. Observations of the 2020 Glass Fire progression. Darker colours represent a higher fire emittance, although images are not radiometric.

5. Discussion, Conclusions and Future Work

Systematic observation of fire behaviour is essential to support ongoing efforts in other areas like fire modelling, fire risk assessment and fire ecological studies. Acquiring fire behaviour observations is challenging, especially at the landscape scale. Remote sensing capabilities provide unprecedented opportunities to overcome the logistical challenges of fire behaviour observation. This paper discusses state-of-the-art data collected during firefighting operations in 2020 in California.

Our preliminary assessment of the data encourages further analysis. The ability to precisely locate active fire lines, track the fire perimeter and detect spot fires allows documenting fire progression and contextualizing it with terrain characteristics, vegetation properties and weather conditions. The primary limitations detected in this dataset relate to the unavailability of accurate radiative measurements and the inconsistent temporal resolution. Suggestions for the improvement of future fire observation systems include the addition of radiometric capabilities and the increase of frequency in observations.

Future work regarding this dataset includes (i) the development of an automated methodology to process the complete dataset, (ii) the development of a database with fire behaviour information collocated with topography, vegetation and weather data, and (iii) the detailed analysis of fire behaviour in individual fire events.

Burned land mapping, rule-based, vegetation indices, Landsat, Sentinel-2

Abstract

At local or regional scales, where Landsat has been extensively applied to monitor burned areas, semi- or fully-automated methods are not very common. Koutsias et al. (2013) developed and improved (2021) a semi-automatic method to map burned areas consisted of a set of rules that are valid especially when the post-fire image has been captured shortly after the fire. However, the rule-based approach is not free of errors that eventually create limitations to adopt this method for reconstructing the fire history in a fully automated mode. In this work, we improved the method by incorporating vegetation indices. The vegetation indices evaluated were the: (i) Normalized Difference Vegetation Index (NDVI), (ii) Ratio Vegetation Index (RVI), (iii) Normalized Burn Ratio (NBR), (iv) Normalized Difference Water Index (NDWI) and (v) Shortwave Infrared Water Stress Index (SIWSI).

1. Introduction

There is a long history of mapping burned areas and other forest disturbances using satellite images of multiple resolutions either at research level to develop and improve the mapping methods or to create operational products at global scale (Chuvieco et al. 2019). Maps of fire occurrence can improve our understanding for the protection and restoration of fire-affected natural ecosystems worldwide. Satellite-based remote sensing has been an ideal tool to create maps of fire scars by collecting and processing the required data, as it covers large spatial and temporal extents within a cost- and time-efficient framework (Koutsias et al. 1999).

At global scale, there are unique fire-products, such as those based on MODIS (Justice et al. 2002), however they are mostly devoted to continental scale studies. However, at regional scales, such systematic fire products are not very common mainly due to cost constraints on gathering and processing medium or high-resolution satellite data series that until almost a decade ago were not freely available at no cost although recently such products have started to appear (Hawbaker et al. 2020).

Currently, United States Geological Survey (USGS) archived Landsat images are freely available to the public from the USGS Earth Resources Observation and Science (EROS) Center (http://glovis.usgs.gov/). These historical archives cover large spatial and temporal extents at continental scale and provide a unique opportunity to overcome cost constraints when reconstructing fire history globally at low-to-high spatial resolution. However, one problem that exists is how to process successfully with high accuracy the time series of satellite images consisting of thousands of images without the human interference. The training phase of an algorithm, when needed, is a time-consuming procedure that if omitted would be an advantage of the approach by saving processing time and cost. This is a critical issue in cases where many satellite images need to be analyzed, such as for the spatially explicit reconstruction of fire history, where thousands of images might be used in the processing chain.

2. Mapping burned areas at local scale

2.1. The rule-based approach

There have been efforts to develop automatic or semi-automatic techniques to map burned areas using medium-high resolution satellite images such as those of Landsat satellites (Bastarrika et al. 2014; Hawbaker et al. 2020; Koutsias et al. 2013), Sentinel-2 data (Roteta et al. 2019). Recently, USGS delivered to the users Landsat Level-3 Burned Area (BA) that contains two acquisition-based raster data products that represent burn classification and burn probability using Surface Reflectance data from the U.S. Landsat Analysis Ready Data (ARD) (Hawbaker et al. 2020).

Koutsias et al. (2013) developed a semi-automatic method to map burned areas using multi-temporal acquisitions of Landsat satellite data, considering a pre- and post-fire image as a pair of images that could minimize spectral confusion with unburned surfaces. The proposed method consisted of a set of rules that are valid especially when the pre- and post-fire image has been captured shortly before and after the fire event respectively when the signal has its highest separability from other land cover types.

2.2. Improvement of the method

The rule-based approach is not free of errors (e.g. omission or commission), that eventually create limitations to adopt this method for reconstructing the fire history in a fully automated mode. Therefore, the development of completely automatic techniques to successfully map the burned areas is a challenge. In this work we improved further the method by incorporating vegetation indices.

To revise the old set of rules and create the revised rules we followed the same methodology as in the original paper from Koutsias et al. (2013) where the rules had been developed on the basis of spectral properties of burned areas as compared to the pre-fire unburned vegetation and to the spectral signatures of other land cover types found in post-fire satellite scenes. Therefore, sampling plots that correspond to burned surfaces were located on the post-fire Landsat images to capture the whole variability found within the burned area class. Additionally, other important land cover types were delineated on the satellite images using the pan-European CORINE 2000 Land Cover database.

The digital VI values of the sampling plot pixels were extracted and simple statistics were generated to characterize the spectral properties of the various land cover categories including the burned area class. Histogram and signature data plots were created to graphically represent the spectral profiles for all land cover types including burned areas. It was also used to compare them with patterns of unburned vegetation when using multi-temporal satellite images and with other land cover types when using only single-date post-fire satellite images.

2.3. Vegetation indices

A Vegetation Index (VI) is usually a linear transformation of two or more spectral bands aiming to enhance the spectral signal of the original spectral channels by creating a new spectral space which is sensitive to variations of vegetation attributes as for example leaf area index (LAI), percent green cover, chlorophyll content, green biomass and ab-sorbed photosynthetically active radiation (APAR). In our study we chose few of them that are considered typical and have been extensively applied for vegetation studies or in remote sensing of wildland fires, it is beyond our purpose to make an extensive evaluation of vegetation indices concerning their phenology between low and high fire-prone areas. The vegetation indices chosen were the: (i) Normalized Difference Vegetation Index (NDVI), (ii) Ratio Vegetation Index (RVI), (iii) Normalized Burn Ratio (NBR), (iv) Normalized Difference Water Index (NDWI) and (v) Shortwave Infrared Water Stress Index (SIWSI).

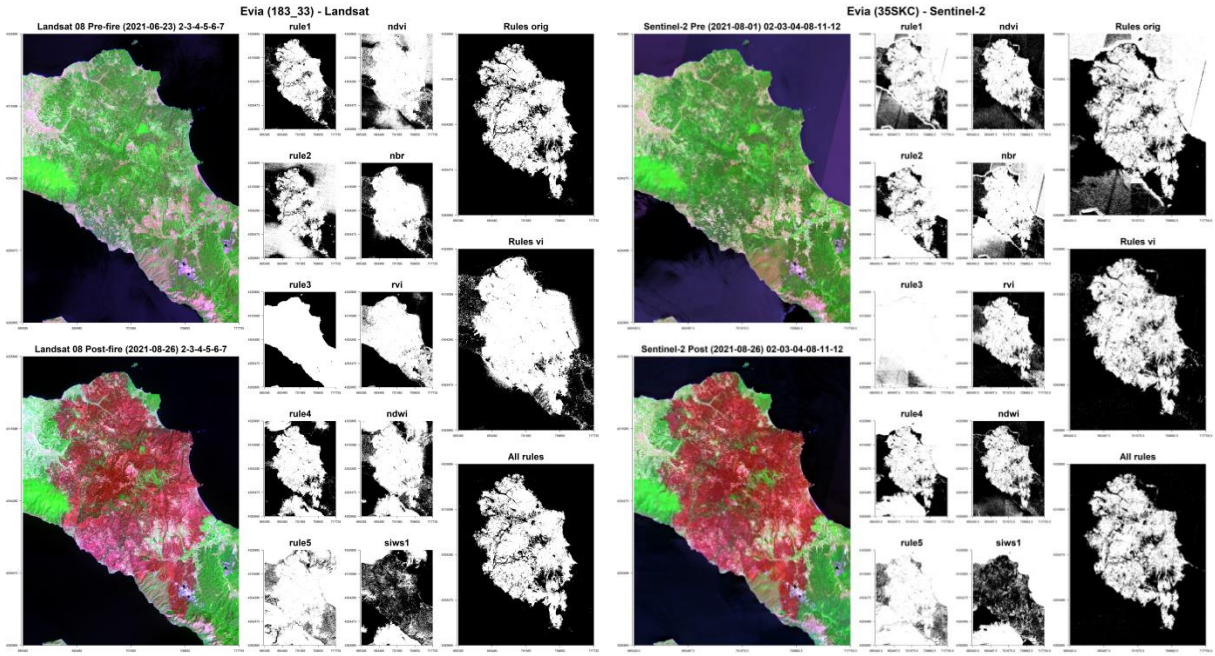

Figure 1- Mapping of burned areas with the rule-based approach as improved by the incorporation of the vegetation indices for Landsat and Sentinel-2 data.

Resilience; Spectral post-fire recovery; TCT; MODIS; Iberian Peninsula

Abstract

Wildfires can profoundly impact many aspects of matter flows and energy budgets in ecosystems. Exacerbated by projected shifts in climate, land use, and forest management, changes in fire regimes can lead to decreased ecosystem resilience, regime shifts, and ecosystem collapse. Thorough assessments of ecosystem resilience to wildfires are thus critical to bridge gaps between science, policy, and management. To that end, approaches based on ecosystem functioning offer an integrative view of ecosystem responses to wildfire-induced changes and provide quicker, quantifiable responses to disturbances that are more directly connected to ecosystem services. In that regard, satellite remote sensing can be employed to easily and frequently monitor multiple dimensions of ecosystem functioning over large areas and across time, and to evaluate ecosystem functioning resilience to wildfires. This study describes an approach for identifying potential regime shifts based on satellite-based surrogates of four key dimensions of ecosystem functioning: primary production, water content, albedo, and sensible heat. To that end, we classified the trajectories after wildfires in 2005, in NW Iberian Peninsula, for the 2000–2018 period, into five main types, using two metrics of medium-to-long term spectral post-fire recovery. Then, we derived a synthetic indicator to analyse the overall "strength-of-evidence" of potential regime shifts across dimensions. Potential regime shifts were identified for each dimension of ecosystem functioning considered, with the main effects associated with the sudden removal of vegetation. For primary production, regime shifts may be linked to changes in land cover and use, as well as management. Changes in the concentrations of impervious and radiation-absorbing materials following wildfires may be responsible for regime shifts in water content and albedo, with loss of canopy moisture due to fire-related damage leading to vegetation mortality during post-fire recovery. On the other hand, regime shifts in sensible heat were less frequent, since wildfires tend to have transient effects on this dimension of ecosystem functioning. Overall, our results show that our approach successfully captured different patterns of post-fire recovery and resilience across multiple dimensions of ecosystem functioning. We argue that our approach can provide an enhanced characterization of ecosystem resilience to wildfires, and support the identification of potential regime shifts after such disturbances, ultimately upholding promising implications for post-fire ecosystem management.

1. Introduction

Fire is an integral part of many ecosystems worldwide, playing a key role in their structure, composition, and functioning. However, wildfires can pose a major threat to a wide range of environmental, social, and economic assets (Adámek et al., 2016; San-Miguel-Ayanz et al., 2013). Changes in fire regimes can reduce the ability of ecosystems to recover and persist in the face of disturbances, eroding ecosystem resilience, which can lead to ecosystem collapse, with subsequent impacts on human societies (Folke et al., 2004; Johnstone et al., 2010; Scheffer et al., 2015). Moreover, wildfire disturbances can trigger sudden regime shifts in ecosystems, leading to critical transitions from one dynamic equilibrium to an alternative stable state (Boettiger et al., 2013; Scheffer et al., 2012). Furthermore, fire activity is projected to increase in the next decades, exacerbated by shifts in global climate, land use and forest management (Bowman et al., 2009; Tedim et al., 2013). Therefore, conserving fire-resilient ecosystems is a key priority (Willis et al., 2018).

Thorough assessments of ecosystem state and resilience to wildfires are thus critical to bridge gaps between science, policy, and management, with more comprehensive indicators needed for a better understanding of post-fire processes (Baho et al., 2017; Gouveia et al., 2010; van Leeuwen et al., 2010). To that end, approaches based on ecosystem functioning offer an integrative view of ecosystem responses to wildfire-induced changes, since fire can cause rapid modifications in key aspects of matter and energy flows in ecosystems (B. Marcos et al., 2021; Petropoulos et al., 2009). Furthermore, ecosystem functioning provides quicker, quantifiable responses to disturbances than structure or composition, and are more directly connected to ecosystem services (Alcaraz-Segura et al., 2008). Satellite remote sensing (SRS) has been increasingly employed for a wide range of applications related to both fire and ecosystem functioning, making it a major asset for risk assessment and governance, and post-fire restoration and management (Keeley, 2009; Parks et al., 2019; Smith et al., 2014). Having unlocked our understanding of global fire activity, satellite remote sensing has contributed to advancing wildfire science and management (Szpakowski & Jensen, 2019), allowing us to overcome scale-dependent limitations (Benali et al., 2016). Indeed, multiple aspects of ecosystem functioning — such as carbon and water dynamics, as well as energy budgets — can be easily and frequently monitored over large areas through SRS, due to their strong relation to biophysical properties and ecosystem processes (Villarreal et al., 2018). Nevertheless, multi-dimensional satellite-based assessments of ecosystem functioning resilience to wildfires are still scarce (Frazier et al., 2013). Moreover, the utility of SRS to evaluate ecosystem functioning resilience, and to anticipate potential regime shifts — through the translation of spectral indices into meaningful, informative ecosystem variables — is still largely under-explored (B. Marcos et al., 2021).

In this study, we propose an approach for identifying potential regime shifts based on satellite-based surrogates of four key dimensions of ecosystem functioning, related to the carbon, water and energy exchanges: primary production, water content, albedo, and sensible heat. For each one of those four dimensions of ecosystem functioning, we classified the post-fire trajectories into five main types, using two metrics of medium-to-long term spectral recovery. Finally, we derived a synthetic indicator of "strength-of-evidence" of overall regime shifts across dimensions. We discussed the potential and added value of the proposed approach to improve satellite-based characterization of ecosystem resilience to wildfire disturbances, and to identify potential regime shifts after those disturbances, over multiple dimensions of ecosystem functioning.

2. Materials and Methods

2.1. Study area

To illustrate our approach, we analysed all areas that burned in 2005 in the northwest Iberian Peninsula (NW-IP). This is an area with high wildfire activity, in the last decades — both in terms of ignitions and burned area —, despite the enormous investments in fire suppression (Catry et al., 2009; Moreira et al., 2020). Furthermore, the year 2005 coincided with severe drought, with over 340,000 ha burned in this area (Bastos et al., 2011). The NW-IP features diverse environmental characteristics, with strong environmental gradients, a major climatic and biogeographic transition, diverse land cover classes and land uses, and vegetation types. Moreover, historical land uses and management made this area a highly fire-prone landscape.

2.2. Satellite data preprocessing

Firstly, we identified the areas that burned in 2005, within the study area, with a contiguous area above 100 ha (i.e., "big fires"; following (B. Marcos et al., 2019)), using the MCD64A1 product (Giglio et al., 2018) from the

Moderate Resolution Imaging Spectroradiometer (MODIS). Then, to inform on the four ecosystem functioning dimensions of primary production, water content, and surface albedo, we used time-series of the three Tasselled Cap Transformation (TCT) features of "Greenness" (TCTG), "Wetness" (TCTW), and "Brightness" (TCTB), as well as land surface temperature (LST), respectively. The three TCT features are sensor-specific linear combinations of bands in the visible, near-infrared, and short-wave infrared regions of the electromagnetic spectrum that maximize the association with biophysical parameters such as the amount of photosynthetically active vegetation, water content and soil moisture, and albedo (Lobser & Cohen, 2007; Mildrexler et al., 2009). The LST is a calibrated measure of the thermal emissivity of the land surface. We extracted these satellite image time-series (SITS) from the MODIS MOD09A1 (Vermote, 2015) and MOD11A2 (Wan et al., 2004) products, for the years ranging from 2000 to 2018, with a frequency of 46 images per year (i.e., one image for each 8-day period), at 500m spatial resolution.

Spurious values in each of the four SITS were corrected using a filtering procedure based on the Hampel identifier (Hampel, 1971, 1974). Time-series were seasonally adjusted using Seasonal and Trend decomposition using Loess (STL; (Cleveland et al., 1990; Hyndman & Athanasopoulos, 2018)), to establish pre-fire conditions, by defining reference intervals corresponding to one median absolute deviation around the median, from all values in the three years brfore the date of the fire occurrence. On the other hand, the trend component was used to compute moving-window medians (i.e., incremental steps in the post-fire trajectories).

All data was processed and analysed using software packages within the R statistical programming environment (Busetto & Ranghetti, 2016; Hijmans, 2020; R Core Team, 2019), and the Python programming language (Gillies et al., 2013).

2.3. Extraction of resilience indicators

To support the identification of potential post-fire regime shifts in ecosystem functioning, we first determined — for each pixel and each of the four dimensions of ecosystem functioning — the date of the first directionality inflexion in the trend component curve (t_{INF}) after the date of the wildfire occurrence (t_{FIRE}). This moment represents the first major change of directionality — from divergent to convergent with the pre-fire conditions — in the post-fire trajectory, which can be regarded as an approximation of the date of the start of recovery.

Then, we computed two related but independent "return time"-type metrics related to post-fire (spectral) recovery at medium-to-long term:

- "Return-to-Reference Time" (RRT) — the duration of the period between t_{FIRE} and the first moment in the post-fire recovery when the post-fire trajectory returns to within the pre-fire reference interval — t_{REF}; and
- "Return-to-Equilibrium Time" (RET) — the duration of the period between t_{FIRE} and the moment in the post-fire recovery when the trajectory is stabilized (according to a predefined threshold value for the change rate) — t_{EQ}.

The RRT metric provides an estimate of the amount of time needed to return to the pre-fire conditions (if and when applicable), whereas RET provides an approximate measure of the amount of time needed to achieve a stable state after a fire (if and when applicable) — which can be different from the pre-fire conditions.

2.4. Identification of potential regime shifts

Based on different combinations of the outcomes of the RRT and RET metrics, we classified the post-fire trajectories of each of the four dimensions of ecosystem functioning into four main types of medium-to-long term spectral recovery (Fig. 1):

- "Return to pre-fire" — equilibrium reached within pre-fire reference interval;
- "Under-recovery" — equilibrium reached outside pre-fire reference interval, but pre-fire reference interval not crossed;
- "Over-recovery" — equilibrium reached outside pre-fire reference interval after pre-fire reference interval was crossed;
- "No equilibrium" — pre-fire reference interval crossed, but no equilibrium achieved; and

- "(not detected)" — no recovery detected because either: (i) t_{REF} and t_{EQ} not successfully found; or (ii) inflexion point not found, or not within the pre-fire reference interval.

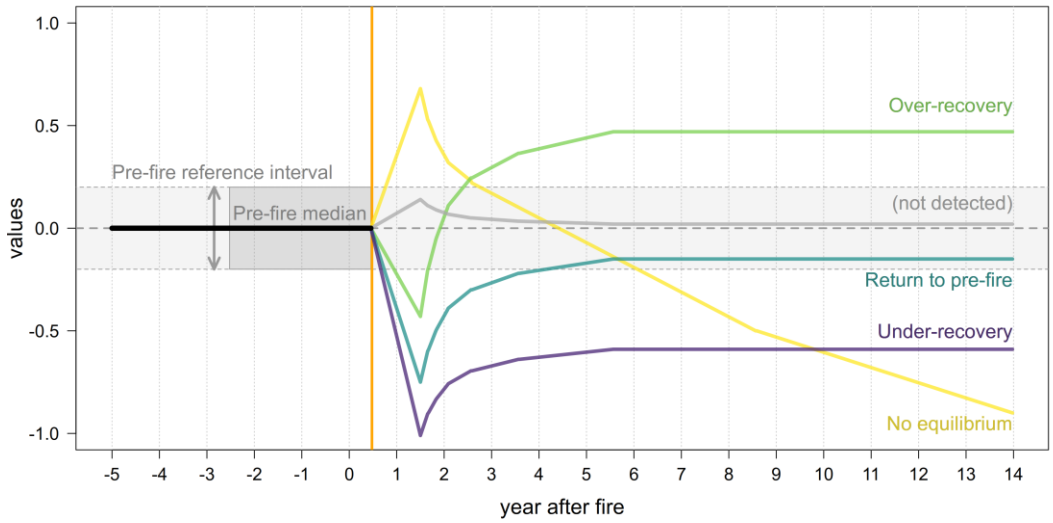

Figure 1 – Illustration of the different classes obtained from the post-fire resilience classification, based on the two independent metrics of "Time to Return-to-Reference" (RRT) and "Time to Return-to-Equilibrium" (RET), respectively measuring the time needed after the wildfire to return to pre-fire conditions, and to achieve a stable state.

Finally, we mapped the percentage of the four dimensions of ecosystem functioning with potential regime shifts (i.e. that were classified as either "Under-recovery" or "Over-recovery"), as a synthetic, multi-dimensional indicator of the overall "Strength-of-Evidence" for potential post-fire regime shifts in ecosystem functioning.

3. Results and Discussion

Overall, most burned pixels in NW-IP were classified as either "Return to pre-fire" or "(not detected)", within each dimension of ecosystem functioning (Fig. 2) — except for albedo ("Albedo"). This suggests an overall high resilience capacity of ecosystems in the study area. Furthermore, the percentage of the "(not detected)" class was highest for sensible heat ("Heat"), corresponding mainly to areas located either near or adjacent to the periphery of the burned patches (Fig. 3). These results, allied to the low percentages of the "Under-recovery" and "Over-recovery" classes, point to the effects of wildfires on Heat being mostly transient (E. Marcos et al., 2018; Quintano et al., 2015). On the other hand, the main effects on primary production ("Productivity"), water content ("Water"), and Albedo can be linked to the sudden removal of vegetation (Veraverbeke et al., 2012).

Regarding potential regime shifts, considerable portions of the analysed burned areas were classified as either "Over-recovery" — with the highest percentage for Productivity and Albedo —, or "Under-recovery" — with the highest percentage for Water and Albedo. Regime shifts in Productivity may translate land cover conversions, particularly when associated with land abandonment (Silva et al., 2011), invasions by exotic plant species (Nunes et al., 2020), or direct human interventions (Silva et al., 2011). Regime shifts in Water can be associated with the loss of moisture in canopy foliage due to fire-related damage — which can sometimes persist for up one year after the fire —, leading to vegetation mortality (Beringer et al., 2003; Senf & Seidl, 2020; Viana-Soto et al., 2020). Also, the increased concentrations of quantities of impervious materials (such as ashes, char, and soot) after a fire can clog soil pores, leading to decreased water retention capacity, and increased post-fire water repellency, surface runoff, and soil erosion rates (Bodí et al., 2014; Hubbert et al., 2012; Ramanathan & Carmichael, 2008). These materials can also be responsible for the observed regime shifts in Albedo, since they absorb visible solar radiation, translating into a darkening effect immediately after the fire that tends to dissipate before the regeneration of vegetation, leading to a temporary brightening effect one to two years after fire (Lentile et al., 2006; Quintano et al., 2019; Ramanathan & Carmichael, 2008; Saha et al., 2019). Whichever the specific driver responsible for regime shifts in each particular case, these qualitative changes can denote a depletion in the resilience capacity of ecosystems, with potentially severe consequences (Gatebe et al., 2014; Saha et al., 2017).

Finally, the "No equilibrium" class may translate either incomplete recovery or unforeseen interferences on the detection of post-fire inflexion points. Nonetheless, the percentages obtained for this class were low across dimensions.

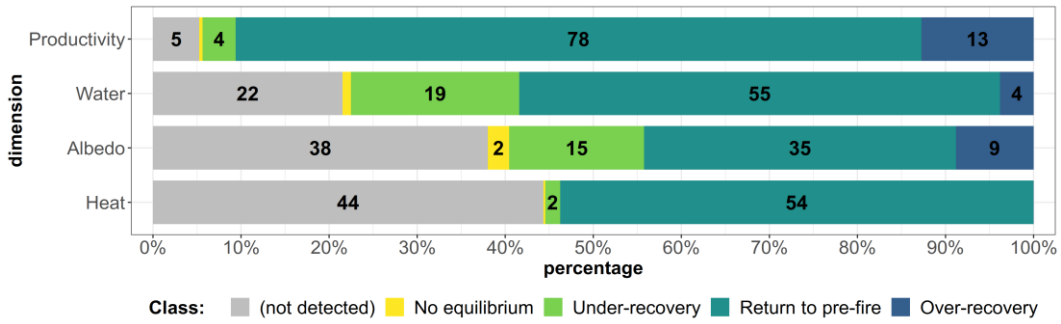

Figure 2 – Relative frequencies obtained for each post-fire resilience class, for each of the four dimensions of ecosystem functioning considered — primary production, water content, albedo, and sensible heat —, across all patches burned in 2005 in NW Iberian Peninsula, up until 2018. Numbers in bold are only shown for percentages above 1%.

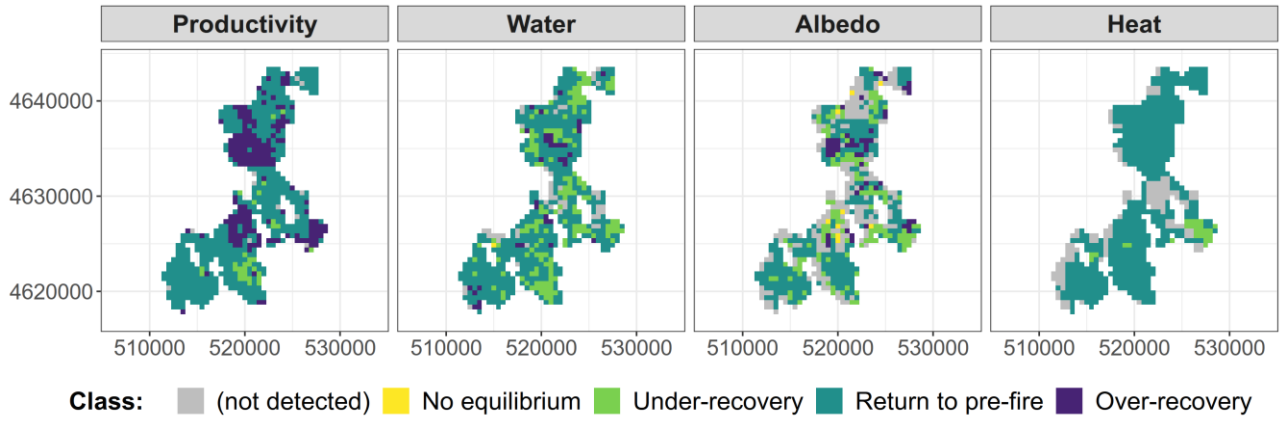

Figure 3 – Post-fire recovery and resilience classification map for a selected burned area, for each of the four dimensions of ecosystem functioning considered — primary production, water content, albedo, and sensible heat.

Maps of the overall "Strength-of-Evidence" of regime shifts, across the four dimensions of ecosystem functioning (Fig. 4), clearly show areas overall more likely to have experienced regime shifts in ecosystem functioning, with particular "hot-spots" being observable in darker colours.

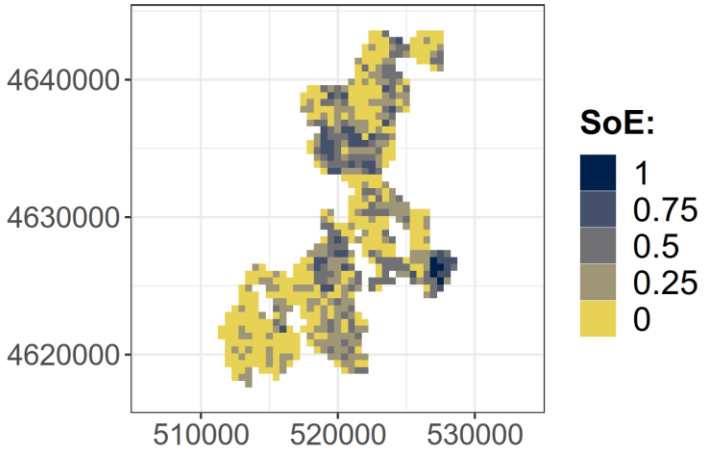

Figure 4 – Maps of "Strength-of-Evidence" for regime shifts across the four dimensions of ecosystem functioning considered — primary productivity, vegetation water content, albedo, and sensible heat —, for a selected burned area.

4. Conclusions and future outlook

In this study, we described an approach for characterizing ecosystem resilience to wildfires, across multiple dimensions of ecosystem functioning, as well as for identifying and mapping potential post-fire regime shifts, using metrics extracted from SITS. Furthermore, the proposed approach can be applied in a wide range of geographic and environmental contexts, using data from different satellite-sensor platforms. Together, the results obtained allowed us to highlight the added value and the potential of the proposed approach. Potential applications include regional-scale, spatially explicit prioritizations for management or conservation purposes, and as a precursor analysis to more detailed, local-scale assessments, investigating specific patterns. Potential future improvements include accounting for the duality in post-fire trajectories of albedo, as well as validating the obtained results through field-collected data such as spectral readings, and aerial ("drone") imagery. Overall, our approach successfully captures different patterns associated with key features of the post-fire processes in ecosystem functioning, pointing to a high degree of complementarity between different dimensions, and highlighting the added value of such multi-dimensional. We argue that such frameworks can provide an enhanced characterization of post-fire ecosystem resilience, ultimately upholding potential implications for post-fire ecosystem management.

Abstract

Nowadays, the needs for decision making tools useful for people involved in firefighting and/or in landscape management becomes more and more crucial, especially with the dramatic increase of the fire dangerousness and fire severity. These tools have to be accurate enough and faster than real time. Up to now, simulators and other tools are mainly based on empirical or semi-empirical models but the lack of physics in their formulation is a major limitation. The Balbi model is a simplified physical propagation model for surface fires which explicitly depends on the topography, the wind velocity and several fuel characteristics. It is a set of algebraic equations built from usual physical conservation laws (mass, momentum etc.) with some strong assumptions. This work aims at providing a new version of the Balbi model in which the resolution of the rate of spread (ROS) does not need any iterative method any more. This simplification is helpful in implementing the equations set into a fire propagation simulator or a coupled fire-atmosphere simulator. It needs a complete change in the structure of the model and the predicted ROS was tested at the field scale against 179 shrubland fires (burnt in Australia, South Africa, Turkey, Portugal, Spain, New Zealand) and 178 Australian grassland fires with a very good agreement with the observed ROS. Two statistical tools are used to check this agreement (Normalized Mean Square Error, NMSE and Mean Absolute Percentage Error, MAPE) and the Fractional Bias (FB) aims at understanding when the model over-predicts or under-predicts the ROS. The proposed model is accurate and its model parameters are calibrated against a small training dataset which makes it fully predictive whatever the environmental and topographic conditions and the fuel bed characteristics. Its more simple structure allows it to be a good candidate for the heart of a simulation or land management decision making tool.

1. Introduction

Climate change is one of the reason that increases the number of severe wildfires or extreme fire events (European Science & Technology Advisory Group, 2020). The response found by the firefighters to this new type of high intensity fires has to be fast and reliable. Another response consists in shifting from suppression to prevention with efficient fuel mitigation policies or an increase of safety zones and fuel breaks for instance. In both cases, the use of decision making tools is crucial for people involved in firefighting and in landscape management.

The fire behaviour modelling has been considerably improved for the last fifty years. Three main approaches in fire modelling have been emphasized by several authors (Weber, 1991; Perry, 1998; Pastor *et al.* 2003; Sullivan 2009a,b,c): (1) empirical models, (2) semi-empirical models and (3) physical models.

Empirical models are very simple and usually defined thanks to a correlation between ROS and the main parameters influencing the propagation (wind speed, fuel moisture content, fuel height, etc.). They are constructed over a large set of experimental fires (Anderson *et al*. 2015 for instance). Semi-empirical models are based on very simple physics principles but they don't differentiate the heat transfer mechanisms. Because of their simplicity and quickness, both empirical and semi-empirical models were the best candidates to be

incorporated into fire simulators. For instance the semi-empirical Rothermel's model (Rothermel, 1972) is the core of the FARSITE simulator (Finney 1998) or of the coupled fire-atmosphere WRF-SFIRE simulator (Mandel *et al.* 2011). The main limitation of these models is the lack in the physics of the phenomenon and the high cost of the large campaign of experimental burnings.

Detailed physical models — e.g. Firestar 2D (Morvan *et al.* 2009) and 3D (Frangieh *et al.* 2018), Firetec (Linn and Cunningham, 2005), WFDS (Mell *et al.* 2007), are based on multiphase formulations which consists in solving the partial differential equations obtained from the gaseous and solid phases. The main interest of these models lies in improving the comprehension of the fire dynamics but because of their high computational cost, they can't be used to perform numerical simulations in real time situations.

Simplified physical models (Pagni and Peterson, 1973; Albini, 1985; Balbi *et al.* 2010) combines the advantages of the three previous categories. The Balbi model (Balbi *et al.* 2020; Chatelon *et al.* 2022) is a simplified physical propagation model for surface fires at the field scale. It consists in a set of non-linear algebraic equations depending on the triangle of fire (fuel, wind and slope) and built over three heat transfer mechanisms: (1) radiation from the flame base, (2) radiation from the free flame and (3) convection inside the vegetal stratum. The model parameters are calibrated upon a small training dataset of experimental fires found in the literature. The Balbi model is physics-based, fully predictive and faster than real time; it is then designed for an implementation in decision making tools for people involved in firefighting or in fire management.

This work deals with a change in the structure of the Balbi model in order to obtain a brand-new version which aims at simplifying the resolution method for an easier implementation. The predicted ROS is compared to the ROS measured in 179 shrubland fires and 178 grassland fires using some usual statistical tools: (1) Normalized Mean Square Error (NMSE) and Mean Absolute Percentage Error (MAPE) to measure the model's accuracy and (2) Fractional Bias (FB) to check if the observed ROS is overestimated or underestimated.

2. Changes in the structure of the Balbi model

The main equation of the Balbi model presented by Chatelon *et al.* (2022) concerns the calculation of the ROS as the sum of three components derived from: (1) the radiative heat flux from the free flame F1 (see fig.1) on the unburnt fuel (R_r), (2) the radiative heat flux from the flame base (R_b) and (3) the convective heat flux inside the vegetal stratum (R_c) which involves the flame F2. The main equation of the model is then the following:

$$R = R_b + R_c + R_r \tag{1}$$

All details and nomenclature can be found in (Chatelon *et al.* 2022).

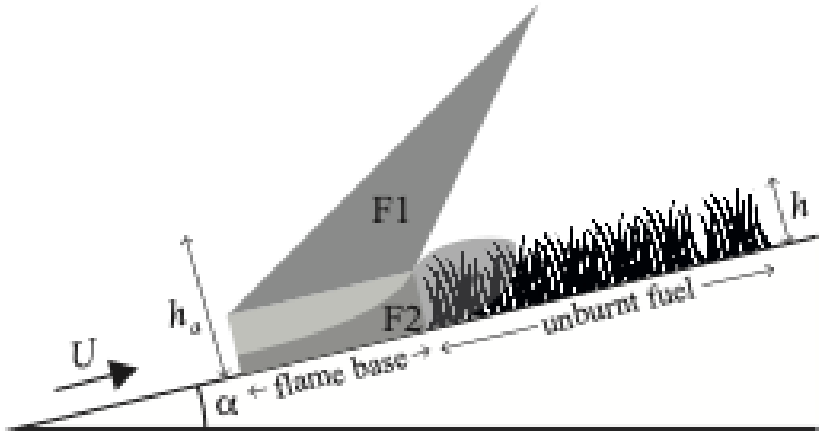

Figure 1- An idealized representation of the flaming zone combustion profile

Both terms R_c and R_r depend on the ROS R and thus, eq. 1 is an implicit algebraic equation that must be solved using an iterative method, which could be difficult to implement in fire simulators. In order to obtain an explicit equation, eq. 1 is changed by the following

$$R = \max(R_b\ ;\ R_c\ ;\ R_r) \tag{2}$$

The term R_b is defined thanks to a usual Stefan-Boltzman modelling that does not depend on the wind speed (Chatelon *et al*. 2022) and:

$$R_c = \frac{b\,U}{1+K\,b\,U} \tag{3}$$

$$R_r = s\,\frac{r_{00}}{u_0}\,(2A-1)(U - u_0\frac{A}{2A-1}) \tag{4}$$

Where *b* is a convective coefficient and *K* represents the drag forces law that are assumed to linearly depend on the total packing ratio. These coefficients (and R_b) mainly depend on fuel characteristics:

$$b = d\ \min\left(\frac{W}{W_0};1\right)\frac{\Delta H}{q\,\tau_0}\,s\sqrt{h} \tag{5}$$

$$K\ = 5\,\beta_t \tag{6}$$

The expressions of the radiative coefficient *A* and the upward gas velocity u_0 are the same as in (Chatelon *et al*. 2022).

The convective coefficient *b* depends on the fuel bed arrangement through the scaling factor *d*. Indeed, at the field scale two different type of fuel arrangement are considered: (1) isotropic (shrub species) and (2) vertical (grass). The expression of this scaling factor is the following:

$$d = d_0 * \begin{cases} 1\ (isotropic\ fuel) \\ 1+\frac{0.3}{h}\ (vertical\ fuel) \end{cases} \tag{7}$$

Finally, all the three components of the ROS (eq. 2) does not depend on the ROS anymore. So eq. 2 has become an algebraic explicit equation.

The value of the radiative coefficient *A* defines the fire regime expressed by eq. 2. Indeed two different regimes can be found:

(1) If $A < ½$, the component Rr (obtained from the free flame radiative heat flux) is a negative term and then:

$$R = \max(R_b\ ;\ R_c) \tag{8}$$

The fire turns into a radiative regime for weak wind values (when $U < U_{bc}$, see fig. 2) and into a convective regime otherwise.

(2) If $A > ½$, the radiation from the flame base is still the dominant heat transfer mechanism for weak wind speeds ($U < U_{bc}$, see fig. 2). Beyond the threshold wind speed U_{bc}, the convective effects are dominating up to a second threshold wind speed U_{cr}. For greater wind speed values, the role of the free flame radiation as heat transfer mechanism on the fire propagation highly increases.

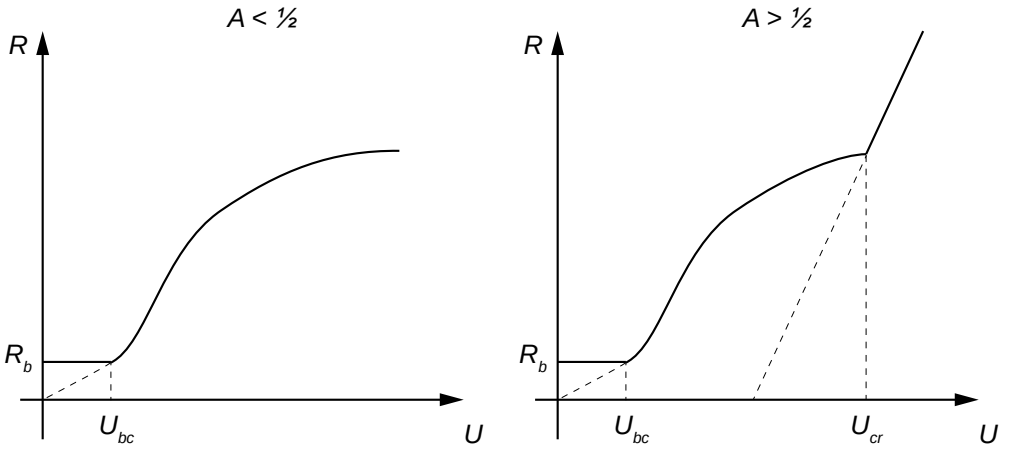

Figure 2- A qualitative representation of the two fire regimes exhibited by the proposed model.

The proposed model is composed of several equations for the calculation of the main physical characteristics of the fire front (flame tilt angle, flame height, flame length, upward gas velocity, flame temperature etc.) and the main equation for the ROS in combining all the previous equations:

$$R = \max\left(R_b\ ;\ \frac{b\ U}{1+K\ b\ U}\ ;\ s\ \frac{r_{00}}{u_0}\ (2A-1)(U-\ u_0\frac{A}{2A-1})\right) \quad (9)$$

As the proposed model is a strong simplification of the Balbi model presented by Chatelon *et al*. (2022), an increase in the overall deviations is expected considering that only the main heat transfer mechanism is taken into account.

The proposed model is fully predictive because its model parameters, especially d_0 (see eq. 7) is fitted once against a small set of experiments. Indeed, this coefficient was derived from the set of 25 fire experiments carried out by Bilgili and Saglam (2003) for shrubland fires and from a subset of 10 grassland fires (location: Ballarat) proposed by Cruz *et al*. (2018).

3. Numerical results and discussion

The proposed model is tested against a large set of fire experiments at the field scale. This set picked up in the literature is composed of 179 shrubland fires (Anderson *et al.* 2015; Bilgili and Saglam, 2003; Marsden-Smedley and Catchpole, 1995; van Wilgen *et al.* 1985) and 178 grassland fires (Cheney *et al.* 1998; Cruz *et al.* 2018) burnt in several regions of the world (Australia, New Zealand, Spain, Portugal, South Africa, Turkey). This set can be distinguished by a wide range of fuel characteristics and wind velocities. Some fires (van Wilgen *et al.* 1985) spread on sloped terrains.

The agreement between observed and predicted rate of spread is assessed using three statistical tools. Both Normalized Mean Square Error (NMSE) and Mean Absolute Percentage Error (MAPE) are useful for estimating the overall deviations and the Fractional Bias (FB) allows to understand if a model shows under-predictions or over-predictions. An ideal model is obtained for a zero NMSE, MAPE and FB.

The comparison between predicted and observed ROS against shrubland fires is presented in Fig. 3. The solid line and the dotted lines are the line of perfect agreement and the ±35% error threshold lines, respectively. As expected, the overall deviations (NMSE = 0.163) are barely higher than the value (NMSE = 0.132) found by Chatelon *et al.* (2022). This increase in the error is kept under control and is mainly due to the fires carried out in Australia where the radiation was found slightly higher than the convective effects. In this case, the NMSE changed from 0.213 (Chatelon *et al.* 2022) to 0.321 (see table 1). Moreover the relative error is equal to 35% which constitutes an acceptable error for ROS models (Cruz and Alexander, 2013). In spite of it, the proposed model provides high NMSE and MAPE for the Portugal fires group (see table 1). Although this fires group was used by Anderson *et al.* (2015) to build their empirical model, both the Anderson's model and the Balbi model (Chatelon *et al.* 2022) generated a poor agreement between predicted and observed ROS. So, it does not seem to be a specific limitation of the proposed model.

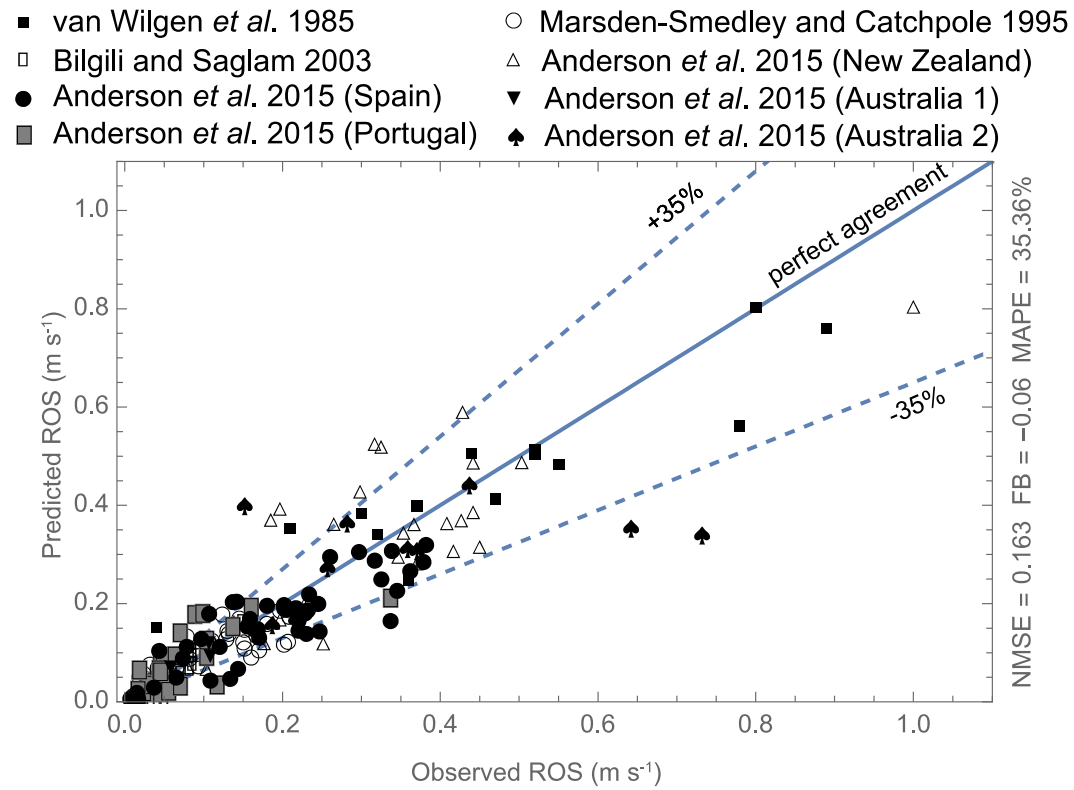

Figure 3- Comparison of predicted ROS vs ROS observed in the shrubland fires dataset.

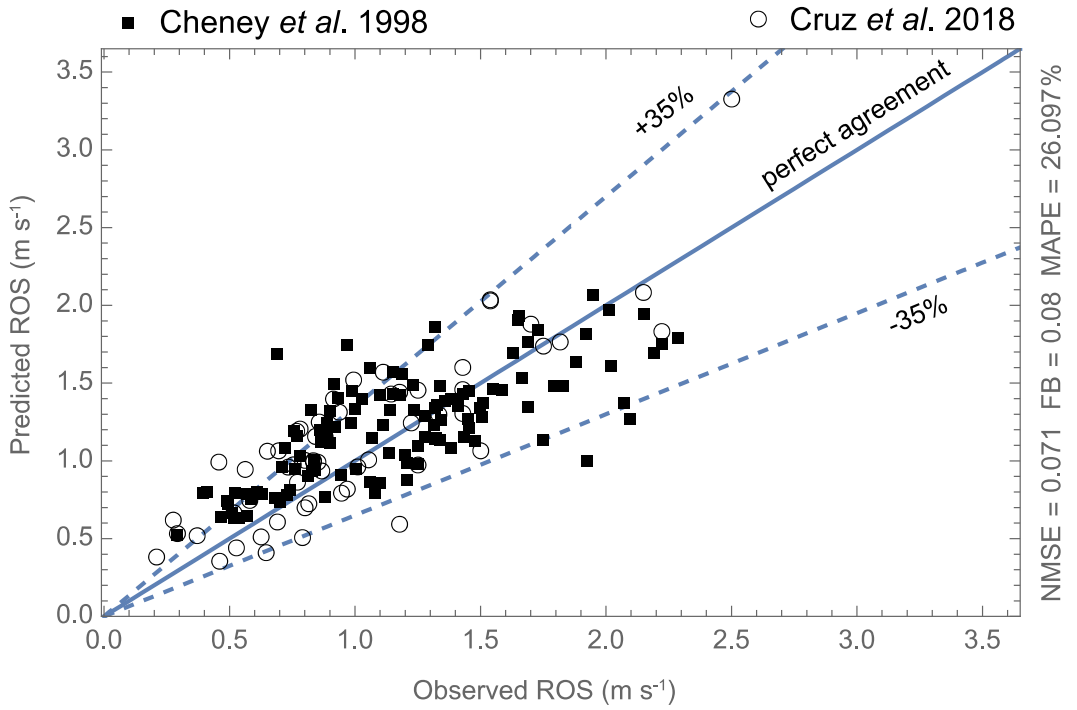

Figure 4- Comparison of predicted ROS vs ROS observed in the grassland fires dataset.

Fig. 4 shows the predicted ROS vs observed ROS in grassland fires. The numerical results provided by the proposed model are very good with small NMSE (0.071) and MAPE (26%). Note that contrary to the shrubland

fires group, the confrontation of the proposed model to grassland fires produces a slight overestimation of the ROS (FB = 0.08).

Table 1- Agreement between observed and predicted rate of spread estimated with three statistical tools (NMSE, Normalized Mean Square Error, MAPE, Mean Absolute Percentage Error and FB, Fractional Bias)

Fuel (location)	Reference	NMSE	MAPE	FB
Shrubs (South Africa)	Van Wilgen *et al.* 1985	0.045	35%	0.06
Shrubs (Turkey)	Bilgili and Saglam 2003	0.046	25%	0.11
Shrubs (Australia)	Marsden-Smedley and Catchpole 1995	0.123	37%	-0.03
Shrubs (New Zealand)	Anderson *et al.* 2015	0.109	29%	-0.02
Shrubs (Portugal)	Anderson *et al.* 2015	0.425	63%	-0.16
Shrubs (Spain)	Anderson *et al.* 2015	0.115	29%	-0.18
Shrubs (Australia)	Anderson *et al.* 2015	0.321	31%	-0.07
Shrubland fires		**0.163**	**35%**	**-0.06**
Grass	Cheney *et al.* 1998	0.068	24%	0.06
Grass	Cruz *et al.* 2018	0.079	30%	0.12
Grassland fires		**0.071**	**26%**	**0.08**

4. Conclusion

This work deals with a simplification of the simplified physical propagation model for surface fires called Balbi model in order to make its incorporation into decision making tools easier. In order to obtain an explicit formula for the ROS, several assumptions are made. The major assumption consists in considering only the main heat transfer mechanism as the mainspring of the propagation. Because of this simplification, the deviations provided by the proposed model are expected to be higher than the ones obtained by Chatelon *et al.* (2022). The numerical results against shrubland fires show a slight increase of the error which remains controlled. The predicted ROS against grassland fires is in a good agreement with the observed ROS. These good results and the characteristics of the proposed model (more simple, accurate, physics-based, fully predictive) confirm that the proposed model can be easily incorporated into decision making tools for operational people (firefighters, landscape managers etc.)

Abstract

The expression of flames and smoke in the existing VR engine is an image-based fake flame and smoke that does not have a physics analysis process. In this study, after converting the operation data analyzed in the wildland-urban interface fire dynamics simulator (WFDS) into an FGA file containing vectors and physical quantities at intervals of N seconds, the 3D Unreal engine developed an expression technology for values and vectors movement for smoke and heat. In addition, a visualization program was developed for the movement of flames and smoke according to wind speed and direction in the Unreal engine using a physics analysis model. As a result, the grid data values of the SMV and the UE virtual reality engine showed a 100% coincidence rate, and the visual difference between heat and smoke showed similarity through contrast ratio and lighting effect. The fire visualization expression of the 3D object value of combustibles according to the reduction in mass due to combustion was expressed by automatically updating the 3D object combustible material per unit time through material rendering for each combustion stage.

1. Introduction

The deaths and injuries of firefighters due to forest fires occur continuously around the world every year. In order to effectively suppress forest fires and prevent safety accidents for firefighters, forest fire-related organizations are operating forest fire education programs. Due to the nature of wildfires, firefighters must improve their ability to respond to each forest fire situation for effective suppression at the fire site based on their knowledge of the forest fire environment. However, there are many differences from the actual forest fire suppression environment in theoretical learning and training on the nature of wildfires on a laboratory scale. Recently, building fire education and training simulators using 3D virtual reality technology and game-type forest fire suppression training programs are being developed. Here, the expression of flame and smoke, which are the main components of fire, is used by a training instructor to create each fire situation by adding a simple image as a fire icon. This does not apply chemical species and physical analysis. Therefore, this study proposes to develop a 3D virtual reality education and training authoring tool based on chemical species and physics analysis for more realistic forest fire field experience and effective education by firefighters. This study proposes a technology and method to visualize forest fire flames and smoke through physical analysis in 3D virtual reality UE using the temperature and smoke results analyzed in WFDS.

2. Methods

2.1. WFDS analysis

WFDS was developed to analyze fire spread in open spaces adjacent to forests by applying topography and vegetation fuel by extending FDS developed for structural fire analysis. In this study, the X-axis, Y-axis, and Z-axis were set to 200 m, 160 m, and 50 m, respectively, and the cell spacing was set to 2 m, resulting in a total of 200,000 cells were configured as 100 cells on the X-axis, 80 cells on the Y-axis, and 25 cells on the Z-axis.

For forest fuel, a combustion material, combustion properties were applied to Pinus densiflora with an average height of 17 m and 400 trees/ha, and Cone type was applied for the grid configuration.

2.2. Visualization of VR contents forest fires spread simulation

Result values analyzed with WFDS are stored as Plot3Ddata files, velocity vectors, and physical quantities for fire analysis, and then extracted as vector files FGA files with a cycle of N(3~5) seconds so that they can be imported into 3D Unreal Engine. The FGA file contains data values of vectors and physical quantities in the analysis result. FGA file imported from 3D UE is created as a vector field, and Boundary values such as position, rotation, stile, intensity, and tightness are set. With the generated vector field, the particles are completed by applying the fire and smoke effect used in VR 3D contents. For visualization of forest fire diffusion and forest fuel combustion, first, for visualization of flames and smoke, FGA temperature and smoke (CO, CO_2) concentration data are expressed through particle contrast and lighting effect functions. Second, image change due to forest fuel combustion used the Mesh Decal function as a visualization method with image values created according to the mass reduction rate. Mesh Decal uses the mixed function of semi-transparent Blend Mode and Deffered Decal by updating GBuffer and DBuffer after rendering 3D object surface geometry. In addition, it was configured so that external results such as changes in heat flow of each grid value, wind speed, and wind direction in the UE can be reflected in the impact effect. This is useful for expressing the movement and concentration of smoke in each grid cell differently.

3. Study Results

As a result of expressing the file extracted from the WFDS analysis result as an FGA file with the Unreal Engine, the vector and physical quantity data values such as heat and smoke of each 200,000 grid cells expressed 100% the same value without error even with time series changes. For the visualization of the flame temperature and smoke values for the grid cell, the color and smoke concentration of the flame were adjusted and expressed through the particle contrast and lighting effect on the grid. The results are shown in Figures 1 and 2. The accuracy of the visualization image for the flame intensity and smoke concentration was implemented so that it could be adjusted through the particle lighting function.

4. Conclusions

As a result of this study on the visualization program of VR UE for virtual reality forest fire training, the following conclusions were obtained.

First, the SMV data and the UE visualization program grid value showed 100% agreement with respect to temperature and smoke, which are the calculation results of WFDS.

Second, in the comparison of the displayed images of flame and smoke concentration, there was a difference in visual brightness and contrast.

Third, the difference in the visual effect was developed to be similar to the SMV visualization data by adjusting the color and smoke concentration of the flame through each particle contrast and lighting effect of the 3D UE.

Fourth, through this study, a methodology for visualizing the accuracy of the properties of forest fires for realistic experience among various element technologies of forest fire education and training contents using virtual reality was presented. However, in this study, visualization studies that reflected real-time changing weather conditions were not yet reflected in the study.

In the future, if the development of fire training contents in virtual space, including the development of educational and training evaluation scenarios, along with the results of this research, is made, it will be a more useful and safe learning tool for forest fire extinguishers.

A study on the standard scenario and training evaluation system for the development of virtual forest firefighters training system

Abstract

This study relates to the establishment of a virtual reality training system that can reproduce various forest fire situations in a limited indoor space and evaluate the training results quantitatively for fire suppression and evacuation situations of forest fire extinguishers. For individual and team training of firefighters in a virtual space, it is necessary to create SOP-based various forest fire scenario scenarios and training evaluation tools for the development of virtual training contents S/W. In this study, first, a method for creating a standard scenario for virtual reality forest fire extinguishing training was presented and a standard scenario was presented. Scenarios were standardized to be prepared according to 4 types of forest fire environmental data, 4 types of firefighting environmental data, and training difficulty level. Forest fire environmental data was defined as 4 types of forest fire site spatial environment, forest fuel environment, meteorological environment, and fire environment. It was made possible to set the difficulty level of fire drills using 8 types of scenario configuration data. In the survey on the suitability of firefighters for the standard scenario content, it was found to be 95.8±2.5%. In the second scenario-based training competency evaluation tool, forest fire extinguisher CTA (Cognitive Task Analysis) job analysis was conducted to systemize the evaluation items for task performance, mutual cooperation and reporting system for each scenario staged event. Using the CTA model, job structure analysis was conducted on the professional characteristics, procedural skills, best mission performance, and cognitive process for maximizing the training effect of the firefighters. Based on this, a virtual training evaluation item and evaluation score table for each firefighter according to the scenario-based mission performance stage were prepared. In the evaluation of the suitability of the firefighters for each item's evaluation content and points, it was found to be 93.5±2.5% and 97.5±2.5%, respectively.

1. Introduction

In Korea, training of forest firefighters is generally conducted through theory and experiential learning. Theory learning is representative of the principles of forest fire, fire theory, forest fire spread, forestry and meteorology, command system and role, and case study. The experiential learning includes a program to strengthen individual field response capabilities such as how to use hand tools, how to read a map, and evacuation learning, and group training according to the division of roles for each team. Here, experiential learning has a disadvantage in that it is impossible to conduct firefighting training by actually generating a fire in a forest or outdoors. This study intends to establish a virtual reality experience forest fire extinguishing training system that can reproduce various forest fire situations in virtual reality in a limited physical indoor space and quantitatively evaluate the training results. It has been studied that the learning effect using virtual reality is 10 times higher than that of the theoretical lecture in general, and it is known that the training safety and economic feasibility are high. Therefore, this study intends to provide a basis for the production of virtual reality forest fire extinguishing training contents using the virtual reality standard scenario and training evaluation tool proposed through this study. First, an optimal standard scenario was developed by collecting the opinions of firefighters by creating a scenario necessary for virtual reality training by examining and analyzing past forest fire cases. Next, a tool was developed to evaluate the training process of each firefighter based on a scenario through job analysis of each member of the forest fire fighting team.

2. Methods

2.1. Standard scenario development

The virtual reality training system requires an SOPs-based standard training scenario that can be trained by experiencing rescue and evacuation along with the evolution in various forest fire situations in a virtual space.

In this study, in order to create a standard scenario for virtual reality fire training, events for each forest fire situation were defined in a total of four stages through past forest fire cases. Stage 1 (introduction stage: occurrence and growth of wildfires), stage 2 (deployment stage: establishment and implementation of an extinguishing strategy after arrival at the site), stage 3 (growth stage: types of damage caused by spread and accidents, evacuation and rescue request), the fourth stage (end stage: remained fire monitoring and suppression completed), and the worst-case wildfire scenario for the unpredictable dangerous event was written in the third stage.

The details of the standard scenario created by the entire four-step process were prepared by analyzing the time series work of the evolution firefighters. For the standard scenario prepared, more than 90% conformity was verified by surveying 300 forest fire firefighters.

2.2. Training evaluation tool

The evaluation tool for each individual team for virtual reality training based on standard scenario was performed through field work CTA job analysis of forest firefighters. As shown in Figure 1, for the job analysis procedure, procedural technical analysis according to the professional characteristics and firefighting work of the firefighters and the cognitive process structural analysis to maximize the best performance and efficiency are performed. For evaluation items and score distribution table, more than 90% conformity was verified by surveying 300 forest fire firefighters. The training evaluation table was divided into personal equipment, rescue/evacuation equipment, firefighting activity, and rescue/evacuation activity items according to the task of each team member, and detailed evaluation criteria and evaluation methods and weights were applied.

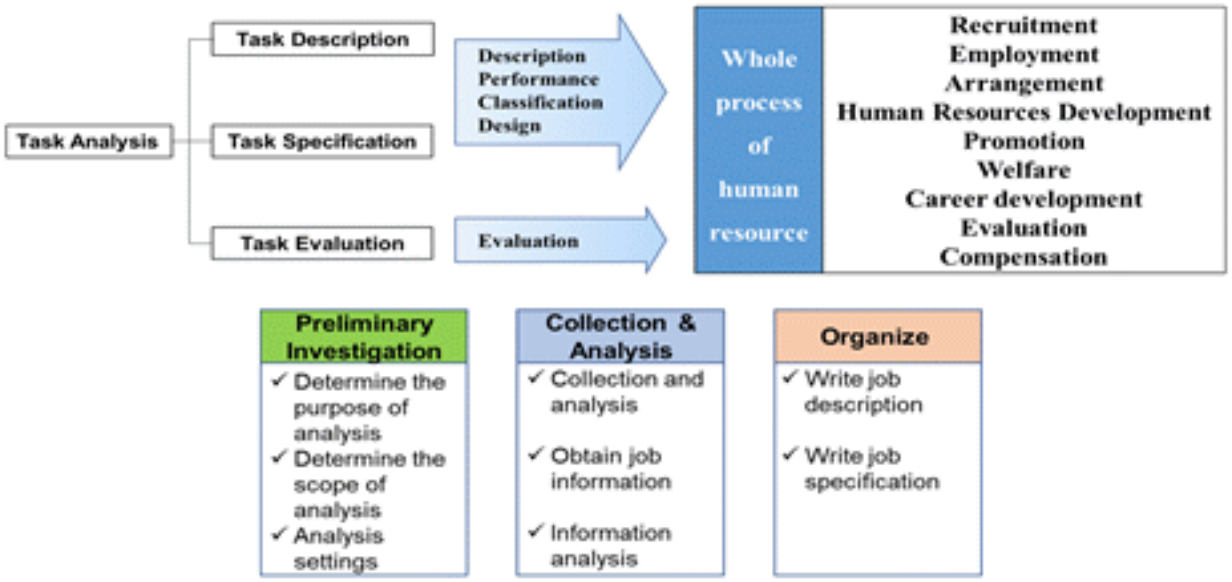

Figure 1- CTA job analysis flow chart and contents

3. Study Results

3.1. Standard scenario

Scenario composition is divided into 4 stages: introduction stage, development stage, growth stage, and termination stage according to the forest fire spread according to the time series. The details are shown in Figure 2.

■ Fire Scenario Composition

S#.	Event	Sub_S#	Contents	Pages
#1	Fire detection and reporting	1	Fire detection and reporting	3~4
#2	Report reception and response	1	Confirmation and Response Preparation	5~6
#3	Arrival at the fire site	1	On-site dispatch	7
#4	Check forest fire situation	5	Fire line, Head fire, Terrain, Weather, Fuels	8
#5	Establish strategy for fire fighting	5	Strategy depends on each fire situaction	8
#6	Start of firefighting work	5	Fire fighting work	9~10
#7	Fire spread growth	3	Crown fire, Spotting Fire, Rapidly fire spread	11~13
#8	Unexpected situation(Spotting, Rolling stone and wood etc.)	5	Observation and congnition, Decision making to work	13~15
#9	Use of fire extinguishing equipments		Proficiency in using the equipment	15~17
#10	Evacuation		Planning, Safety	18~19
#11	Build a fire break line	-	Proficiency in working	20~21
#12	Protected object protection activities		Check for success	22~23
#13	Report to the commander center		Compliance with communication procedures	24
#14	Remaining Embers Management and the end		Check the embers management process	25
Forest Fire Hazard Level 4/5 : Large scale fire spread and damage				

Figure 2- VR training scenario composition for forest firefighters

The scenario details were standardized to be prepared according to 4 types of forest fire environment data, 4 types of firefighting environment data, and training difficulty level. Forest fire environment data is defined as four types of forest fire site spatial environment, forest fuel environment, meteorological environment, and fire environment. It is possible to set the difficulty level of fire drills using a total of 8 types of scenario configuration data. In the survey of firefighters on the training evaluation tool, the suitability evaluation was found to be 95.8±2.5%.

3.2. Training evaluation tool

In this study, evaluation items were classified according to the tasks of each crew member for a team of 10 firefighters in each scenario stage, and the evaluation score was designed to be evaluated as a total score of 100 points through the majority evaluation. The format of the evaluation tool is shown in Figure 3.

Figure 3- Individual virtual reality forest firefighter training evaluation table

A total of 14 evaluation items for each scenario are as follows.

①Whether or not information on forest fire situation is collected and confirmed, ②Establishment and feasibility of firefighting strategy, ③Selection of location for firefighting work, ④Construction of fire line, ⑤Effect of ground firefighting work, ⑥Preparation and use of ground firefighting equipment, ⑦Sudden situation (Spotting fires, Fire Storm, Rolling Stone or wood etc) check and response, ⑧ Use of evacuation equipment, ⑨Secure an evacuation route and a safe place, ⑩Feasibility of evacuation judgment and method, ⑪Arrangement of remaining balance, ⑫Communication by team, ⑬ Report the situation to the command center and make an emergency request, ⑭Protection object protection.

In the survey of firefighters on the training evaluation tool, the suitability evaluation was found to be 97.5±2.5%.

4. Conclusions

The following conclusions were drawn as a result of the study on the scenario writing and training evaluation system, which are the main technologies for the development of the forest fire training system using virtual reality technology.

First, the scenario writing stage through forest fire case analysis was divided into 4 stages, and detailed contents were standardized to be prepared according to 4 types of forest fire environment data, 4 types of firefighting environment data, and training difficulty level.

Second, the evaluation of the suitability of the firefighters for the prepared standard scenario for the virtual forest fire training was found to be effective at 95.8±2.5%.

Third, the evaluation items for each scenario stage through CTA were defined as a total of 14 evaluation items, and a virtual training evaluation system was created with a total of 100 points by assigning different points for each evaluation item.

Fourth, the evaluation of the suitability of the distributed evolution team for the virtual training evaluation tool was found to be effective at 95.8±2.5%.

By using the results of this study on virtual reality scenarios and evaluation tools, virtual reality 3D content work is performed to contribute to the construction of an overall system for individual and team virtual training.

AI-driven Real-time Forecast of Wildfire Development in Hong Kong

Fire Perimeters; Wildfire Forecast; TCNN; Smart Firefighting

Abstract

Climate changes have already altered the wildfire regime and increased the wildfire frequency and severity in Hong Kong. Hong Kong is a typical wildland-urban interface, where small high-population urban areas are surrounded by 70% wildland. Statistics show that the burning areas in over 80 % of accidents are less than 1,000 m2, and the burning time cannot last for 24 hours in Hong Kong. To improve the wildfire response and reduce the life and property loss in fires, a real-time fire forecast is required to achieve the most accurate and real-time fire forecast. This study firstly introduced the development of the wildfire spread models and then reviewed the AI-based model emphatically in the wildfire simulation and prediction. The blank parts in the short time series wildfire prediction aroused the attention of authors. Thus, an AI-based method was proposed to predict the wildfire front in real time. This study currently aims to establish the virtual wildfire scenario database in Hong Kong and realizes the AI-driven wildfire prediction model for suppressing fire spreading.

1. Introduction

Wildfire has been a long-existent phenomenon on Earth. It is an important natural process to consume the fuel accumulation in the wildland. The wildfire happens even without human behaviors interfering. However, with the expansion of human living space, urban cities are gradually occupying the wildlands where human behaviors have a great effect on wildfire, increasing the frequency of wildfires. Simultaneously, wildfire can negatively influence the residents who live in the wildland-urban interface (WUI) (Manzello, 2020). The wildfire is a global natural disaster that is concerned by many countries and regions (Fig. 1). Hong Kong is such a typical city full of wildland-urban interfaces (WUIs), as 70% of its land is covered by woodland, Shrubland, and wetland (Civil Engineering and Development Department Hong Kong, 2014; Warren-Rhodes & Koenig, 2001).Thus, Hong Kong cities are constantly threatened by wildfires. There have been more than 1,000 times wildfire accidents reported per year over the last 10 years, according to the data provided by Fire Service Department in Hong Kong (Hong Kong Fire Services Department - Access to Information, 2021). Thus, it is crucial to control the wildfire in time to prevent the hazard from causing huge damage to the city.

(a) California WUI wildfire in 2018 (b) Australia WUI wildfire in 2019 (c) Hong Kong WUI wildfire in 2019

Figure 1- Global wildfire accidents in (a) the USA, (b)Australia, and (c) Hong Kong, China.

After the occurrence of wildfire, grasping the spreading trends is always one of the most effective strategies in controlling the fire. Therefore, Scholars have been devoted to developing the wildfire spreading prediction tools in the last decades (Fig. 2). Overall, the trends are evolving from statistics-based models to physical-based models. The data acquired from the computation tools are no longer the static burning probability. Instead, the

information turns into the intuitive spreading perimeter to guide the fire scientists to locate the flame front based on mathematical physic-based models.

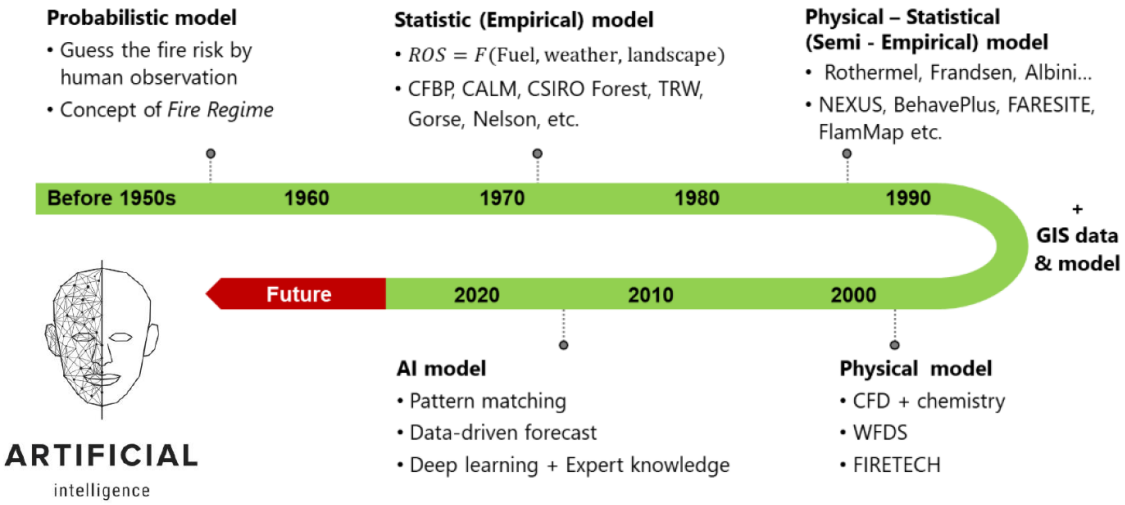

Figure 2- Computational tools for wildfires over the last several decades.

At first, the wildfire spreading models were merely based on static possibility until the empirical models were come up with to transform the likelihood into the statistic question before the 1990s. The turning point was that, according to the empirical models, Finney (1998) developed the FARSITE software to simulate the fire propagation, which was subversive work at that time to make the wildfire visualized in 1998. It combined the GIS data with the statistic data, rendering the prediction convincing. Since the 2000s, a number of numerical methods came out, such as HIGRAD/FIRETEC and Fire Dynamics Simulator (FDS). These numerical methods pay attention to the physical laws of combustion, which make the simulation exquisite but consume a huge amount of time and computation costs.

Gladly, the AI models were proposed to change the way researchers dealt with wildfire spreading. The physical-based computation can be switched into a data-driven matchup in the database. The AI-based models largely decrease the computation time and make real-time prediction possible. In 2019, Hodges (Hodges & Lattimer, 2019) firstly combined FARSITE software with AI algorithms. In his work, he successfully converted the physical-based numerical method into a phenomenological model, which cut the running time when ensuring the prediction accuracy. His job reflected the long-time series wildland fire and the output results were a fire spreading figure in 6 hours. His successful applications in California pave the way for the AI-based wildfire prediction globally.

However, according to the statistics, the burning areas in over 80 % of accidents are less than 1,000 m^2 and the burning time cannot last for 24 hours in Hong Kong. Nevertheless, the short time series real-time wildland fire spreading prediction and local database is blank. There is no current guidance for firefighters, warning them of the wildfire spreading trends. Therefore, it is urgent to make up this field of study in Hong Kong to reduce the danger of wildfire. The real-time wildfire prediction is the basis for the Hong Kong wildland digital twin, which can interact with the firefighters to ensure the city safety.

2. Dataset

FARSITE is widely used by the U.S. Forest Service as an effective tool for simulating the growth of natural fires in wilderness areas (Srivas et al., 2016). It requires an input set that contains different parameters before running the spreading prediction. Due to the lack of real-scenario wildfire data, all the wildfire scenarios are numerical generated by the software FARSITE. It is worth noting that the AI-based algorithm cannot distinguish the difference between numerical simulation results and real-scenario wildfire data, so the model cannot result in huge biases. It is feasible to validate the model in the temporary simulation data. The next action is to replace the original simulation data with real-scenario wildfire data step by step.

FASITE is a mainstream software used by American wildfire researchers. The related input database can be acquired from the Interagency Fuel Treatment Decision Support System (IFTDSS) website. However, it lacks the geography information in Asia. Therefore, it is important to pre-process the local geography parameters to make use of this software in Hong Kong. In this study, the Hong Kong Sunshine Island is chosen as the study area where it is an isolated island in Hong Kong with few species of vegetations. The pixel resolution is 5 m × 5 m, which is much finer than usual 30 m × 30 m.

At the early stage, the software FARSITE is used to add up the dataset. The parameters to be inputted into the software include five compulsory geography information, such as elevation, slope, aspect, fuel model, and canopy cover (Fig. 3). Three optional parameters are stand height, canopy base height, and canopy bulk density respectively to reflect the crown fire. These are the basic information for the wildfire simulation starting. After obtaining all the data, the ignition boundary should be decided. As for the ignition boundary, the ignition locations will start as a point, following the development of a short-time series wildfire. Then the fuel moisture, the temperature, the wind speed, the wind direction, the relative humidity, and cloud cover percentage are required to input, starting the wildfire spreading in the regulated burning periods.

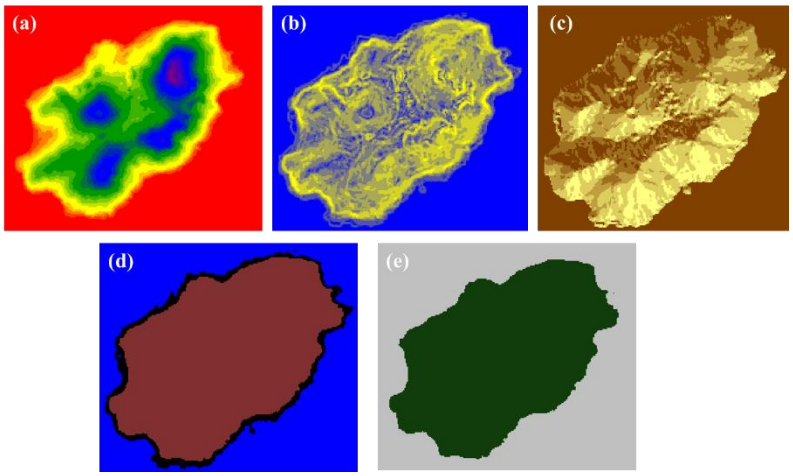

Figure 3- Geography information, (a) elevation, (b) slope, (c) aspect, (d) fuel model, and (e) canopy cover.

To ensure that the dataset has enough data and convincing results, the temperature, the wind speed, the wind direction, the relative humidity, and the cloud cover percentage are seen as five variances to control the simulation results. Because the research area is given and confirmed, while the five parameters in the geography model do not need to change. Likewise, the fuel moisture data is also calculated based on the automatic generation by the software. Once the ignition location is confirmed, the wildfire spreading will get into calculation according to the parameters which is set beforehand.

3. Methodology

3.1. Forward model for spreading simulation

The Rothermel and Albini spread models (Albini, 1985; Rothermel, 1972) were used to calculate the wildfire surface spread rate. In the model, $V_{s,\,peak}$ is calculated according to the following equations:

$$V_{s,peak} = \frac{Q''\zeta}{\rho\epsilon Q_{ig}}(1 + \phi_s + \phi_w) \tag{1}$$

where Q'' is the heat release rate per unit area, ρ is the fuel density, Q_{ig} is the heat of pre-ignition, ζ is the propagating flux ratio (percentage of heat released which pre-ignites fuel), ϵ is the effective heating number (percentage of fuel which is involved in ignition), ϕ_w is the wind coefficient, and ϕ_s is the slope coefficient (Hodges & Lattimer, 2019).

It is widely recognized that the Rothermel and Albini spread models can be applied to predict the wildfire spread perimeter in the peak spreading direction. Therefore, the combined model will be the basis of the spreading model to build the wildfire scenario dataset.

3.2. Forward model for AI-based prediction

The total flow chart of this paper is proposed in Fig. 4. The core of this study is to turn the mathematical spread model into an AI-based algorithm model. The huge difference is that the wildfire front prediction is no longer based on the physical laws proposed by the previous researchers. Instead, the model will find the inner connection among the input parameters to describe the wildfire fronts.

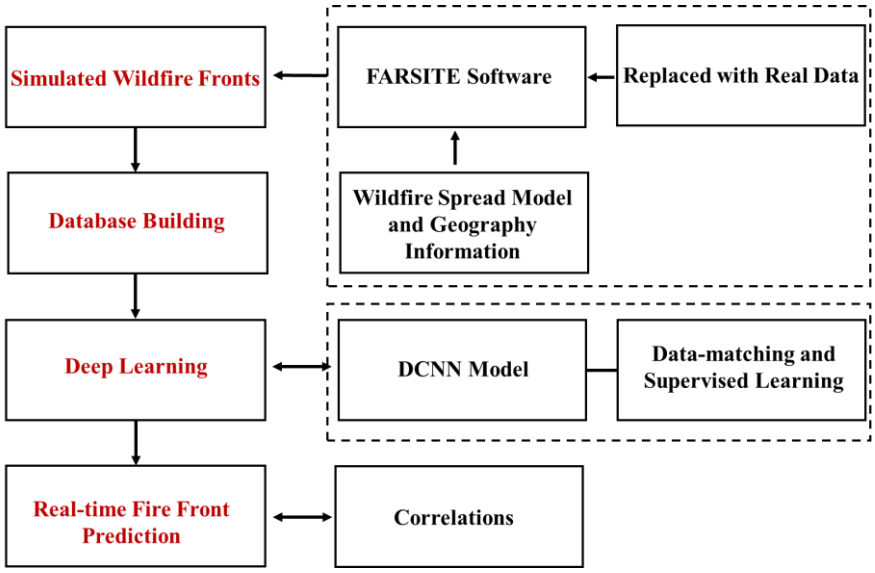

Figure 4- Flow Chart for the AI-based prediction

In order to reasonably find the connection of spreading trends in geo-information, this paper will use Deep Convolutional Neural Network (DCNN) as the basis to build the above-mentioned AI algorithm. The DCNN method (Krizhevsky et al., 2012)consists of many neural network layers. Two different types of layers, convolutional and pooling, are typically alternated. The depth of each filter increases from left to right in the network. The last stage is typically made of one or more fully connected layers (Fig. 5):

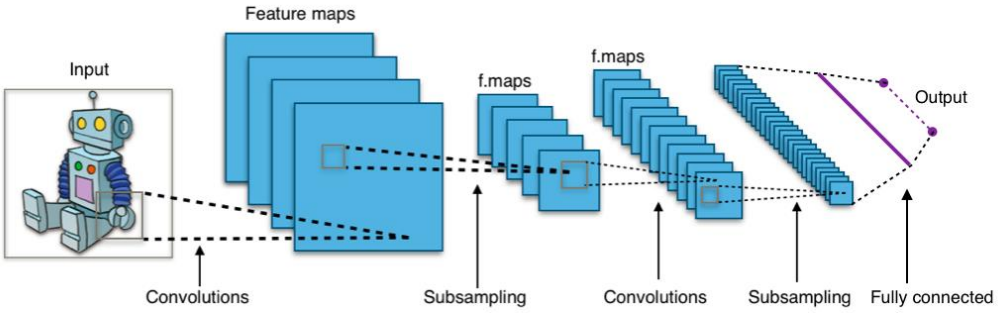

Figure 5- DCNN visualization (Deep Convolutional Neural Network — DCNN | Deep Learning with Keras, n.d.).

The local features of small sub-regions in the images which contain geography information are extracted by neurons, and then the information of these features can be fused into the subsequent processing stage to detect more advanced features such as the probability of fire or spreading trends. Compared with the visual tasks (target detection, classification, segmentation, and motion tracking) in computer vision that involve images with only three color channels as input, the input involved in this paper is more complicated: in addition to basic geographic information, it needs to be added the factors affecting combustion, such as elevation, slope, fuel model, etc. Therefore, the use of mature computer vision DCNN is higher computational cost and poorly robust. For this reason, we have proposed two feasible improvement methods.

First, use a smaller but sparse perception field. In the first layer of DCNN, each convolution kernel is used to connect sub-regions of the picture, and the size of the sub-region is called windows or perceptual field. Traditional visual tasks use overlapping windows to ensure that the convolution kernel can obtain global information. Compared with the computer vision dataset which includes Strenuous sway and changes, the merge of input images has three characteristics: fixed; the field affected by wildfire is limited; the information density of the unified field is large. Therefore, smaller windows can only use the information needed for DCNN learning to associate high-level features. The sparse perception field is to trade off the accuracy and computational cost. As the perception field becomes sparser, the number of convolution kernels that need to be learned will be less, and the weight parameters that need to be updated can usually be reduced exponentially. Although it will bring a loss of accuracy, it is worthwhile for spreading trends tasks that do not require pixel-level accuracy.

Second, partial pooling is performed. The pooling layer in DCNN is used to filter the repetitive and redundant information brought by the convolutional layer. In the images, the information density of the same area under different channels is different. If the same pooling strategy is used for all channels, some of the information in the high-density channel will be lost, while the information of the low-density channel will be retained. Therefore, the DCNN performs small-size pooling on high-density channels (Elevation, Slope, Aspect, Fuel Model, and canopy cover), and large-size pooling on low-density channels (temperature, relative humidity, wind speed, wind direction, and cloud cover).

Besides, the model can be correlated with the updated parameters to realize the data assimilation to some extent. It gets rid of the traditional frameworks that the data cannot be changed during the simulation. In summary, it can be a good reference in the wildfire front prediction in the short-time series wildfire, combined with traditional spread model and geography information using a deep learning method.

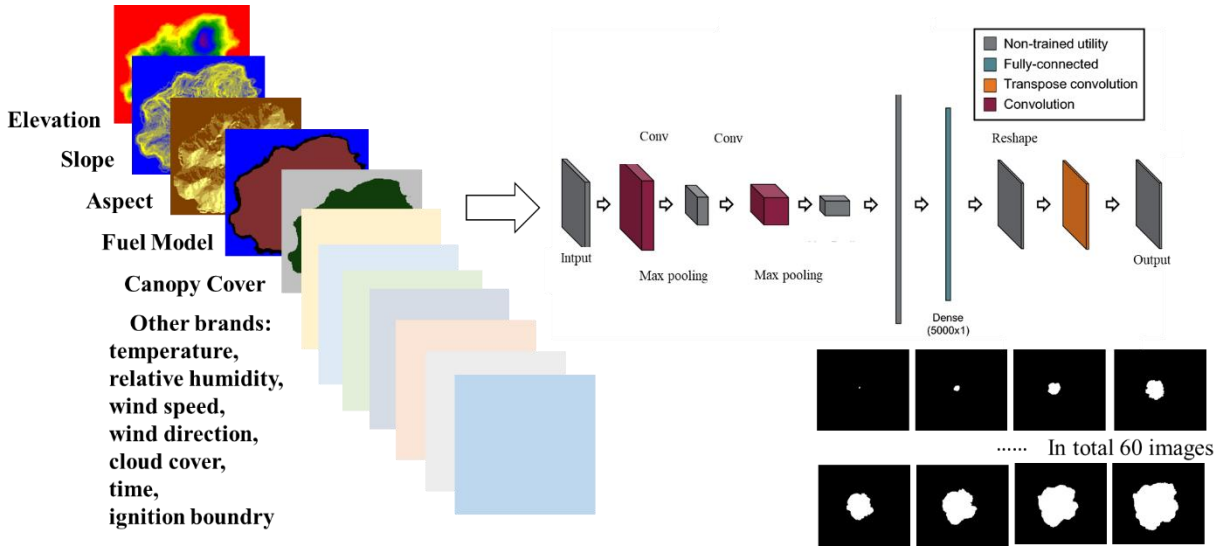

Figure 6- DCNN training model in the paper.

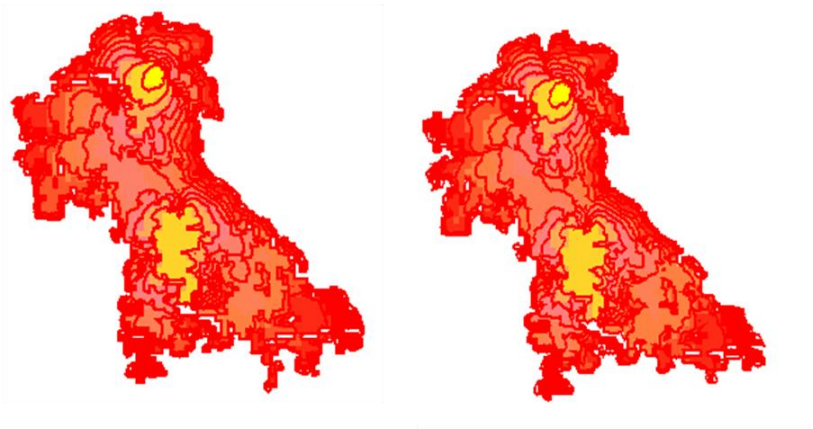
The input images (Tiff format) were 225 × 199 pixels with 12 brands, while 60 output images represent the location of wildfire front with the time step of 5 minutes in five hours (Fig. 6). Six hidden layers are included in the network, including two convolutional, two max pooling, one fully connected classification, and one transpose convolutional layer, which is referred to as Hodges (Hodges & Lattimer, 2019).

The layers in the model made full use of used leaky rectified linear unit (ReLU). The hidden layers in the model are to calculate the pixel possibility whether they need to be colored based on the dataset. In total, the DCNN model works depending on the convolutional layers to form the colored pixel instead of forming the wildfire front according to the traditional spread model.



(a) FARSITE simulation (b) DCNN-based Prediction

Figure 7- Wildfire perimeters in (a) FARSITE simulation, and (b) proposed DCNN-based prediction.

4. Conclusion

This paper firstly introduced the development of the wildfire spread models and then reviewed emphatically the AI-based model in the wildfire simulation and prediction. The blank parts in the short-time series wildfire prediction aroused the attention of authors. Thus, a new AI-based method was proposed to predict the wildfire front in a short time response. This study currently aims to establish the virtual wildfire scenario database in Hong Kong, and realizes the AI-driven wildfire prediction model for suppressing fire spreading. The more detailed analysis and applications of this algorithm will be conducted in the future journal paper.

Decision Support System, Fire Danger indices, Fire behaviour

Abstract

The project OFIDIA2 (Operational FIre Danger preventIon plAtform 2), funded by the Interreg Greece-Italy 2014-2020 Programme, proposed a pragmatic approach to improve the operational capacity of the stakeholders to detect and fight forest wildfires. A data analytics system was designed and implemented within the project to manage, transform, and extract knowledge from heterogenous data sources, through forecasting models such as weather, fire danger, and fire behaviour models, as well as monitoring data from sensors, weather stations, cameras, and drones. Additionally, the project has developed an innovative DSS that provides complete coverage of technical activities to support wildfire hazard management and decision makers in real time.

In this work, we present the OFIDIA2 platform architecture and then we focus on the main findings concerning the component "fire behavior" of the project. Indeed, fires, fuel, topography and weather data were collected from several sources and used to run and calibrate two fire models (FlamMap and Wildfire Analyst) in the project regions. Based on the analyses of recurrent weather conditions leading to large fires, fire metric's maps for prevention and fire-fighting activities were produced. The final information was then included within the DSS to support and improve firefighting and fire management programs.

1. Introduction

Forest fires are a critical problem in Mediterranean regions, especially during summer, threatening ecosystems biodiversity, human life, and high-value assets. High temperatures, strong wind, and low precipitations are the ideal conditions for the occurrence of intense and rapidly spreading fires. In this context, it is of utmost importance to provide fire managers and civil protections with an adequate fire-intelligence system that can provide information to support effective management of wildland fires and decision-making, from the optimization of wildfire prevention and firefighting resources and reducing fire effect impacts on valued resources.

Towards this aim, the project OFIDIA2 (Operational FIre Danger preventIon plAtform 2, https://www.interregofidia.eu/), funded by the Interreg Greece-Italy 2014-2020 Programme, proposed a pragmatic approach to improve the operational capacity of the stakeholders in Apulia (Italy) and Epirus (Greece) regions to detect and fight forest wildfires.

The main goal of OFIDIA2 Project was the development of a software platform for fire danger prevention, able to predict fire risk and danger in case of fire outbreak, based on the constant measurement of several environmental variables detected through appropriate sensors across Apulia and Epirus Regions. The project started in May 2018 and ended in May 2021.

In this short paper, we will present the OFIDIA2 platform architecture and related services (section 2) and then we will focus on the main findings concerning the component "fire behavior" of the project (section 3).

2. OFIDIA2 platform architecture and related services

The project OFIDIA2, based on the results of previous project OFIDIA (Mirto et al., 2015), has implemented a Decision Support System (DSS) for prevention planning and emergency management of forest fire events that incorporates weather data management, fire danger indices, and fire behaviour models, as well as monitoring data from sensors, weather stations, cameras, and drones.

As depicted in Figure 1, the collection, input, storage, management, and analysis of information rely on advanced and automated methodologies using NetCDF (Network Common Data Form) data, digital mapping, and textual data. NetCDF stores multidimensional (variable) scientific data, such as temperature, humidity, pressure, wind speed and direction. The results include i) short-term dynamic fire danger indices developed for improved and realistic prevention and pre-suppression planning; ii) fire behaviour maps to help determine the impact of fire to a considerable extent; iii) an automatic fire detection technology, based on wireless sensors, weather stations, video cameras and drones, successfully tested on several sites.

Additionally, the project has developed an innovative DSS that provides complete coverage of technical activities to support wildfire hazard management and decision makers in real time. The main DSS services are:

- *Forecast Weather maps*: each day an operational chain at the CMCC Supercomputing Center, located in Lecce, produces 72hr forecast data by the WRF meteorological model (Michalakes et al., 2004) with 2x2km resolution. These data are used both for calculating fire danger indices and selecting the fire behaviour maps.
- *Fire Danger indices*: Starting from the WRF data, the maps of three fire danger indices were produced: Canadian, Fosberg and Ichnusa for a time period equal to 72h.
- *Fire Behaviour*: Landscape fire spread and behaviour models have been applied. Two fire simulation models were used for a mean weighted scenario to define the fire weather scenarios and to assess key wildfire characteristics.
- *Dashboard Monitoring*: Regarding sensor monitoring, innovative sensors named Tree Talker Fires send data to a web server every hour. With the same frequency they are downloaded and analyzed at the Supercomputing Center. Data quality and cleaning routines are applied to extract the variables of interest and store them in structured form in the monitoring system. Data are also transferred to the Civil Protection. The variables are displayed in graphs. In the event of an alarm, the system sends an email to the control room manager and commands the cameras to acquire a small piece of video and send it to selected members of the control room.
- *Video cameras*: The system allows monitoring of cameras installed in the forest sites and their geolocation.
- *Historical drone videos*: It is also possible to view the history of the videos acquired with the drones supplied by the Civil Protection.
- *Fleet management*: The fleet management service was born as a support to the group of Civil Protection volunteers. The alarm system implemented in OFIDIA2 allows optimized management of volunteer teams, called teams. Each team is geolocated through our mobile APP. When an alarm occurs, the operator in the control room displays either the single sensor that triggered the alarm or a group of sensors determined by a polygon. Then the operator can see the real position of the teams and select the team that is closest to the site that generated the alarm. Then the system calculates the optimal path that the team must take. The route will be displayed to the team via the mobile App. It is also possible to guarantee the team's interaction with the Control Room operator through a messaging service that remains stored for further analysis.

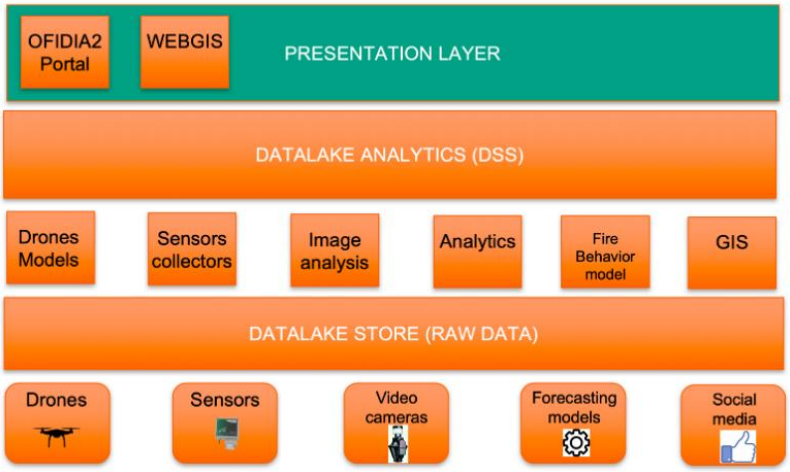

Figure 1- OFIDIA2 architecture

3. Fire behaviour modelling component

In the framework of the "*Fire Behaviour*" DSS service, two fire behaviour modeling tools were run to provide a set of fire behavior characteristics, assessed for a set of fire weather scenarios. This information was then included within the DSS to support and improve firefighting and fire management programs.

3.1. Input data, fire weather scenarios, and fire modelling

We firstly acquired available information on fire ignition for the period 2007-2017 and then the gridded ERA5-Land dataset at 0.1° of resolution through the Copernicus website. A set of multivariate statistical procedures were applied to the database to explore potential associations between fire weather variables and the incidence of large fire events (>100 ha). Clustering technique was applied to weather data looking for groups of observations, evaluating all possible pairs of clusters with the cluster that results in the smallest increase in error sums of squares is used (Everitt and Hothorn, 2011). Thus the parallel coordinate plot (PCP) technique for the visualization of multivariate quantitative data was applied. Finally, to visualize and understand the cluster solution and to highlight an individual observation that represents each cluster, medoids (Kaufman and Rousseeuw, 1990) were calculated to succinctly represent a cluster, also called fire weather scenarios (FWS). Each FWS was made thus of mean wind speed, wind direction, and relative humidity data.To define fuel type and canopy cover layers, the 2012 Corine Land Cover map was reclassified following the methodology in Salis et al. (2013). As a result, 13 fuel types were obtained and associated to the standard or custom fuel models from the original 44 Corine land cover categories present in the study area.

FWS, togheter with information on fire ignition, topography and fuel models, were then used to simulate fire behavior characteristics (e.g., rate of spread, fire intensity, burn probability, fire potential index) through two fire propagation tools, WildFire Analyst (WFA, Monedero et al., 2019; Ramírez et al., 2011) and FlamMap (Finney, 2006). We simulated 36,000 fires (~2 fire per km^2) taking into consideration the historical ignition density of the study area for the period 2007–2017. The simulations were conducted considering constant fuel moisture, wind speed, and wind direction according to the FWS. Fire spread duration was set of 10 h, which is a common average duration of large historical fires in the Mediterranean area. Fire suppression operations as well as barriers to fire spread were not considered.

3.2. Main results

For sake of conciseness, only the results for a mean weighted scenario (i.e. the weighted mean of each single model output according to the relative frequency of each weather scenario) in Apulia region for both simulators WFA and FlamMap are presented here below.

3.2.1. Fire weather scenarios for Apulia region

Analysis of weather data across fire size showed that large fires (>100 ha) mainly occurred under low humidity and high temperatures (Figure 2a). Despite winds from different directions blow in fire days, south west

direction at 15 km hr^{-1} (on average) is one the most common situation in the region (Figure 2b). The cluster analysis revealed four wheatear scenarios in which two have low relative wind speed but contrasting directions whereas the other two have higher wind speed and different directions (north and southwest) (Table 1). Spatial analysis of fire weather scenarios showed that the 1st and 4th clusters (i.e. south west winds) mainly occur in the northern and mid provinces (i.e. Foggia, Barletta-Adria-Trani and Bari). Instead, the other climatic clusters are observed across the Apulia region.

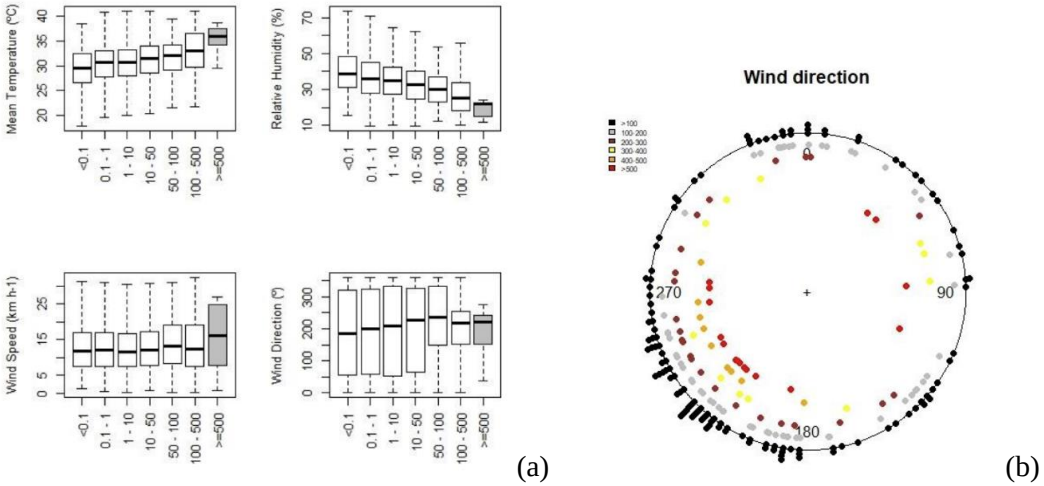

Figure 2 – (a) Distribution of weather variables across fires size categories. (b) Wind direction across fire size categories over 100 ha

Table 1 – FWS according to cluster medoids

Description	*Wind direction (°)*	*Wind speed (km h^{-1})*	*Relative humidity (%)*	*Days (%)*
Sud-ovest calmo	*217*	*6*	*23*	*28*
Est	*72*	*6*	*25*	*19*
Nord	*346*	*18*	*42*	*19*
Sud-ovest forte	*254*	*20*	*19*	*33*

3.2.2. WildFire Analyst simulations

Simulations showed that for all three variables, i.e. flame length, fire intensity and rate of spread, higher values are mainly observed on Foggia, Bari and Taranto provinces. Furthermore, these higher values are mostly observed in the forest protected areas of Gargano, Alta Murgia e Terra delle Gravine (Figure 3). Greatest flame length and fire intensity are projected for shrublands (i.e. maquis) but also in forest of different types whereas fire; rate of spread is projected also higher in maquis and herbaceous vegetation. Fire length and fire intensity are tightly related variables whereas the rate of spread is mostly uncoupled with the previous ones.

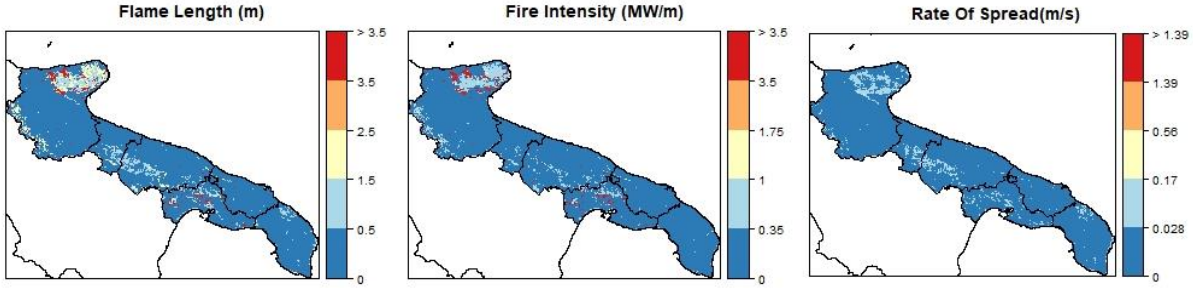

Figure 3 – Flame length (left), fire intensity (center), and rate of spread (right) maps of the Apulia region simulated by WildFire Analyst

3.2.3. FlamMap simulations

FlamMap simulations showed that burning probabilities based on historical fire distribution might be higher in mountain areas of costal Foggia province and along the western axis crossing Barletta-Adria-Trani, Bari and Taranto. Flame length and fire size were also predicted higher over the Gargano in Foggia province. Burn probabilities and fire size showed a quite similar pattern (Figure 4). Based on historical records, burning probabilities, fire size and fire potential index are predicted higher over herbaceous and maquis areas. Instead, conditional flame length might higher in maquis but also in all forest types.

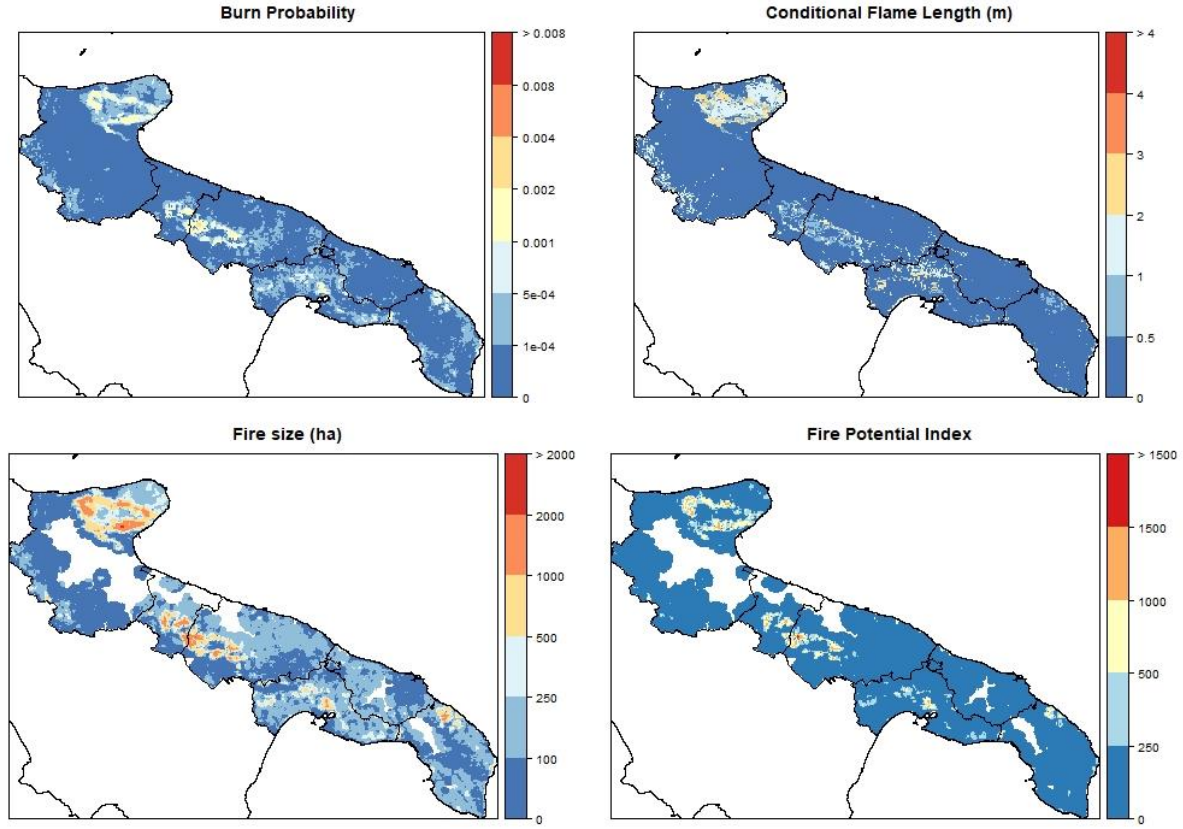

Figure 4 – Burn probability (top left), conditional flame length (top right), fire size (bottom left), and fire potential index (bottom right) maps of the Apulia region simulated by FlamMap

3.3. OFIDIA2 DSS

Finally, fire behaviour characteristic maps for each FWS were imported into OFIDIA2 DSS to allow fast retrieval on user requests. The choice of the FWS depends on the wind speed and direction and relative humidity of that particular day. The variables are request from WRF output. The specific result depends on the definition of the minimum and maximum thresholds (coming from Table 1) that are used to classify a fire day within each FWS. The selected FWS include geotiff images that were imported into a Web GIS (Figure 5). As for the weather forecast of the current day, OFIDIA2 system selects the most appropriate cluster based on the thresholds considered. It is also possible to know the specific value of each variable in the cluster for each latitude and longitude.

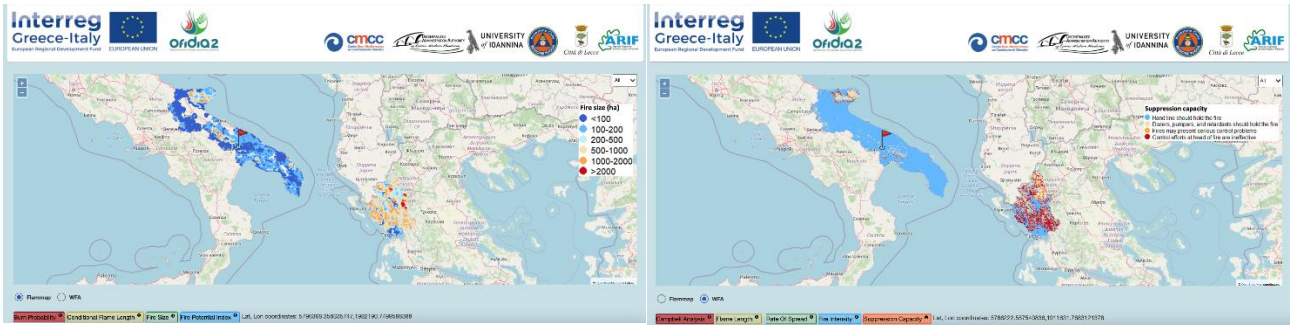

Figure 5 – Examples of the fire behaviour modelling outputs showed by the web GIS of the OFIDIA2 DSS. On the left, fire size calculated by FlamMap; on the right, suppression capacity calculated by WFA.

Abstract

Digital twin, a new concept, which comes from the manufacturing industries, is introduced to different aspects of life. The ever-burgeoning development of digital twin systems lays the path for a new approach to wildfire monitoring and prevention. A real wildfire digital shadow reflects the fire development, providing a promising platform for firefighting decisions. However, currently, static terrain information cannot be integrated with dynamic wildfire locations, which is a great hindrance to the utilization of digital twin systems. The flame trend fails to be mapped in the digital shadow. The key to solving this issue is to ensure real-time data transfer. Thus, UAVs equipped with vision systems could be leveraged to maintain surveillance, transferring the real-time information to the digital twin systems. Initially, the study reviews the UAVs in wildfires. Specifically, the history of UAV tracking is introduced. Furthermore, the autonomous wildfire tracking system is proposed to assist in locating the fire front. A YOLO-based algorithm is utilized to detect the fire front. The UAVs use an orthographic view to locate the wildfire, controlling and maintaining the gesture with a perspective lock on the flame front. Then, UAVs track and follow the flame front without human intervention. In addition, the combination of UAV location information based on GPS and camera view information depicts the wildfire in the digital twin systems. This study aims to act as a pre-processing step for wildfire digital twin data transfer. It will provide a basis for the precise wildfire portrait in the virtual systems.

1. Introduction

1.1. UAVs in wildfire

The usage of unmanned aerial system (UAS) is not really a new concept, particularly in military uses throughout human civilization. An interesting early use of unmanned aerial technologies was the use of hot air balloons during the US Civil War or the installation of cameras in Kites during the Spanish-American War (Manzello, 2020). Yet, there are also historical accounts that pre-date these events by hundreds of years that have used the concept of unnamed aerial technologies for various purposes.

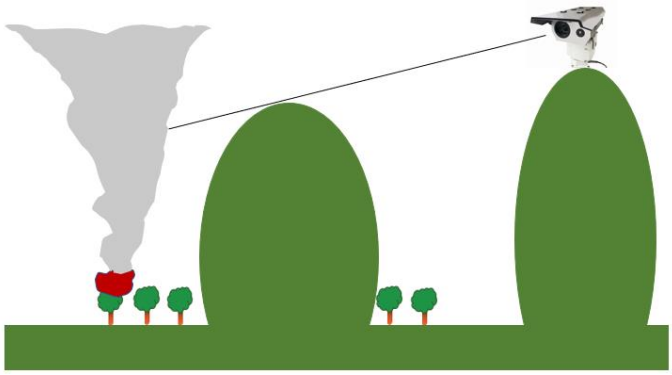

Figure 1- Restrictions of watch towers and fixed cameras installed on mountaintops

In wildland fire detection, monitoring and fighting, a view from higher elevations is desired to gain overall and unique fire information. Compared to a fixed camera network installed on mountain tops and fire watchtowers

(Fig. 1), the airborne monitoring system is more cost-effective and is not limited by the location of the pre-installed infrastructure. Airborne systems usually include high-altitude manned or unmanned aircraft (Allison et al., 2016; Colomina & Molina, 2014) and high-altitude long-duration balloons (Rand, 1994; REGO et al., 2010). As expected, the overall cost of unnamed aircraft and balloons is much lower compared to the manned system. Another important aspect is the risk of having people onboard aircraft during a mission. By using unmanned aircraft, it could avoid putting a crew at risk. Aviation accidents account for 18% of wildland fire fighting fatalities between 2007-2016 (National Wildfire Coordinating Group, 2017). UAVs are undoubtedly one of the most promising technology to ensure the safety of firefighters in wildfires. UAVs can shorten the time of firefighting response and render rescue activities safer, fast er, and more efficient (Khan et al., 2018). It has the ability to access hard-to-reach areas and help gather important data (Reich, 2016). Besides, they can replace the role of helicopters, which may be disturbed by smoke, increasing the risk of pilots in wildfires. The ability to require unmanned control and avoid unnecessary obstacles makes UAVs unique in firefighting. Their safety is not a priority so UAVs could take on more dangerous tasks. The current study about UAV usage in a wildfire is solely about monitoring and putting out fires. Burchan Aydin (Aydin et al., 2019) and his team were entrusted by the fire department of Texas to come up with a fire-distinguishing ball technology and then applied them with UAVs in wildfire fighting. This technology was also utilized to detect and monitor wildfires to reduce false alarms, increasing the efficiency of firefighters (Sudhakar et al., 2020). Since 2021, a platform has been already made use of to manage a number of UAVs in order to spread the liquid on wildland fires (Ausonio et al., 2021). Nowadays, a lot of teams have been focusing on the frameworks of UAV swarms because a single UAV is not enough for a big fire or wildfire so that more UAVs will be applied in the near future (Ausonio et al., 2021; Innocente & Grasso, 2019; Madridano et al., 2021; Roldán-Gómez et al., 2021).

1.2. Digital twin and UAVs

The concept of the digital twin comes from the manufacture industry, and it refers to presenting the real world with virtual methods (Boschert & Rosen, 2016)(Liu et al., 2021), introduced to other industries. Generally, the 3-Dimensional model with real-time data updates is considered as the digital twin/digital shadow, realizing the goal of data assimilation.

The ever-burgeoning development of digital twin systems lays the path for a new approach to wildfire monitoring and prevention. A real wildfire digital shadow reflects the fire development, providing a promising platform for firefighting decisions. However, currently, static terrain information cannot be integrated with dynamic wildfire locations, which is a great hindrance to the utilization of digital twin systems. The digital twin for wildfire is still a terrain model with no updated information. Even when the DJI company launched its newest product in March 2022, Flighthub 2, it simply integrated terrain models with real-time camera information (Fig. 2).

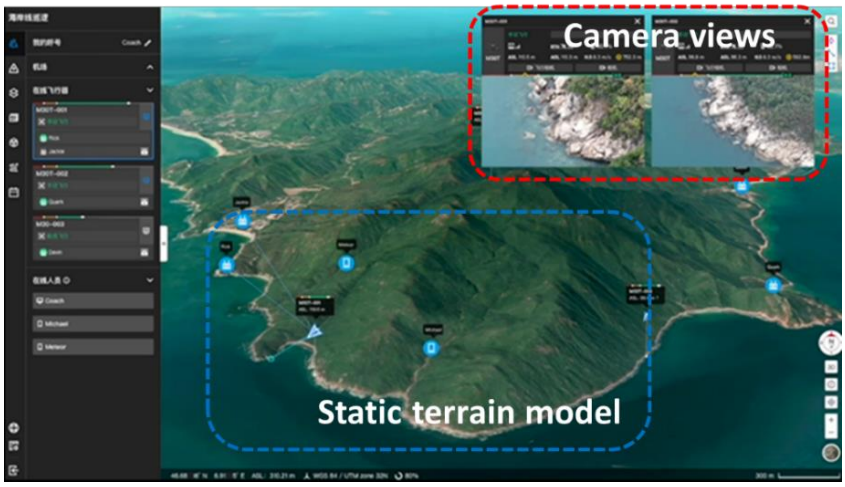

Figure 2- Terrain models integrated with camera views by DJI Company (from DJI FlightHub Website)

The wildfire head fails to be mapped in the digital shadow. The wildfire portrait in the digital twin systems is always a huge difficulty waiting to be solved. The issue lies in the failure of real-time wildfire data transfer. If the fire development trend could be recorded in time. It is possible to depict the wildfire in the digital twin

systems. Gladly, UAVs equipped with vision systems could be leveraged to maintain surveillance, transferring the real-time information to the digital twin systems. However, with the increasing spread of wildfires, it is extremely hard for UAVs to update the geography information of wildfires. Thus, an autonomous wildfire tracking system based on UAVs is proposed to assist in locating the fire front. Since fuels, wind, and other factors resulted in the disordered spreading of wildfire, UAV swarms are utilized to collect information, synchronizing the fire front in the digital twins (Fig. 3).

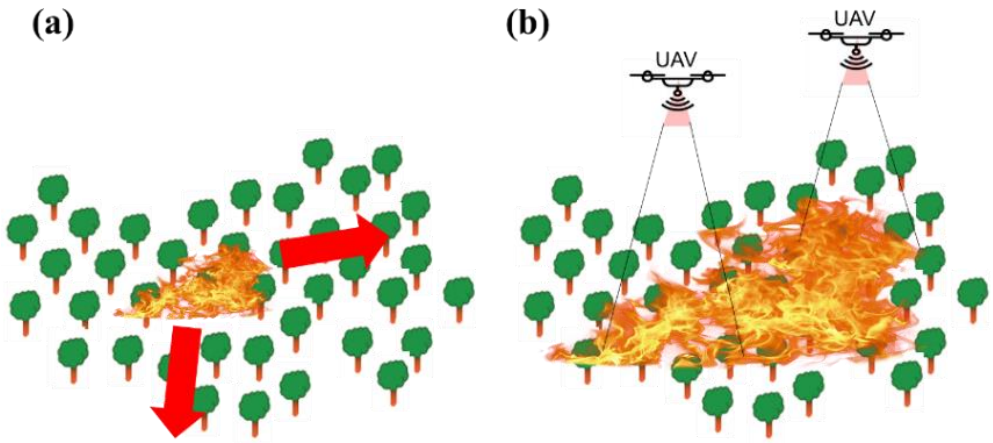

Figure 3- (a) Wildfire spreads following the wind, and (b) UAV follows wildfires in the main directions

The study aims to act as a pre-processing step for wildfire digital twin data transfer. It will provide a basis for the precise wildfire portrait in the virtual systems.

2. Methodology and framework

Object tracking in vision-assisted UAV systems requires three major steps, object detection, object tracking, and relative move of the UAV under control (Lo et al., 2021; Wise & Rysdyk, 2006). The whole structure is shown below (Fig. 4). The UAVs are equipped with both visible and infrared cameras to collect information.

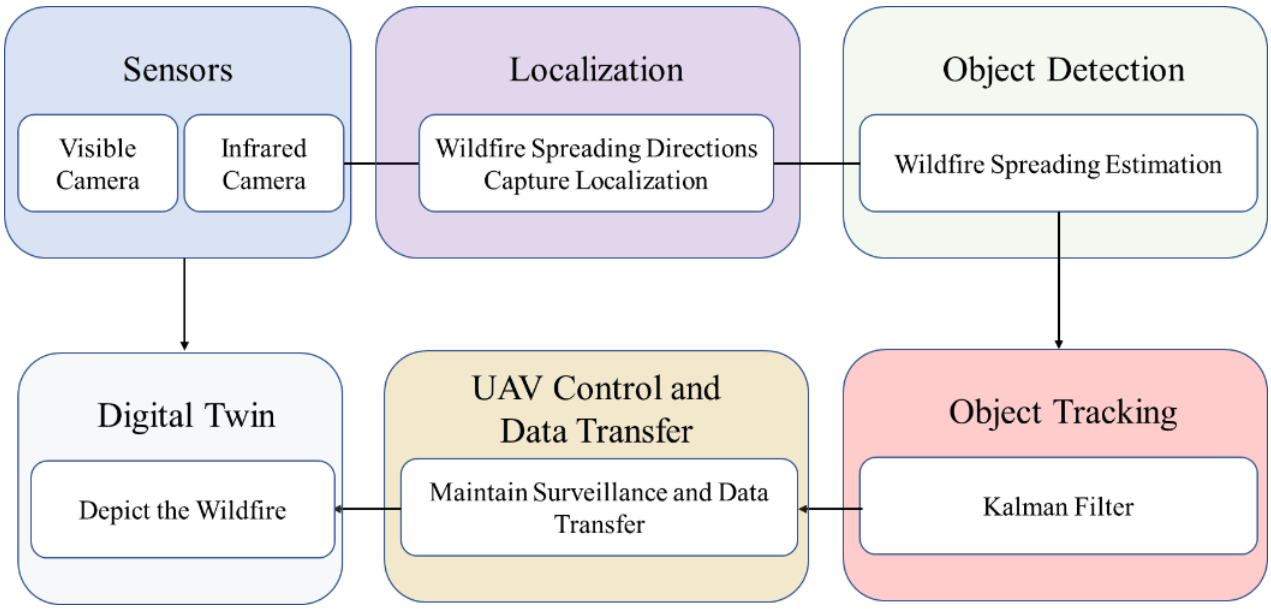

Figure 4- Proposed architecture of autonomous wildfire tracking system

2.1. Fire front detection

Object detection also contains object localization and classification. Compared to traditional algorithms for detecting objects, deep learning-based algorithms have many advantages in robustness, speed, and accuracy. In

this study, a deep learning-based approach has been adopted to detect the wildfire front. It is called You Only Look Once (YOLO), which is a state-of-the-art, real-time object detection system. Many researchers (Lestari et al., 2019; Wu & Zhang, 2018) proved the function of YOLO algorithms in fire detection.

Figure 5- YOLO applied in fire detection (Wu & Zhang, 2018)

2.2. Fire front tracking

Fire front tracking is much more challenging than detection due to faced uncertainties and complexities in aspects. Finally, the Kalman filter method (Welch & Bishop, 1995) was chosen to realize the motion association of object tracking. Compared to normal object detection, the major difference is that fire would spread while UAVs have to follow the wildfire front. To solve this issue, thermal infrared cameras would assist in reducing the uncertainties of flame waves. It conveys the temperature information to the tracking algorithm to ensure a correct path.

Figure 6- Wildfire tracking and UAV moves

2.3. UAV control and data transfer

UAVs are controlled based on the ROS software in the Linux system. Then instructions are programmed into the control commands. In terms of data transfer, the image transmission technology of UAVs themselves can build communication with servers.

2.4. Wildfire portrait

Finally, the combination of UAV location information based on GPS and camera view information could be sent to the virtual systems, promoting to depict of the wildfire fronts in the digital twin systems. The positions on the wildfire front would be updated in time to provide information for wildfire decision makers.

3. Conclusions

In this study, an autonomous wildfire tracking system based on UAV swarms is proposed to assist in locating the fire front. As for this work, we applied the YOLO-v5 object detector and Kalman filter to perform target object tracking. It further proposed an efficient UAV planning to achieve a real-time tracking and autonomous surveillance UAV system. The UAVs use an orthographic view to locate the wildfire, controlling and maintaining the gesture with a perspective lock on the wildfire head. Then, UAVs track and follow the wildfire head without human intervention. In addition, the combination of UAV location information based on GPS and camera view information depicts the wildfire in the digital twin systems. This study aims to act as a pre-processing step for wildfire digital twin data transfer. It will provide a basis for the precise wildfire portrait in the virtual systems.

Wildfire, Remote sensing, dNBR, GEE and Support system.

Abstract

BADE is a support tool for forest researchers and technicians programmed in Google Earth Engine (GEE) platform that serves to detect forest areas that have been burned after a wildland fire, as well as fire severity. It allows the evaluation of vegetation recovery with the visualisation of time series grouped by fire severity and for different spectral indices from which the user can choose. Its use is very simple because of the graphical interface that the user can adjust for a target area of study by selecting the date of the fire, the index to evaluate in the graph and drawing the study area where the dNBR is going to be mapped. Both the map and the graph can be easily downloaded by the user.

1. Introduction

Fire has been a fundamental element in the dynamics of ecosystems in Mediterranean landscapes (Keeley et al. 2012) and for many forest ecosystems, it is the main one (González et al. 2006). These processes were used as a management tool in many rural areas, but the depopulation of these areas in southern Europe during the 20th century has made fires a major environmental problem, as they have become more frequent and more extensive (Pereira et al. 2006). According to data from the European Forest Fire Information System (EFFIS) (http://effis.jrc.ec.europa.eu/), between 2010 and 2019 there were about 19,000 ignitions in Portugal with a burned area of about 140,000 ha. The scenario in Spain during the same period is not much more encouraging, with 12,000 fires burning approximately 123,000 ha in Spain.

After a forest fire, it is necessary to carry out emergency works for the protection of soil and vegetation in the short term and long-term forest management to encourage the recovery of unfavourable areas and the reduction of vegetation in those areas where the fire has been good for recovery (Francos et al., 2016). Planning these types of actions is difficult because covering the entire burned area is costly and time-consuming. Therefore, use is made of remote sensing techniques that assess vegetation recovery by means of spectral indices (White et al. 1996). This is often difficult to apply for untrained technicians in remote sensing applications, who have to carry out a first evaluation followed by forest planning. This is where decision support tools come in to help managers make the right decisions. The objective of this work is to show the creation of the BADE tool, which is an easy-to-use support system for the detection of burned forest areas and that evaluates the recovery of vegetation and is based on remote sensing techniques accessible to everyone.

2. Material and Method

This tool is built on the GEE platform, which allows users to work and download the available large catalog of satellite imagery and other planetary-scale geospatial data. In addition, it allows the use of Google's servers to process and analyse all this information.

GEE allows the use of multiple remote sensing processes with simple steps, which can be replicated and used in other works avoiding repeating long processes. In this way, it makes the work more efficient and avoids human error when repeating the same steps for similar studies.

Such is the power of this platform, that it allows users to create their own applications once they have programmed some processes, and share them with other users who are not so fluent in programming. In this way, advanced users can generate a graphical interface that processes multiple tasks to produce a final result that is the desired result for the creator of the app. For all these reasons, GEE was the solution for the creation of the BADE tool.

2.1. BADE Architecture

BADE is a decision support tool for forest managers who need to detect burnt areas after a wildfire has occurred, along with the severity of the fire and the recovery of the vegetation up to 10 years later. It uses the Landsat mission to work from 1984 to the present day, together with a set of operational processes that can be easily adjusted by the user with its interface to set the survey configuration inputs, such as date of the fire, spectral index to be obtained and region of interest. A map and time series are automatically obtainable and reconfigurable as downloadable results (Fig 1).

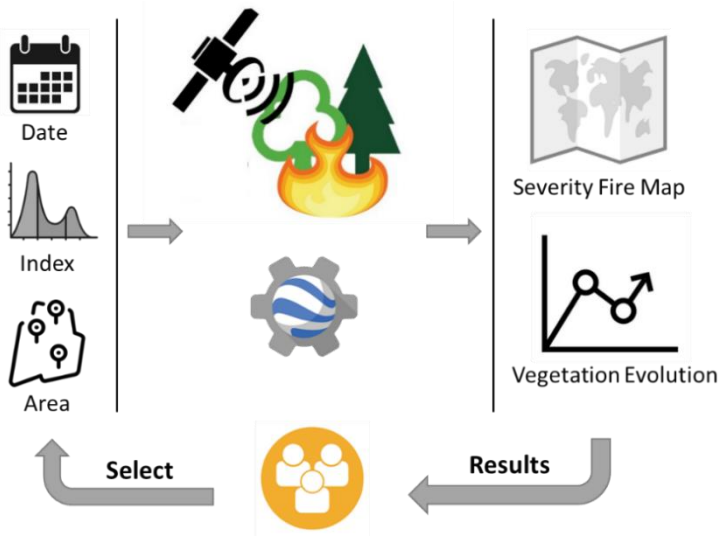

Figure 1: Scheme of the decision support tool, BADE.

BADE performs a large set of geospatial processes in an iterative and replicable way in GEE so that the user obtains its results over and over again each time the process is executed. The steps that this tool continuously performs are as follows:

First, a function is applied to each Landsat mission (5-7-8) that calculates with the spectral bands various indices (Nbr, Ndvi, Msi, Ndii, Rci, Gci, Evi2) for each of the images in each collection, followed by another function that removes to each image the pixels that have clouds or leftovers according to a quality control band that the Landsat images have (pixel_qa). After this, the 3 collections can be combined as a single collection containing the calculated indices and are cloud-free scenes.

Second, is to divide this collection by the date of the fire (that the user enters in the tool) as a pre-fire collection and a post-fire collection; these collections will be used to calculate both the fire severity map and the time series. Therefore, to obtain the severity map to each of these collections, it is filtered by the time span that the user enters to reduce each collection by a similar range. In addition, these collections are filtered one last time by the region of interest that the user draws on the map with the design tools as the region of interest. On these filtered collections, a reduction is generated that converts it into an average pre-fire image and a post-fire image. These images will have the average value of the bands containing the spectral indices. To obtain the burned area, the nbr index is used, which by means of the difference between the scene before and after the fire (dNBR) can calculate the area of vegetation that has changed between the two periods due to the disturbance. The process of generating the dNBR ends with the filtering of the pixels that are considered as loss of vegetation being the value greater than 0.1 and those that are less are masked because they are surfaces that have not been burned.

Third, the image is reclassified into 3 fire severity classes, low, medium and high. Low being those areas where the dNBR value is between 0.1 and 0.25, medium value between 0.25 and 0.5 and high value greater than 0.5, which the user can export as a result in GEOTIFF format. These three classes (low, medium, high severity) are

vectorized to subsequently evaluate their temporal evolution in the recovery of vegetation by the indices. Prior to obtaining these graphs for each severity, these three classes are dissolved to obtain a single vector (fire perimeter) and also those polygons that have small surfaces are filtered to really leave the burned area and eliminate pixels that introduce noise.

Fourth, the three results obtained are mapped in image format, the continuous and masked dNBR, the fire severity classes and the fire perimeter.

Fifth, the time series for each fire severity is calculated for a maximum period of 10 years after the fire, provided that there is information in the Landsat collection. The graph that is generated is the mean value of the pixels within the fire severity polygons and for the dates that there is scene. In addition, the index that the user selects from all the calculated ones is displayed.

Finally, the user can download the results of the image or the graph.

2.2. Workflow

This tool requires very few user steps to display the results. The first step that every user must perform is to delimit the date of the fire that will be analysed. To do this, the user must select the year, month and day of the fire, together with the time span or range before and after the fire that will be used to calculate the dNBR (this step is variable to generate a complete image of the burned area without clouds and therefore with all the pixels) (Fig 2.1). The second thing the user has to do is to select the index to be plotted to see the time series of each severity (Fig 2.2). The third thing to do is to draw the region of interest to filter the Landsat collection to that study area (Fig 2.3). After performing these steps, the results are generated and the 3 layers (continuous dNBR, damage severity classes and fire perimeter) appear in the map viewer (Fig 2.4) which can be downloaded by clicking on the download button (Fig 2.5) and the time series is shown in the blank space (Fig 2.6) which can also be downloaded later.

Figure 2: Parts of the graphical interface of the BADE tool. 1. fire dates; 2. selected index for the time series; 3. draw region of interest where the fire occurred; 4. layers visible on the map; 5. download image of fire severity classes; 6. time series graph of the selected index.

3. Results

The link to use the tool is as follows: https://javierrieju.users.earthengine.app/view/re-forest-fire that to show the results that this tool offers to users, an example of use has been made for a fire that occurred during the summer of 2017 in the municipality of Altura, belonging to the region of Valencia, eastern Spain. Here, we used the date 2017/07/01 and region of interest in rectangle mode on the location of Altura.

It can be seen in Figure 3 how the map has a three-colour image according to the severity of the fire (low, medium, high), along with two other layers which are the perimeter and the continuous dNBR image that can be viewed by selecting them in the layer tab. In addition, the time graph of the selected index is generated, where the average value of each severity class is shown for the years after the fire (Fig. 3).

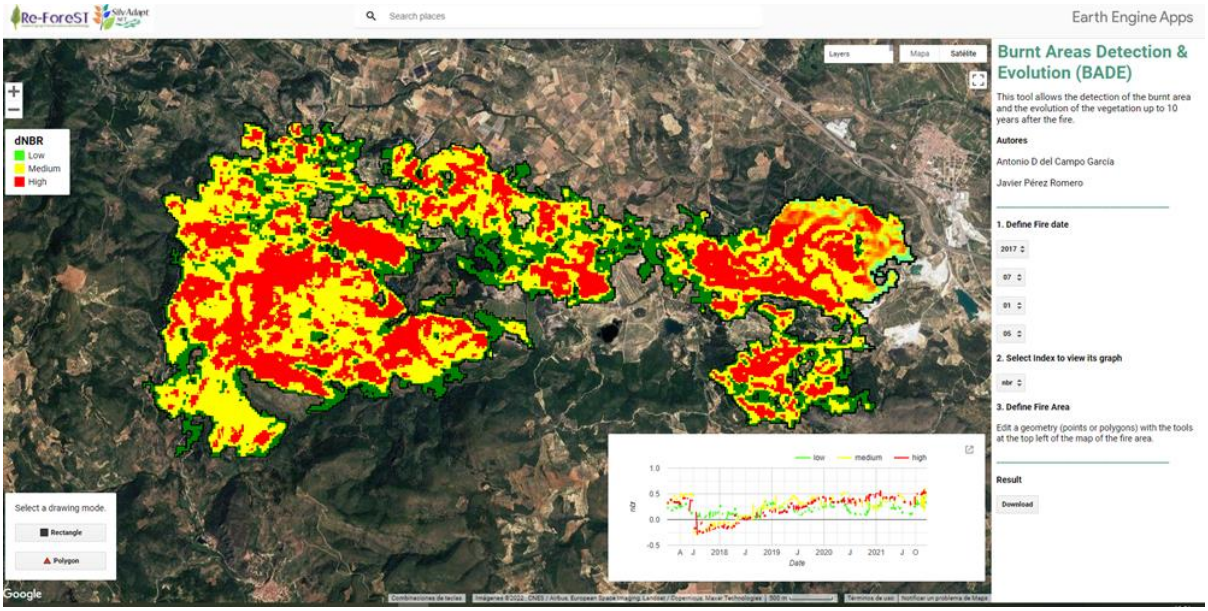

Figure 3: Example execute in BADE tool

These results can be downloaded for use outside the tool. In the first case, the image can be downloaded by clicking on the download button and a new window will open in the explorer for you to choose the directory to save the file in compressed format. The image with the name class_dNBR and the date and time interval set by the user can then be decompressed and is in GEOTIFF format available for use in a GIS (Fig. 4.1).

Finally, you can also download the graph in different formats once you expand it in a new tab. This graph is iterative and the user can consult the values by moving the mouse over the graph. The formats that can be downloaded are CSV, SVG and PNG files (Fig. 4.2).

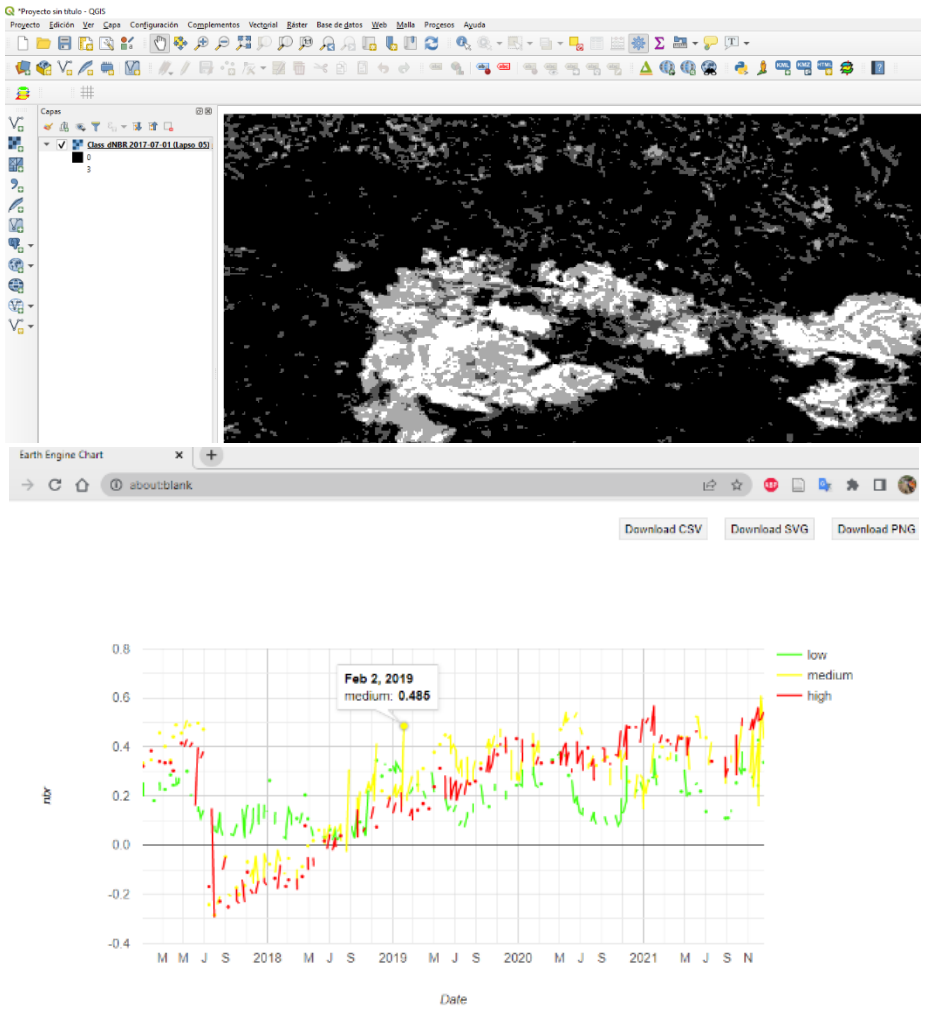

Figure 4: Results provided by BADE tool; 4.1. Map GEOTIFF; 4.2. Iterative Plot.

4. Discussion and Conclusion

The BADE tool allows users to use it easily even if they have no remote sensing experience. Moreover, it is very fast to use and does not require any software or programming knowledge to run it. It simply requires a web browser in which, thanks to its graphical interface, it is easy and intuitive to follow the necessary steps to obtain the results. This makes the tool of great potential for users who are less familiar with computer programs and who work with analysing, assessing or understanding forest fires from three different perspectives. Starting from the technical level, these users can use this support tool to make decisions on forest actions or planning. Then, at the research level, they can use this tool as a method to analyse multiple fires with identical methodologies in order to make meta-analyses or comparisons. At the educational level, this tool allows students to see the potential of remote sensing and new technologies to address the recovery of burned areas.

It is true that BADE needs to continue to incorporate more information for the user to select from all the outputs it generates. These new calculations to be presented and which will be incorporated in future versions will be focused on evaluating with greater precision this evolution, discriminating or differentiating areas with similar characteristics with the help of zonings that consider the physiography of the study area, seeing the trend that the vegetation presents or evaluating how long it takes for burnt areas to reach the pre-fire greenness value. All these improvements will allow managers to evaluate and recognise the study terrain in order to better target the works of action.

Therefore, among the limitations of the current tool are the information on post-fire recovery of vegetation: users know roughly what the average recovery of the entire burned area is like, but there is nothing spatial to help distinguish whether or not, where or when recovery is occurring.

It definitely seems that the tool has the basis to establish itself as a useful tool that should be further developed and complemented so that forest managers who are in contact with fieldwork and that the computer part is a little further away can use it in their daily work. It allows them to know and obtain information on post-fire vegetation quickly and easily without requiring great effort or expertise in remote sensing or programming.

Sentinel, FLEXPART, detection, smoke plume, backtracking

Abstract

Satellite observations are helpful in detecting wildfires. Especially in areas far from populated regions, satellite observations support the identification of wildfires and issuing warnings in case of a developing event. Occurrences of omission and commission errors have decreased significantly over the years, currently used methods focus mainly on improving and refining the already existing algorithms. Combining state-of-the-art earth observation data, specifically data from Sentinel missions, with modelling approaches may contribute to reduce detection errors. Most of the current methods to detect wildfires by earth observations mainly use a single satellite-based data source to retrieve surface information. Sentinel-3 and Sentinel-5P can be used as complementing data sources, the former is able to detect thermal anomalies in the surface, and the latter is capable of detecting direct fire emissions such as CO and HCHO in the atmosphere. The combined use with the Lagrangian particle dispersion model FLEXPART will allow the backtracking of fire emissions plus the aerosol mid height from Sentinel-5P to better identify wildfires sources. For this purpose, so called 'source-receptor sensitivities' are calculated, that provide information on the times and areas potentially contributing to the observed plume. Finally, identified wildfires can be validated using Sentinel-2 images. The innovation of our approach is to combine sentinel observations with atmospheric smoke plume simulations, by applying a dispersion model in backward mode to backtrack the possible source region of the smoke plume.

1. Introduction

During the last decades, there has been an increase in wildfires around the globe (Liu et al., 2010, Jolly et al., 2015). Climate change, with higher temperatures, lower humidity and significant changes in precipitation patterns, is the main factor raising the fire risk. When detecting wildfires by means of satellite instruments, the occurrence of false alarms is unavoidable. Over the last years, major improvements have been achieved to mitigate false alarms. Regarding wildfire detection errors, there are two types: the commission error (a non-existing fire is identified) and omission error (an existing fire is not detected). The former is the known as false alarm. Currently used methods focus mainly on improving algorithms of existing detection methods.

The main goal of this work is to improve the detection of wildfires by using state-of-the-art earth observation data, specifically data from the Sentinel missions, together with modelling approaches in a combined new methodology. This research-based methodology aims at reducing the number of false alarms while exploiting the new Sentinel data.

2. Methodology

The innovation of this work is to combine sentinel observations with atmospheric smoke plume simulations, by applying a dispersion model (with the Lagrarian particle dispersion model FLEXPART) in backward mode to backtrack the possible source region of the smoke plume. If this region coincides with the ground observation of the satellite instrument, it is expected that the detection has been successful. The method consists of exploiting

currently available data from Sentinel-5P (the first Sentinel instrument that observes atmospheric pollutants) combined with the fire confidence derived from the Fire Radiative Power (FRP) from Sentinel-3.

Figure 1 shows the designed work-flow of the methodology. Firstly, a smoke plume is identified with Sentinel-5P data, then the location of the actual fire can be confirmed or rejected by the fire confidence of Sentinel-3. Subsequently, with the dispersion model FLEXPART in backward mode the origin of the smoke plume can be confirmed. In case a high fire confidence is not given for the suspected fire location, the Sentinel 2 can provide evidence of a fire by showing the burned area.

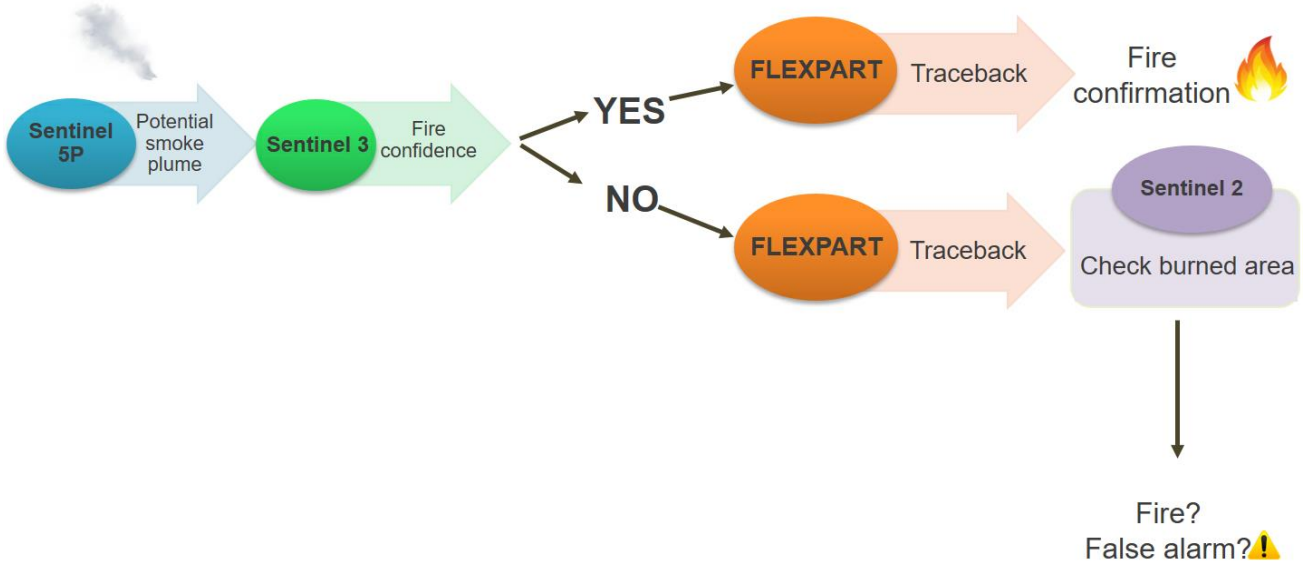

Figure 1. Work-flow including Sentinel-2,-3 and -5P products and dispersion model FLEXPART.

2.1. Sentinel satellites

For the development of this innovative method, the observations from three different Sentinel satellites will be used. Sentinel-5P and -3 provide observations for fire detection, while Sentinel-2 can be used for validation activities.

2.1.1. Sentinel 5P

Sentinel-5 Precursor (Sentinel-5P) is the first Copernicus satellite dedicated to monitor the troposphere, and provides daily global information on concentrations of trace gases (O_3, NO_2, SO_2, HCHO, CHOCHO, CO, CH_4) and aerosols. The mission consists of one satellite carrying the TROPOspheric Monitoring Instrument (TROPOMI) instrument. Its main objective is to perform atmospheric measurements with high spatial resolution (3.5 x 5.5 km), to be used for air quality, ozone and ultraviolet (UV) radiation, and climate monitoring. Because Sentinel-5P observes wildfires emissions (e.g. NO_2, CO, HCHO see figure 9), these observations could potentially be used for the early discovery of wildfires. Once a CO or HCHO plume is selected, in addition, the aerosol layer height product provides the altitude of localized layers of absorbing aerosols in the troposphere for cloud-free conditions.

2.1.2. Sentinel 3

Sentinel-3 has been developed to support ocean, land, atmospheric, emergency, security and cryospheric applications. Its main objective is to measure sea surface topography, sea and land surface temperature, and ocean and land surface colour, with high accuracy and reliability, to support ocean forecasting systems, environmental monitoring and climate monitoring. It carries the SLSTR instrument, a dual-view scanning temperature radiometer, which flies in low Earth orbit (800 - 830 km altitude). There are currently two instruments in orbit, on board the Sentinel-3A and Sentinel-3B satellites. They provide observations across the VIS-to-LWIR spectral range that can be used for active fire detection and FRP retrieval. SLSTR possesses specially designed ‘fire’ channels in the MIR and LWIR, allowing global characterisation of landscape FRP. As stated above, in this work we use the fire confidence derived from FRP, which gives us the information of the probability of a fire pixel.

2.1.3. Sentinel 2

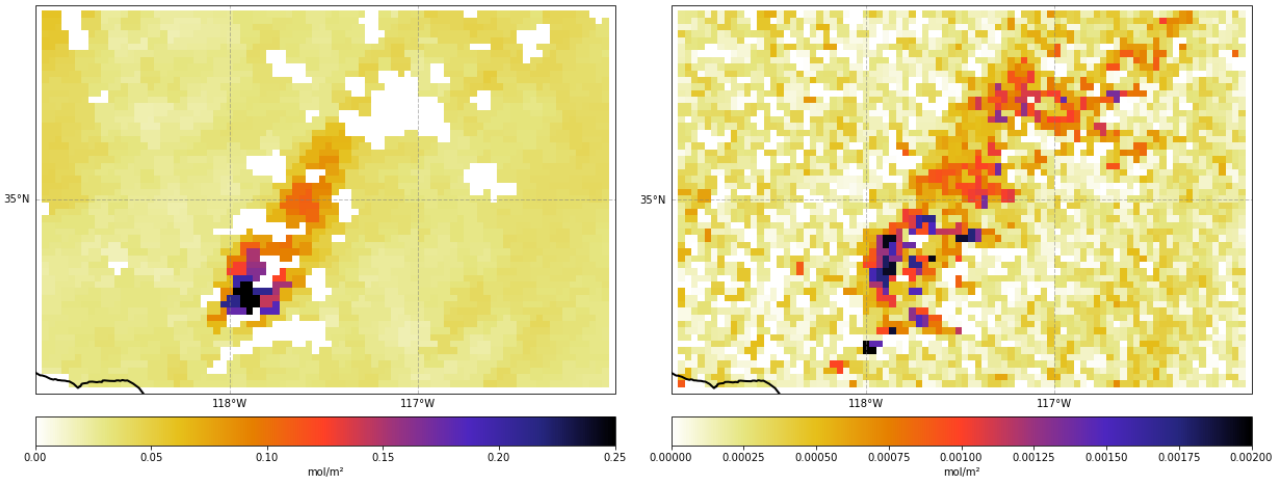
Sentinel-2 consists of two polar-orbiting satellites, and carries an innovative wide swath high-resolution multispectral imager with 13 spectral bands for a new perspective of land and vegetation. The sensor owns one spectral band (band 12, SWIR, 2.190 µm, 20m resolution) that can be used to identify thermal anomalies on the ground. Forest management is included in its main applications. However, using it for validation purposes is not obvious, since it has a long repetition cycle (5 days) and it is difficult to define the fire detection thresholds for SWIR and MIR channels. Therefore, in this work, when available, Sentinel 2 will be used mainly to confirm fires detected by Sentinel 3 and Sentinel 5P and evaluate the accuracy of the method.

2.2. FLEXPART set-up

FLEXPART 10 (Pisso et al., 2019) has been used to simulate the atmospheric transport of wildfire smoke (Pisso et al., 2009, Alvarado et al., 2019 among others), and other types of plumes such as volcanic ash and radionuclides. It can be run in backward mode to provide information on possible source locations. For this purpose, so called 'source-receptor sensitivities' (SRS) are calculated, these provide information on the times and areas potentially contributing to the observed plume. FLEXPART output will also be processed further using a linear regression method. This method is suitable for poorly observed areas, for example, for source apportionment of unusual radionuclides observations, and will here be tested for wildfire plumes. Three selected Sentinel-5P products (CO and HCHO columns and aerosol mid-height) will provide information on plume characteristics needed for the FLEXPART simulations. For this effort, running the backtracking simulations with a tracer is sufficient, while any effort to quantify the sources is out of the scope of this work. FLEXPART will run with meteorological input from the ECMWF fields of the operational stream with a resolution of 0.125°.

3. Results and discussion

Two different test cases will be used from the Californian summer 2020 fire season. To test the developed methodology, the first test case concerns a fire for which observations from all three sentinels will be available. As a second test case, a comission error will be selected: where the Sentinel-3 fire confidence is high, however the combination of Sentinel-5P observations, FLEXPART simulations and, if available, Sentinel 2 data could not provide an estimation of the location of the fire. Here we present the observations of the first test case, where we selected a plume in southern California sensed on the 18th of September 2020. Figure 2 shows the Sentinel-5P CO and HCHO plumes, and in the second row, the Sentinel-5P Aerosol mid-height product and Sentinel 3 Fire confidence are shown.



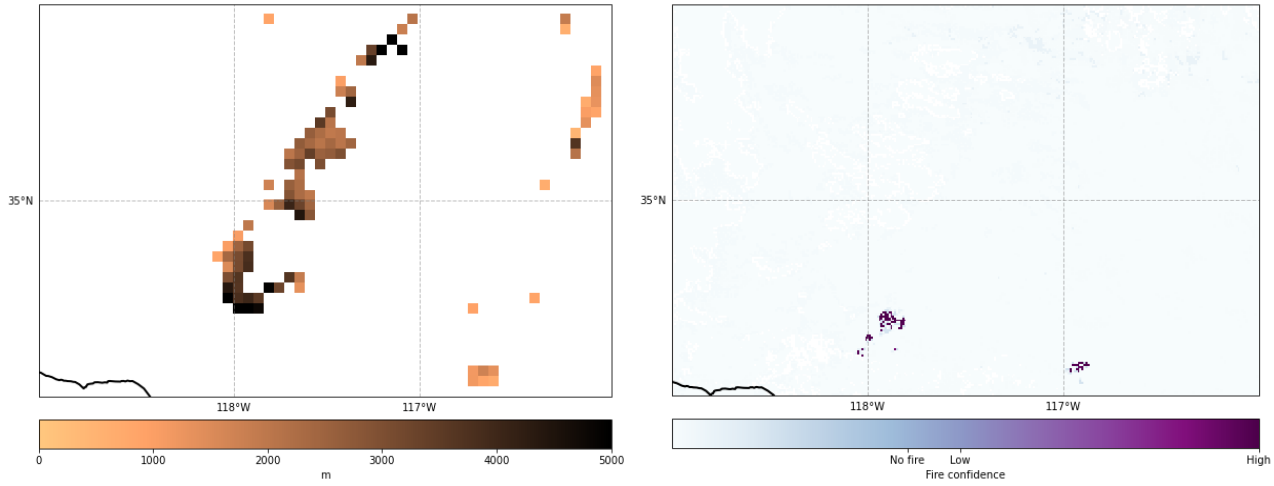


Figure 2. Plots of selected Sentinel satellite products of September 18, 2020. Top left: Sentinel 5P CO column in mol/m^2; Top right: Sentinel 5P HCHO column mol/m^2. Bottom left: Sentinel 5P Aerosol mid-height product in metres; bottom right: Sentinel 3 Fire confidence product derived from FRP.

Subsequently, from the Sentinel-5P products displayed in figure 2, the edges of the CO and HCHO plumes plus the maximum value(s) of the plume will be used as release points in the FLEXPART simulations. Information on the height of the plume will be obtained from the aerosol mid-height product. To evaluate the estimated location of the source of the plume, both the Sentinel-2 images and the Sentinel-3 fire confidence will be used. Finally, the detection is considered successful, if the estimation of the source location coincides with the location identified by the Sentinel-2 images and the Sentinel-3 fire confidence.

The Sentinel-5P CO observations provide relatively clear plume edges, see figure 2, top left, while the HCHO plot (top right) is more noisy yet not interrupted by clouds, hence complementing the CO observations. Circumventing the loss of information due to clouds, can partly abate the disadvantage of long revisiting times, at least of the Sentinel-5P satellite. When successfully tested, our approach paves the way for future applications with Sentinel-4 (launch expected in 2023), which will provide earth observations on a very high temporal resolution (hourly).

The innovation of this work is to combine satellite observations with atmospheric smoke plume observations, and by applying a dispersion model in backward mode to backtrack the possible source region of the smoke plume. To the authors´ knowledge, there are no other studies combining satellite observation and backtracking modelling technique.

Abstract

Fires are not natural phenomena of the Amazon rainforest, therefore, they occur due to human activities, and their occurrences have increased in recent years (Costa et al., 2022). This situation requires continuous monitoring of this vast region, especially in areas where agricultural, livestock, mining, and infrastructure activities are located near protected areas (indigenous lands and nature conservation units). One of the conservation units that has recorded the highest increases in deforestation and fire rates is the Triunfo do Xingu Environmental Protection Area (APA Triunfo do Xingu), which since 2018 has registered the highest rates among other conservation units in the Amazon. The present study aims to develop two databases of burned areas from optical and microwave images for the years 2018, 2019, and 2020 for the APA Triunfo do Xingu using Google Earth Engine; then the results are compared with the DETER, MAPBIOMAS and MCD64A1 burned area bases to estimate existing similarities and divergences. This research uses the images of the Sentinel-2/S-2 and Landsat-8/L-8 optical satellites for the month of August of the years 2018, 2019, and 2020, a period of increased occurrences of active fires in the APA Triunfo do Xingu, to generate the burned area database that will serve as a reference for comparison with other burned area databases. Thus, images with spatial resolution, S-2 with 10 meters and L-8 with 30 meters and spectral (red, near, and medium infrared bands), are suitable for generating information with geometric and thematic quality, as the GEE allows the production of pixel mosaics excluding pixels with cloud and cloud shadows. The Sentinel-1/S-1 images used correspond to the VH cross-polarization, which is the most suitable polarization to map burned area than the VV polarization (Prasasti et al., 2020), having 10 meters of spatial resolution, being with speckle noise filter and with backscatter (DB) values. It is noteworthy that the S-1 images correspond to Band C, the wavelength of 5 cm, which reduces the interference of clouds when imaging the surface. In general, the data sets presented many discrepancies between them, which shows the importance of having a methodology focused on specific areas, such as the Amazon, in order to generate a consolidated information base consistent with the reality of the regime of fire in the studied area. The spatial similarity between the data varied little, with the BA-S1 dataset having the highest overlap rates with the reference base of 19% for 2018, 63% for 2019, and 68% for 2020. Among optical sensor data, the BA-S2L8 datasets for the years 2018 and 2020, and BA-MAPBIOMAS, for the year 2019, presented the highest rates, being, respectively, 13% and 56% for BA -S2L8 and 50% for BA-MAPBIOMAS. We emphasize that the overlaps focused on polygons of burned areas smaller than 6.5 hectares, demonstrating the high spatial similarity between the datasets for small fire areas, despite the BA-MCD64A1 not being the best sensor to detect burns more minor than 100 hectares (Katagis and Gitas, 2022).

1. Introduction

Tropical forests are environments of significant ecological importance, mainly due to their high biodiversity and ecosystem services. However, they have suffered global losses estimated at 420 million hectares since the 1990s (FAO and UNEP, 2020) due to degradation processes and land-use conversion. The Amazon Forest

suffers from this problem, with deforestation and forest fires as the main elements of degradation and transformation of the forest into other uses (Ometto, Aguiar and Martinelli, 2011; dos Reis *et al.*, 2021).

Fires are not natural phenomena of the Amazon rainforest, therefore, they occur due to human activities, and their occurrences have increased in recent years (Costa *et al.*, 2022). This situation requires continuous monitoring of this vast region, especially in areas where agricultural, livestock, mining, and infrastructure activities are located near protected areas (indigenous lands and nature conservation units). One of the conservation units that has recorded the highest increases in deforestation and fire rates is the Triunfo do Xingu Environmental Protection Area (APA Triunfo do Xingu), which since 2018 has registered the highest rates among other conservation units in the Amazon.

The monitoring of fires by remote sensing is performed by recording the brightness temperature to infer high-temperature points that would be active fires (Yao *et al.*, 2020). In addition to registering active fires, mapping the burned area is of great importance for analyzing the fire risk, carbon emissions rates, and the effects of climate change on ecosystems (Liu, Popescu and Malambo, 2019). Although the first study on mapping burned areas was from 1974 and accurately mapped the limits of fire (Hitchcock and Hoffer, 1974) and, in recent decades, produced several data on burned areas on a global scale, such as GLOBCARBON (Plummer *et al.*, 2006), L3JRC (Tansey *et al.*, 2008), Fire_cci (Chuvieco *et al.*, 2018), currently, there is still much uncertainty in the total area affected by fires (Chuvieco *et al.*, 2019) and the products of burned area present many differences between them, which reveals the need for systematic studies on these differences (Humber *et al.*, 2019).

Due to the dense cloud cover that occurs in tropical regions, it is not easy to record phenomena on the surface of these regions. However, a solution is to use optical sensors with high temporal resolution or to use microwave sensors that have a significant ability to cross clouds according to their wavelength. In addition, monitoring large areas, such as Amazon, requires high computing power to process the data, which is currently possible through the Google Earth Engine/GEE platform, enabling access to an extensive collection of remote sensing images.

Thus, the present study aims to develop two databases of burned areas from optical (Sentinel-2 and Landsat-8) and microwave (Sentinel-1) images for the years 2018, 2019, and 2020 at APA Triunfo do Xingu by Google Earth Engine and then compare with the DETER, MAPBIOMAS and MCD64A1 burned area bases to estimate existing similarities and divergences.

2. Materials and Methods

2.1. Study Area

The Triunfo do Xingu Environmental Protection Area was created in 2006 through State Decree 2612 (PARÁ, 2006) with an approximate area of 1,679,280.52 hectares that covers the municipalities of Altamira and São Félix do Xingu. Its objectives are to protect biological diversity, plan the occupation of the territory, and guarantee the sustainable use of its natural resources. However, due to the advancement of farming and livestock activities, there is a growing disorderly occupation and unsustainable use of natural resources through the continuous increase in deforestation and forest degradation by the use of fire. The main economic activity that permeates APATX is cattle ranching, which exerts pressure for the conversion of forest areas into new pasture areas, and this pressure occurs both inside APATX and in the surrounding forests. This situation is reflected in its indication as the conservation unit with the highest rate of deforestation and presence of hotspots over the last few years.

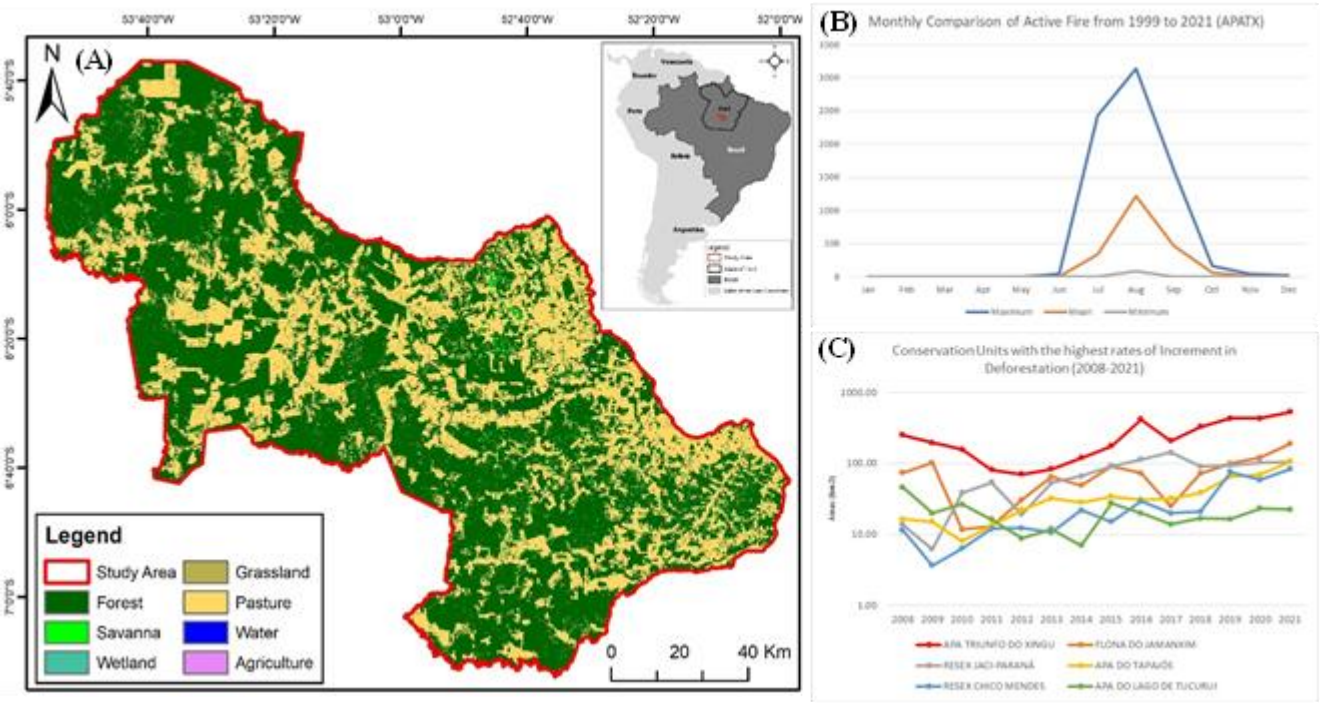

Figure 1- (A) Study Area Location: the APA Triunfo do Xingu located in the southeastern region of the State of Pará/Brazil. Land cover and land use information from the MAPBIOMAS Collection 5 for the year 2020. (B) Monthly comparison of the number of active fires between the years 1999 and 2021 for APATX. Data obtained from the Queimadas Program of INPE/Brazil. (C) Annual comparison of protected areas with the highest deforestation increment rates recorded between 2008 and 2021. Data obtained from the PRODES Program of INPE/Brazil.

2.2. Methodology

The study uses the images of the Sentinel-2/S-2 and Landsat-8/L-8 optical satellites for the month of August of the years 2018, 2019, and 2020, a period of increased occurrences of active fires in the APA Triunfo do Xingu, to generate the burned area database that will serve as a reference for comparison with other burned area databases. Thus, images with spatial resolution, S-2 with 10 meters and L-8 with 30 meters and spectral (red, near, and medium infrared bands) are suitable for generating information with geometric and thematic quality, as the GEE allows the production of pixel mosaics excluding pixels with cloud and cloud shadows.

The Sentinel-1/S-1 images used correspond to the VH cross-polarization, which is the most suitable polarization to map burned area than the VV polarization (Prasasti et al., 2020), having 10 meters of spatial resolution, being with speckle noise filter and with backscatter (DB) values. It is noteworthy that the S-1 images correspond to Band C, the wavelength of 5 cm, which reduces the interference of clouds when imaging the surface.

The processing of the S-2 and L-8 images generated a mosaic of images with minimal presence of clouds and cloud shadows for the month of August of the years 2018, 2019, and 2020. Then, calculate the Burned Area Index (BAI), which highlights pixels with spectral response referring to the absorption of radiation with the biomass burning process. Thus, after identifying the pixels with signs of burning, the image is sliced into determined groups of pixel values and the intersection of the group referring to the burned area with the vectors of active fires obtained from the database of active fires from INPE/Brazil. The intersected pixels are exported as vectors of the burned area class to the GEE database.

The processing of S-1 images starts from the mosaic of images available in each week of the month of August of the year under study. After the mosaic, the change detection processing is performed using the Log-Ratio operator. This logarithmic ratio will highlight the pixels that had a change in values between 2 time periods. Then, I realized the image segmentation process (SNIC), texture index creation (GLCM), and principal component analysis (PCA) to highlight the most significant objects in the images. Subsequently, selected samples for training and classification with the Random Forest classifier. Finally, according to the processing

flow below, intersected the classification results with the active fire data and exported the final result as a burned area database.

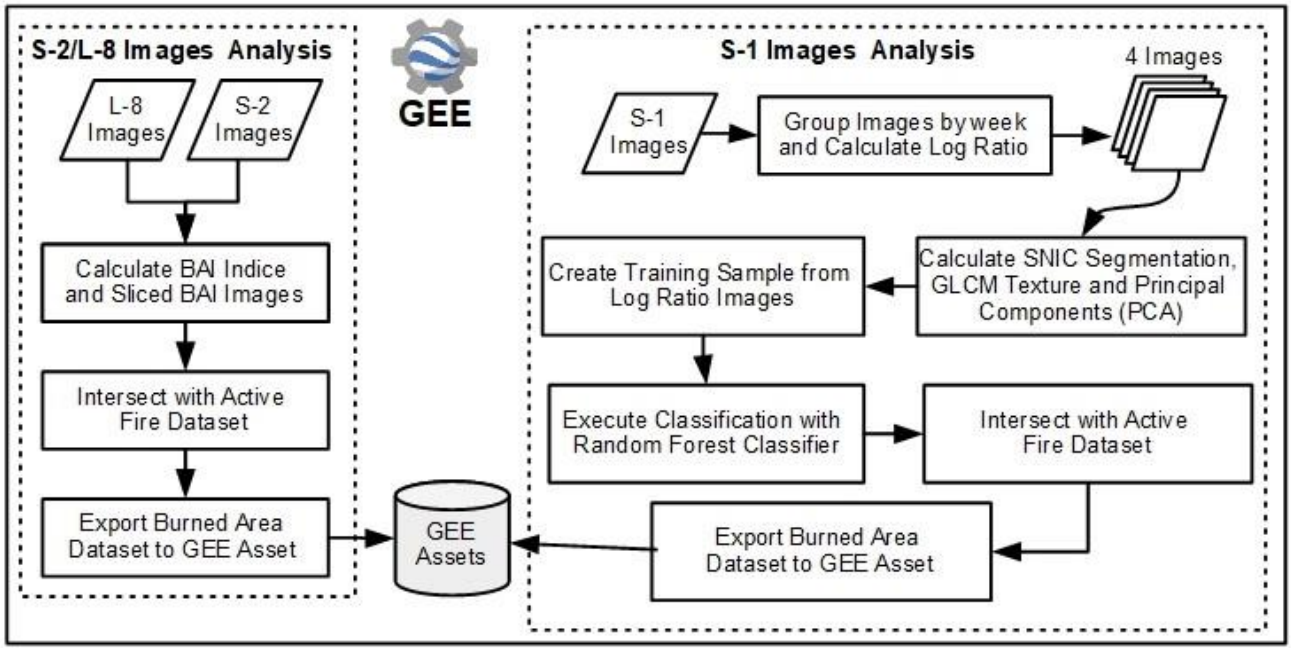

Figure 2 – Images Processing Flow

The burned area data (DETER, MAPBIOMAS, and MCD64A1) are obtained from their electronic addresses and converted into vector shapefile format. It is noteworthy that due to methodological differences between the data, a normalization was carried out with the selection of vectors with a minimum area above 1 hectare. Finally, the comparative analysis evaluated the number of polygons generated in each dataset, their areas, and the overlap rate of the dataset to the reference base, which is the MCD64A1, as the dataset obtained the highest precision for the burned area class at the global level (Padilla *et al.*, 2015).

3. Results and Discussion

The results below demonstrate that for the years 2018, the year with the lowest occurrence of active fires, 2019 and 2020, years that had an increase in active fires, the BA-DETER dataset was the one with the most significant discrepancy in the values of the number of polygons, maximum area and the sum of areas, this is justified because it is a data aimed at alerts and not only to determine the burned area. The reference base (MCD64A1) was different in all the years in the minimum area values, which is due to its spatial resolution being 500 meters. The BA-MAPBIOMAS dataset was the one that had the highest values of the number of polygons in all years, which can be explained by its mapping methodology that operates at the Landsat-8 satellite pixel scale (30 meters). The BA-S1 dataset was the most similar to the reference dataset in terms of maximum area. On the other hand, the BA-S2 dataset was discrepant in all aspects of area in relation to the reference base, which denotes that the difference in spatial resolution has a strong influence on the mapping of the burned area.

Tabela 1- Dataset Area Values

	August 2018 Statistics				
	BA - S2L8	**BA - S1**	**BA - DETER**	**BA - MAPBIOMAS**	**BA - MCD64A1**
Number of Polygons	177	46	4	875	102
Minimum Area	1	1	9	1	24
Maximum Area	2344	189	41	1947	237
Sum of Areas	18537	1048	110	17455	4398
Mean of Areas	105	23	27	20	43

August 2019 Statistics					
	BA - S2L8	**BA - S1**	**BA - DETER**	**BA - MAPBIOMAS**	**BA - MCD64A1**
Number of Polygons	784	1345	153	2048	1861
Minimum Area	1	1	2	1	13
Maximum Area	10066	2375	245	4222	2128
Sum of Areas	152326	36666	4834	69330	93378
Mean of Areas	194	27	32	34	50
August 2020 Statistics					
	BA - S2L8	**BA - S1**	**BA - DETER**	**BA - MAPBIOMAS**	**BA - MCD64A1**
Number of Polygons	772	1471	229	4783	2045
Minimum Area	1	1	1	1	7
Maximum Area	16214	1949	723	3125	1986
Sum of Areas	120419	37585	13877	85217	125222
Mean of Areas	156	26	61	18	61

In general, the data sets presented many discrepancies between them, which shows the importance of having a methodology focused on specific areas, such as the Amazon, in order to generate a consolidated information base consistent with the reality of the regime of fire in the studied area.

The spatial similarity between the data varied little, with the BA-S1 dataset having the highest overlap rates with the reference base of 19% for 2018, 63% for 2019, and 68% for 2020. Among optical sensor data, the BA-S2L8 datasets for the years 2018 and 2020, and BA-MAPBIOMAS, for the year 2019, presented the highest rates, being, respectively, 13% and 56% for BA -S2L8 and 50% for BA-MAPBIOMAS. We emphasize that the overlaps focused on polygons of burned areas smaller than 6.5 hectares, demonstrating the high spatial similarity between the datasets for small fire areas, despite the BA-MCD64A1 not being the best sensor to detect burns more minor than 100 hectares (Katagis and Gitas, 2022).

4. Conclusions

Wildfires are human source phenomena that are present and growing in several areas of the Amazon, being more recurrent in environments naturally prone to fire, such as the cerrado, and areas of expansion of productive activities, mainly livestock and commercial agriculture. The APA Triunfo do Xingu is affected by this dynamic of growth of productive activities and the problems inherent to them, such as deforestation and fires.

The mapping of burned areas in the Amazon still faces many obstacles, especially the limitation of optical sensors in the observing regions with a strong incidence of clouds and the lack of monitoring of the region that uses microwave images, which reduce the problem of limitations of the clouds.

Despite some datasets of burned areas facing the Amazon, there is still a lot of disagreement in the values of burned areas and little spatial similarity between the datasets since we found between 50% and 64% of overlap between some datasets and the reference base. New studies covering longer time intervals and areas with different fire regimes and land use are essential to understanding the limitations that affect the mapping of burned areas. From 2018, the increase in fires inside the APA began, and this problem has worsened since then. Thus, it is of great importance to search for new approaches that allow improving the continuous monitoring of the Amazon, with a focus on deforestation and recording areas burned by fires.

Wildland fire, WFDS Level-set, static wind field, two-way coupling.

Abstract

Operational wildland fire propagation models are typically uncoupled from the wind field or they rely either on estimations extracted from an atmospheric model or on meteorological observations. This leads to a frozen wind field (one-way coupling) with a high degree of uncertainty, thus drifting away from the ground truth. In contrast, fully-coupled models (two-way coupling) comprise more accurate representations of the real phenomena, although they are not viable for operational use due to the hefty computational effort they entail. This article investigates and compares the effects of one-way and two-way wind-fire coupling on the predicted propagation of wildfires. The models are validated against experimental data obtained from grassland experiments carried out by the Commonwealth Scientific and Industrial Research Organisation (CSIRO) in Australia. Simulations are carried out on a flat surface and for different wind speeds. Two scenarious are considered, one with and the other without an obstactle affecting both the wind flow and the wildfire propagation. Results from the simulations indicate that the burnt area and the rate of spread (RoS) are both smaller in two-way coupled than in one-way coupled models.

1. Introduction

Wildfire propagation modelling is remarkably challenging due to the complexity that results from its multi-physics and multiscale characteristics (Grasso and Innocente 2020). Chemical energy is converted into thermal energy during combustion as a result of a high-temperature (exothermic) chemical reaction between a fuel and oxygen. This energy is then transferred to the surrounding unburnt fuel, which ignites if a sufficiently high temperature is reached (ignition temperature). Whilst combustion is a chemical phenomenon, energy transfer is a physics phenomenon that occurs on domains ranging from millimetres to kilometres (Sullivan 2009a). Sullivan classified techniques for modelling wildland fire spread into three categories: *physical models* (Sullivan 2009a), *empirical models* (Sullivan 2009b), and *mathematical analogue models* (Sullivan 2009c). In turn, Innocente and Grasso (2019) classified wildfire propagation models into *theoretical models* (mechanistic, possibly physics-based), *data-driven models* (constructed from or fitted to actual or synthetic data), and *mechanistic surrogate models* (mechanisms not directly related to the phenomena being modelled).

A forest fire substantially affects the wind patterns in the immediate area. Rather than regular wind patterns, localised flow structures are generated by the interaction of atmospheric wind and the convection caused by the flaming combustion front. Thus, precisely forecasting fluctuations in wind velocity components produced by the presence of the fire in the boundary layer around its location is critical for effective fire behaviour prediction (Lopes et al., 2017). Several physics-based models such as FIRETEC (Linn et al. 2002), WFDS (Mell et al. 2007), CAWFE (Clark et al. 1996a; Clark et al. 1996b), WRF-FIRE, ForeFire/Mesho-NH (Filippi et al. 2010), and others have been developed and utilised to model wildfire propagation at various scales. However, these models have not been used within operational settings (Marino et al., 2012; Lopes et al., 2017) due to the computational resources required and the resulting slower-than-real-time simulations. Conversely, operational models such as FARSITE (Finney 1996) produce fast simulations at the expense of removing or weakening their links to the laws that govern the underlying physics. These are characteristically data-driven or mechanistic surrogate models, which only provide information on the propagation of fire lines. Furthermore, they are usually

decoupled from or partially coupled with atmospheric models and therefore do not capture the effect of complex wind patterns on the fire dynamics (Bakhshaii and Johnson 2019). They simulate fire propagation using inputs from an atmospheric model and/or meteorological observations resulting in a frozen wind field unaffected by the fire (Bakhshaii and Johnson 2019). These static wind fields are typically calculated by diagnostic models such as WindNinja (Wagenbrenner et al. 2016) and Nuatmos (Ross et al. 1988). The immediate effect of using these models is an increase in the uncertainty of their output (Bakhshaii and Johnson 2019). A more recent study on the effect of two-way fire-wind coupling in (Lopes et al. 2017) suggests that this results in a significantly smaller burnt area than the one obtained with one-way coupled simulations. Later, Lopes et al. (2019) performed simulations with one-way and two-way coupling and reported that, even though both models over predict the fire area, two-way coupling performs better and provides values which are closer to the real data.

To the best of the authors' knowledge, limited research has focused on the effect of one-way and two-way fire-wind coupling on the simulated propagation of wildfires. Since this may differ depending on the combination of fuel, wind and topography, this paper is limited to flat lands covered with short grass. Two scenarios are considered, one with and the other without obstacles to the wind flow and wildfire propagation, aiming to investigate the effect of the formation of complex wind patterns. Simulations are performed using the WFDS level set model for point fire ignition in both two-way and one-way coupled conditions, and results are compared at different times from ignition.

2. WFDS Level-set method

An extension of the structural Fire Dynamics Simulator (FDS) for vegetative fuels developed by the National Institute of Standards and Technology (NIST) in the United States is the so-called Wildland-Urban Interface Fire Dynamics Simulator (WFDS). The governing equations for buoyant flow, heat transfer, combustion, and the thermal degradation of vegetative fuels are solved using computational fluid dynamics techniques. Solving gas-phase equations on computational grids that are too coarse to directly resolve precise physical events requires large-eddy simulations (LES). WFDS offers three models for simulation of wildland fires, including (1) particle mode, (2) boundary fuel model, and (3) level set method. The *Particle Mode* and the *Boundary Fuel Model* rely on physical principles and may employ grid resolutions as fine as 1 m in their basic implementations (Vanella et al. 2021). They require the thermo-physical parameters of the vegetative fuels whilst they calculate the fire rate of spread (RoS). Conversely, the propagation of the fire front in surface wildfires is modelled based on empirical principles only in the *Level Set Method*. A model for vegetation deterioration is not included, and the no-wind no-slope fire rate of spread (RoS_0) for various kinds of vegetation and wind speeds must be set (Vanella et al., 2021). Variations in the way wind and fire interactions are modelled allow for more than one version of this method. In this paper, we adopt the *Level Set Method* due to its capability of carrying out simulations with both one-way and two-way fire-wind coupling.

3. Results and Discussion

3.1. Validation of results

Simulation results are compared to experimental data obtained from grassland experiments carried out by the Commonwealth Scientific and Industrial Research Organisation (CSIRO) in Australia (Cheney et al., 1998). The selected experiment is the C064, which was performed in the midlle of summer with fully dried kerosene grass on a 100×100 m^2 field with wind gusts of 4.6 m/s, grass height of 0.21 m, and a measured RoS of 1.2 m/s.

For the validation of the two-way coupled model, the class 1 Albini fuel models is used with some modifications, including the height changed from 0.3 m to 0.21 m and and Surface Area to Volume Ratio changed form 11500 to 9770. The resulting fire front position for three different mesh sizes of 1, 3 and 5 m is presented in figure 1, which shows that the *Level Set Method* underpredicts the fire propagation when compared to experimental data. Besides, reducing the mesh size appears to decrease the RoS of the simulated fire.

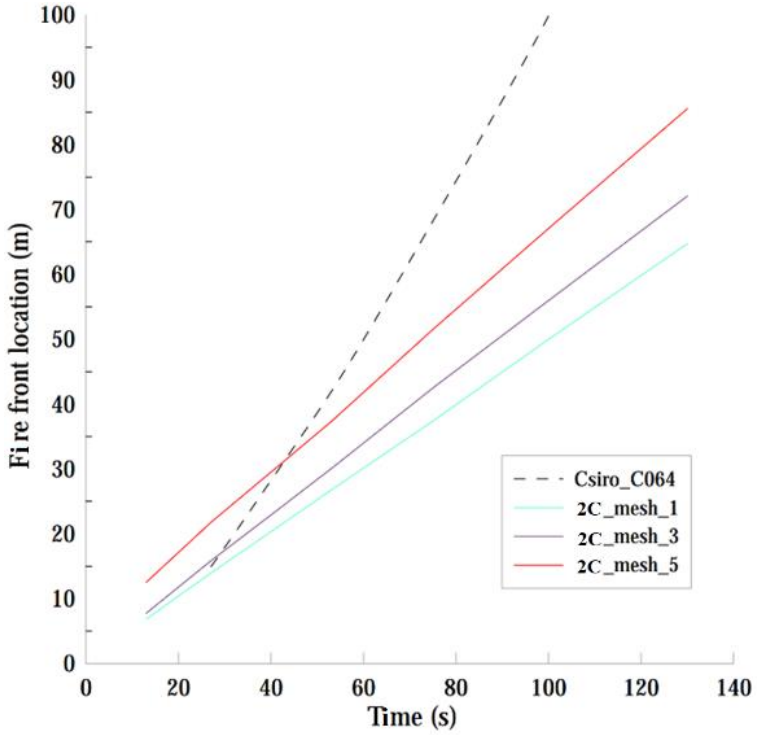

Figure 1- Comparison of fire front position with experimental data of CSIRO-C064 for different mesh sizes.

3.2. Simulations results

The WFDS *Level Set Method* in its two modes, namely one-way (1C) and two-way (2C) fire-wind coupling, is utilised to perform simulations under different conditions to assess the effect of the type of coupling on the prediction of the wildfire propagation. Fire simulations are performed in a 100×100×20 m^3 (x,y,z) domain with a uniform mesh size of 1×1×1 m^3. This results in 100 cells in the x-, 100 cells in the y-, and 20 cells in the z-direction. The fuel is modelled by the type 1 Rothermel-Albini fuel model called "short grass", with a fuel depth of 0.3 m and no-wind no-slope RoS_0 = 0.03 m/s (McGrattan et al. 2019). Fire is ignited at the centre of the fuel area after the wind field has developed. The first mode consists of using a frozen wind field, which is the one developed by the time the fire is ignited. The wind field remains constant for the duration of the simulation. The second mode is a fully coupled simulation, in which the wind is affected by the fire latent heat as it propagates. Figure (2) presents the burnt area 100 s after the fire is ignited, over plain vegetation, for four wind speeds between 1 m/s and 10 m/s, and for both coupling modes: figures (a-d) for one-way coupling or static wind field (1C), and figures (e-h) for two-way coupling or dynamic-wind field (2C). Figure (3) shows the same but in the presence of an obstacle to study the effect of the formation of complex wind structures on the fire propagation.

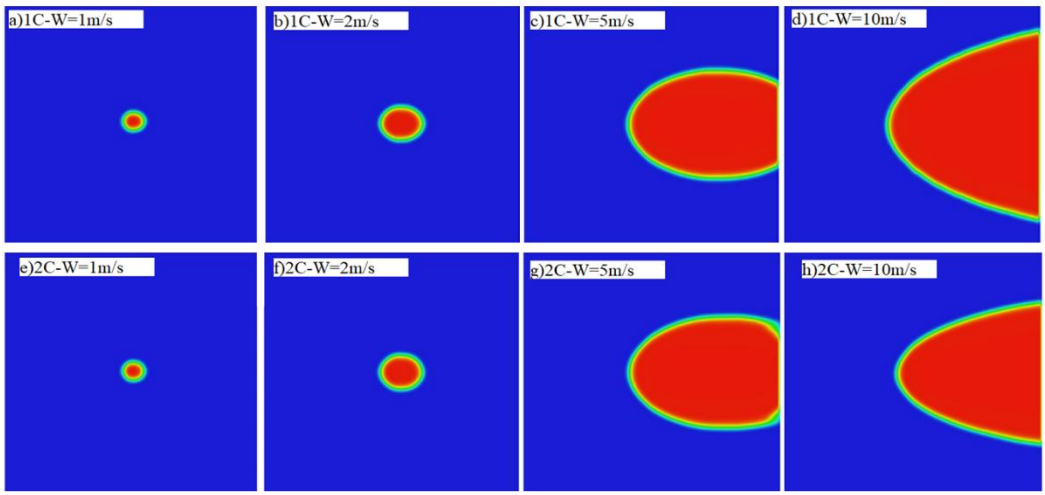

Figure 2- Burnt area at plain surface vegetation in one-way coupling (1C) and two-way coupling (2C) modes.

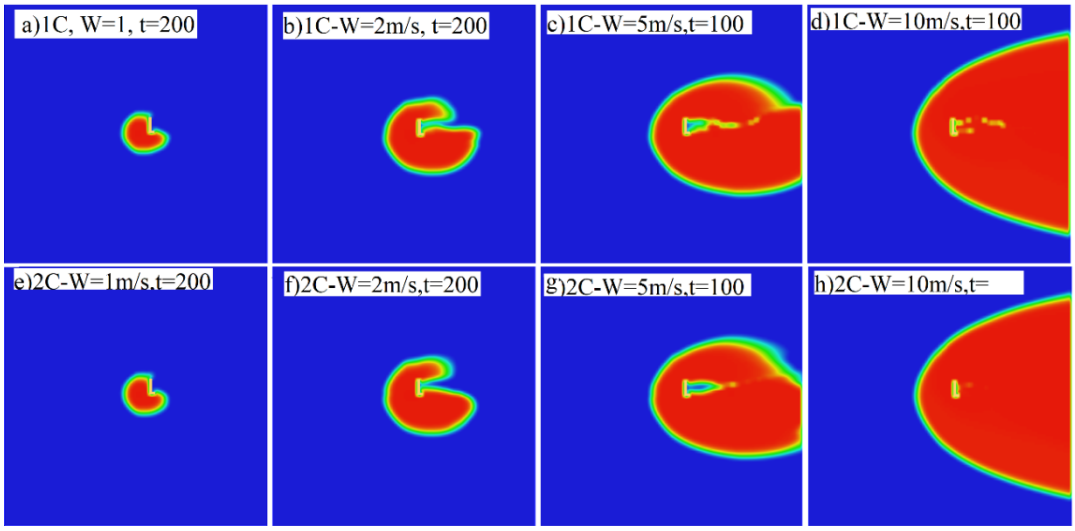

Figure 3- Burnt area at the plain surface with obstacles in one-way coupling (1C) and two-way coupling (2C) modes.

Results indicate that the burnt area is smaller for fully coupled simulations than for frozen wind field, and this difference appears to increase as the fire front propagates. In fact, the RoS is slower in two-way than in one-way coupling, which agrees with (Lopes et al., 2017). For the case with an obstacle, the wind field is highly dynamic, and the fire lines differ significantly depending on the coupling. Furthermore, increasing the wind speed (especially above 5 m/s), the fire intensity increases significantly and the RoS increases exponentially.

Figure (4) presents the fire area for a wind speed of 5m/s at different stages of fire propagation in 1C and 2C modes. As can be seen, the area and shape of the burnt area and fire front at different times of the fire propagation differ substantially. The fire front in two-way coupling is affected significantly by the wind structure. This is directly related to the in-draft flow caused by the convection column, which is not accounted for in the frozen wind field approach and becomes more dominant as the fire propagates over a larger area.

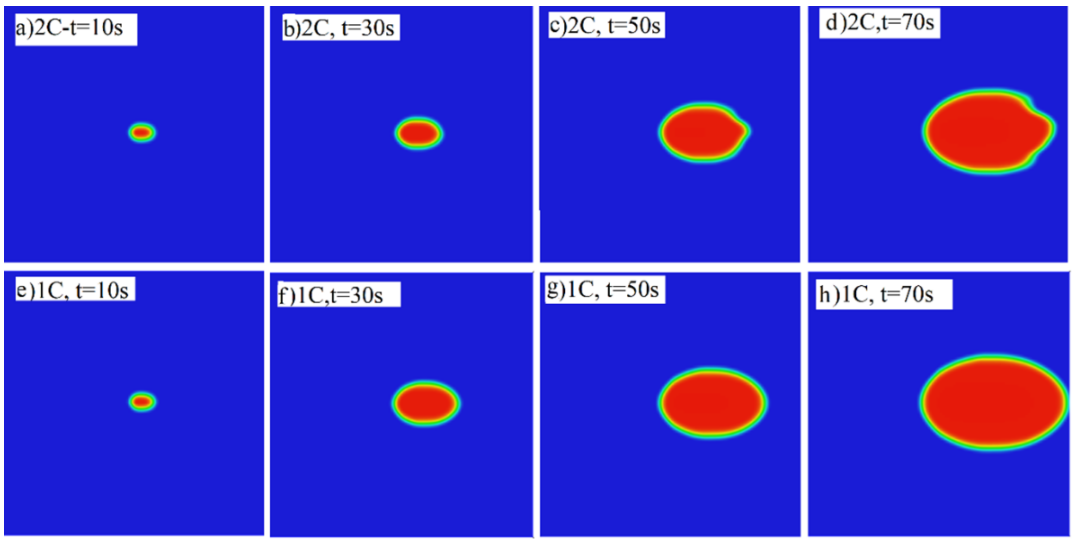

Figure 4- Burnt area at plain surface vegetation in one-way coupled (1C) and two-way coupled (2C) modes at different times.

Figure (5) presents the wind field around and above the fire, which induces the shape of the fire front. The wind which passes above the fire is heated by the latent heat and moves upwards (updraft column). This induces an inward wind field (indraft flow) from the flanks towards the centre line of the fire (green lines), which in turn induces the new shape of the fire front and reduces its RoS compared to the one-way coupling. Figure (6) presents the wind field at different times of the fire propagation for the cases with and without obstacles in wind

speed equal to 5 and 4.6 m/s, respectively, with the fire line depicted in white. The indraft flow at the rear sides of the front fire is clearly visible (figure 6 a-e). Besides, a low-speed zone which turns to recirculation flow forms in front of the fire. This seems to be responsible for reducing the fire RoS in two-way coupled simulations. Variations of the vortex area and structure behind the obstacle is depicted in figure (6 f-j). It is indicated that the area of the vortex behind the obstacle is reduced as the fire front propagates, yet it is the main responsible for the slow propagation of the fire front behind the obstacle, especially in two-way coupled simulations.

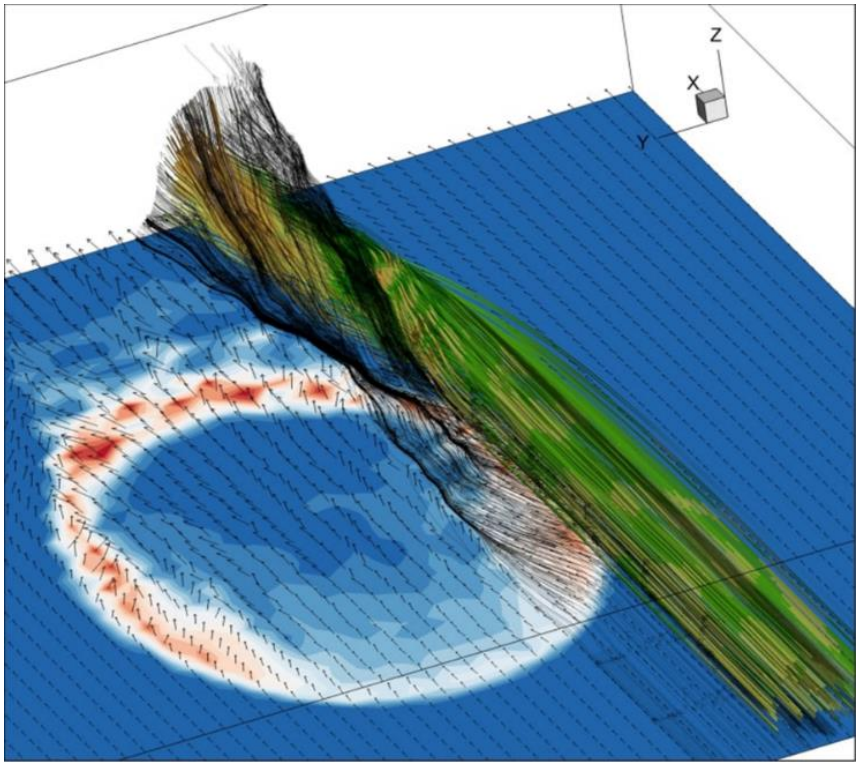

Figure 5- Wind field around and above the fire line.

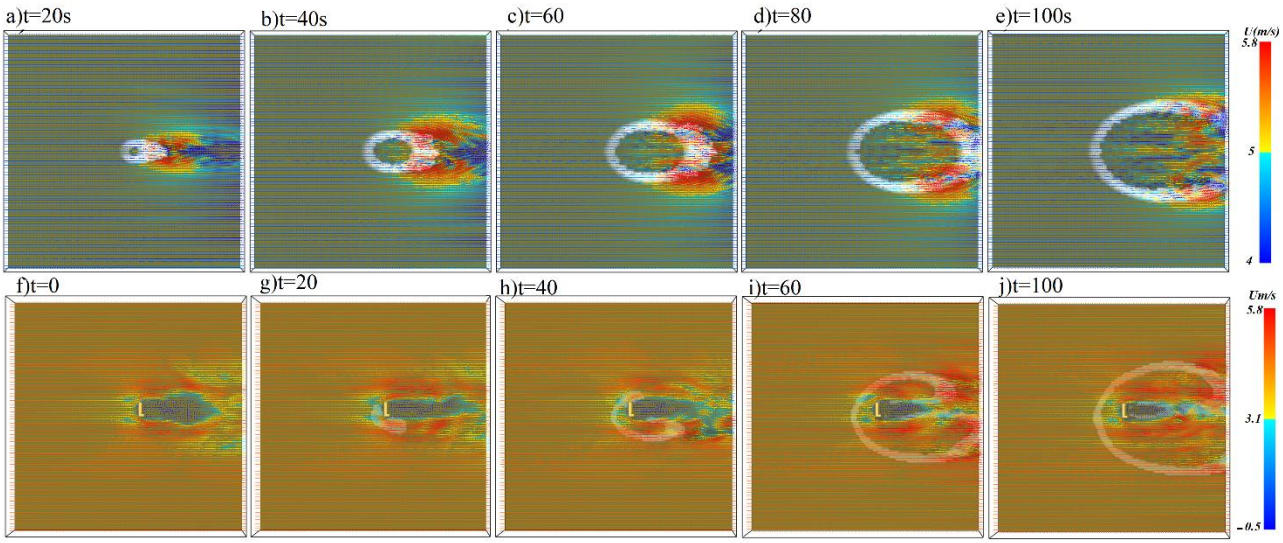

Figure 6- Wind field at z = 1m above the ground in different stages of fire propagation.

4. Conclusion

This paper discusses the effect of utilising one-way and two-way fire-wind coupling strategies on the simulation of wildfire propagation on a flat land covered with short grass, with and without the presence of obstacles. It is observed that the rate of spread (RoS) of the front line in the two-way fire-wind coupling is lower than that for

one-way coupled simulations. It is hypothesised that the main reason for this behaviour is the formation of the indraft flow from the back front and flanks of the fire front caused by the updraft column convection, as well as the formation of wind recirculation (vortex) zones in front of the fire line. It is also observed that the vortex structure behind the obstacle becomes smaller as the fire spreads behind the structure, and yet it reduces the fire propagation speed and its intensity in these areas.

Dataset, forest disturbance, changepoint detection, time series, Landsat

Abstract

Quality data is of the utmost importance to effectively evaluate any classification technique. In the realm of remote sensing, more precisely forest disturbance, different studies use different custom datasets. This paper shows the methodology used to create a forest disturbance dataset for continental Portugal. The dataset contains 664 forest points generated from a stratified random sampling based on the tree species and climate zone covering continental Portugal. Every point contains the auxiliary data used and a thorough list of all years where a disturbance occurs and the respective reason for the disturbance; the years span from 1986 until 2019.

The analysis was performed with the Google Earth Engine platform for a fast and flexible solution, tailored to the dataset's needs. To complement the satellite time series, five auxiliary datasets were used to understand the cause of the disturbances and increase confidence.

The resulting dataset shows known differences among various parts of the county. While the north area of the study contains a bigger number of points with multiple disturbances, the south is exactly the opposite with an abundance of undisturbed points. These asymmetries are also reflected in the species present in these different regions.

This dataset may be of interest for studies that need to evaluate forest disturbance techniques, or even changepoint detection techniques, and it may also be useful in studies that focus on differentiating types of forest recovery.

The dataset is available on GitHub at https://github.com/EduardoFAFernandes/portuguese-forest-disturbance-dataset/ 3

1. Introduction

In the remote sensing community, there have been studies that propose or improve disturbance detection techniques, either covering all types of land-covers (Kennedy et al., 2010; Zhu & Woodcock, 2014) or focusing only on forests areas (Brooks et al., 2014; Vogelmann et al., 2012). All face a common challenge: evaluating their approaches. Some make a qualitative evaluation (Vogelmann et al., 2012) while others strive for a quantitative evaluation that inherently needs solid reference data (Brooks et al., 2014; Huang et al., 2010; Vogelmann et al., 2012; Zhu & Woodcock, 2014). Obtaining this type of data is not easy and the aforementioned studies even felt the need to create their datasets. TimeSync (Cohen et al., 2010) was created for this purpose, it is a tool to visualise Landsat time series and collect annotated data; this tool is used in (Kennedy et al., 2010) and (Cohen et al., 2017) to generate disturbance datasets for the USA. We have created our tool to do this type of analysis, the reason will be explained in **Section 2.3**.

This paper will describe the creation of a forest disturbance dataset for continental Portugal and perform a small analysis and interpretation of the collected data.

This work was partially supported by Fundação para a Ciência e a Tecnologia (FCT.IP) through project Floresta Limpa (PCIF/MOG/0161/2019) and NOVA LINCS (UIDB/04516/2020).

2. Materials and Methods

To create the dataset three main steps were taken. The first step was to select points to be analysed. The second step was to gather auxiliary information like fires and land cover data to support evaluation, and to create a sample that would be representative of continental Portugal. The third and final step consisted of individually validating and analysing every point using Landsat time series, auxiliary information, and historical images from Google Earth Engine (GEE) (Gorelick et al., 2017).

2.1. Points to Evaluate

To select only points from forest areas two data sources were used: Inventário Florestal Nacional (IFN) the Portuguese forest inventory and a custom climate region dataset created with feedback from IPMA. To know what species were present at every point we sampled the latest available IFN at the time (2015), using a stratified random sampling based on the species and the climate region. For the species stratification, the classes in IFN 2015 were used, namely: Acacias, Carob Tree, Chestnut, Cork Oak, Eucalyptus, Holm Oak, Maritime Pine, Oak, Other Hardwoods, Other Softwoods, and Stone Pine. Regarding the climate region, five distinct regions were used: North Coastal, North Interior, Centre Coastal, Centre Interior, Alentejo and Algarve.

2.2. Auxiliary Information

Four official data sources were considered relevant for the creation of the dataset describing land cover, species, and burned areas (see **Table 1** and **Figure 1**), the datasets, have been regularly updated throughout the years providing a more complete and detailed history of the forest. Every property in the resulting dataset is represented by a list of values that represent the history of that property across all updates. For instance, if a point has the IFN species list [“Oak”, “Oak”, “Oak”, “Eucalyptus”], this represents that between 2010 and 2015 there was a change in the species present in that point. To gather this information, we intersected the points to evaluate with the auxiliary data sources, and only the precise point locations were taken into account.

Table 1 - Data sources used with their respective updates and the relevant properties that were extracted. (1*https://geocatalogo.icnf.pt/catalogo_tema3.html ; 2*https://geocatalogo.icnf.pt/catalogo_tema5.html ; 3*https://snig.dgterritorio.gov.pt/rndg/srv/por/catalog.search#/search?anysnig=COS&fast=index ; 4*https://land.copernicus.eu/pan-european/corine-land-cover)

Data Source Name	Updates	Relevant properties	Source
Inventário Florestal Nacional (IFN)	1995, 2005, 2010, 2015	id, land cover, species	1*
Burned Area Cartographic Data	Yearly from 1975 until 2018	id, year	2*
Carta de Uso e Ocupação do Solo (COS)	1995, 2007, 2010, 2015	id, land cover	3*
CORINE Land Cover (CLC)	1990, 2000, 2006, 2012	id, land cover	4*

2.3. Point Analysis Methodology

Next, we analysed each point individually supported by our own developed GEE application that, for a particular point, presents the auxiliary information, a Landsat satellite image of the area surrounding the point and the NDVI and NBR time series from 1985 onwards (**Figure 2)**. The index NDVI provides information about vegetation health, while NBR is used to confirm fire occurrences. The time series are interactive; one can click a particular observation and view the respective satellite image for obtaining additional visual context. The time series and RGB images are obtained from the Landsat program remote sensing imagery from missions 4, 5, 7 and 8, collection 1 tier 1 calibrated to top-of-atmosphere reflectance due to the adequate timespan for our objective (as detailed in **Figure 1**). While we could use TimeSync to create this type of dataset, GEE offers a more customizable product at the expense of requiring more user knowledge. The main difference was the temporal resolution of the analysed time series, TimeSync uses annual Landsat composites while our solution uses all the available observations.

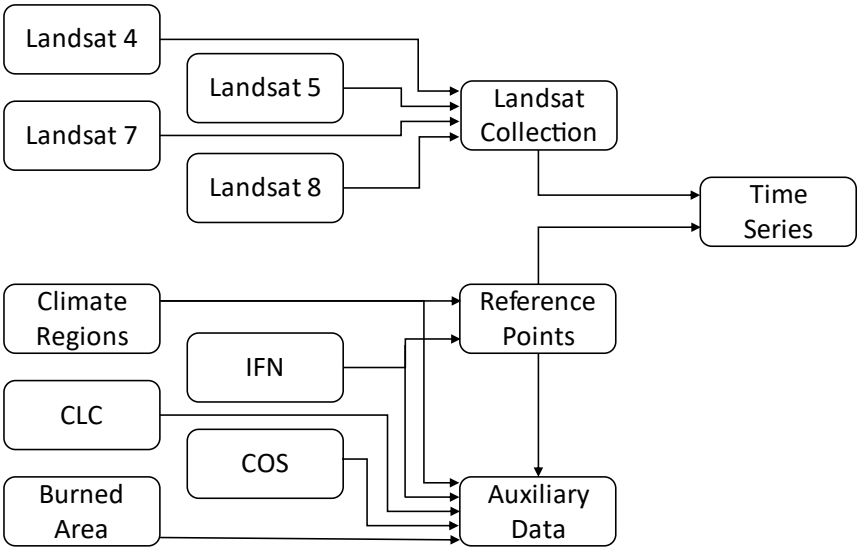

Figure 1 - Diagram of the workflow inputs

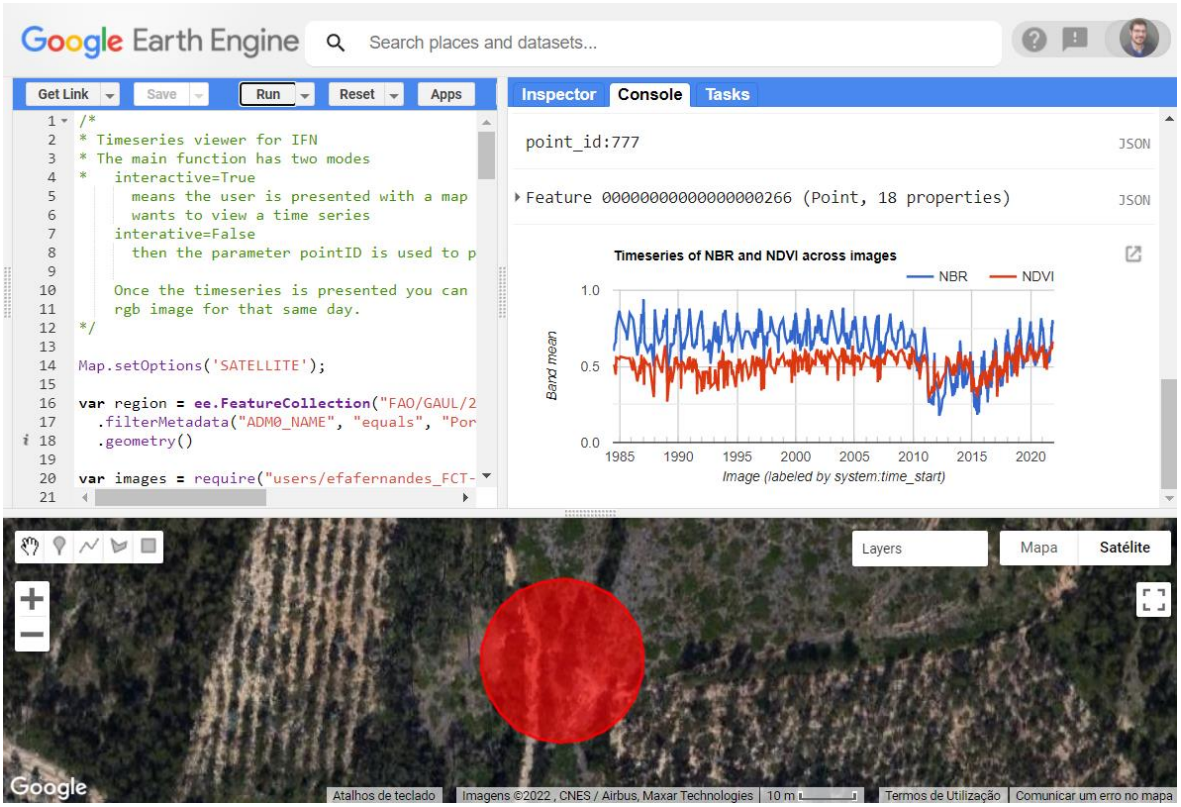

Figure 2 - GEE interface with interactive timeseries, satellite image and auxiliary information. The red circle indicates area to be analysed. In the time series plot we can observe two breakpoints.

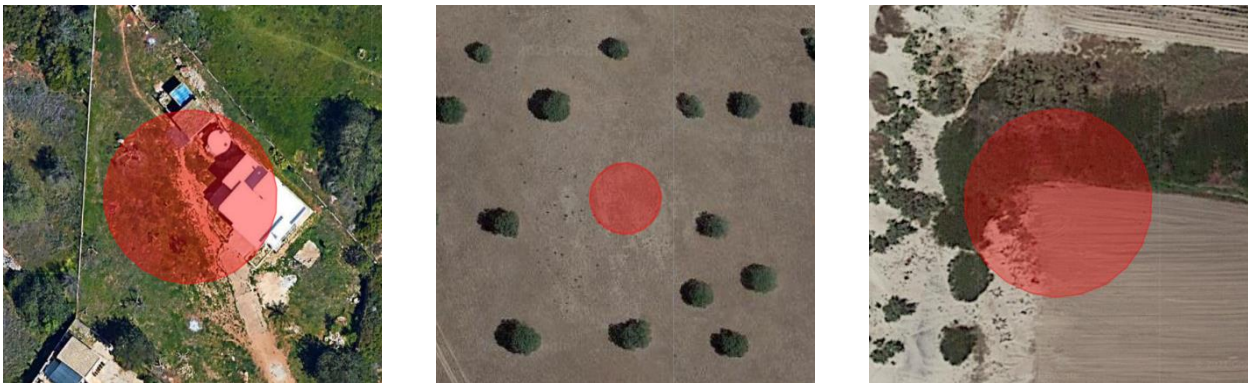
The analysis of each point proceeded in three distinct steps described below: validation of the point, selecting changepoints and understanding the cause of the changepoint.

To validate one point, the surrounding circular area with a radius of 15m must meet four conditions. The area must not contain an artificial area, for example, if an area contains buildings or large roads as depicted in **Figure 3a** it is invalidated. The area must not be a low-density tree area, for example, if most of the area is bare soil or ground vegetation as shown in **Figure 3b** the point is considered invalid. The area must be a contiguous plot of land, if the area contains multiple plots of forest area with substantial differences as seen in **Figure 3c** then the

point is invalidated. The final condition is related to the time series, its analysis must be conclusive and decisive, if the time series is somehow erratic, hard to analyse or raises doubt, the point may be invalidated and classified as "other reason".



a. Artificial area ***b. Low-density area*** ***c. Different plots of land***

Figure 3 - Examples of three reasons for invalidation

After validating a point, the second step is to look at the time series and determine when the disturbances occur. In Figure 4, we find an NBR index time series with four clear moments where a disturbance occurs, these happen in the years a) 1987, b) 1997, c) 2005 and d) 2015. Not all time series are as clear as this one, some require a more thorough analysis.

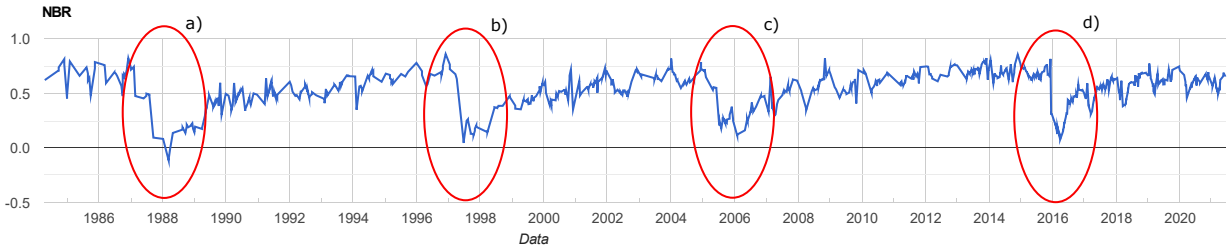


Figure 4 - Example of an NBR time series with four marked changepoints

The third step requires us to understand the cause of the disturbances, this is achieved by cross-referencing information throughout the auxiliary data described in **section 2.2** and using historic high-resolution satellite images from Google Earth Pro (GEP). For this dataset, four changepoint causes were considered: fire, harvest, unknown and other. Continuing with the example in **Figure 4** the auxiliary data says that fires occurred in the years 1987 and 2005, resulting in the annotation of Fire as the cause for changepoint a) and c). The remaining auxiliary data specifies that a eucalyptus forest has always occupied this point. Using GEP, it was possible to deduce that d) is most likely caused by a harvest. With the available data it was not possible to conclude what caused changepoint b) it will be marked as unknown.

3. Results

Having the dataset fully annotated we can turn our attention to its analysis. We will first examine the reason for invalidation, secondly their causes, thirdly we will assess the number of disturbances per valid point and finally evaluate the causes for the disturbances. It should be noted that oak, other softwoods, carob tree and acacias have an extremely small number of samples. Therefore, although represented in the figures, they will not be considered when extracting general conclusions based on species.

3.1. Number of invalidations

From a total of 998 sample points, 664 were considered valid and 334 were deemed invalid. This invalidation is not equally distributed through the species and consequently not uniformly distributed through the study area. When analysing **Figure 5**, we can see that the south and interior of the country have a higher density of invalidated points. The south of Portugal is dominated by cork oak, and we can see that this species is more

affected by invalidation than eucalyptus or maritime pine. The next subsection section will further explain this asymmetry.

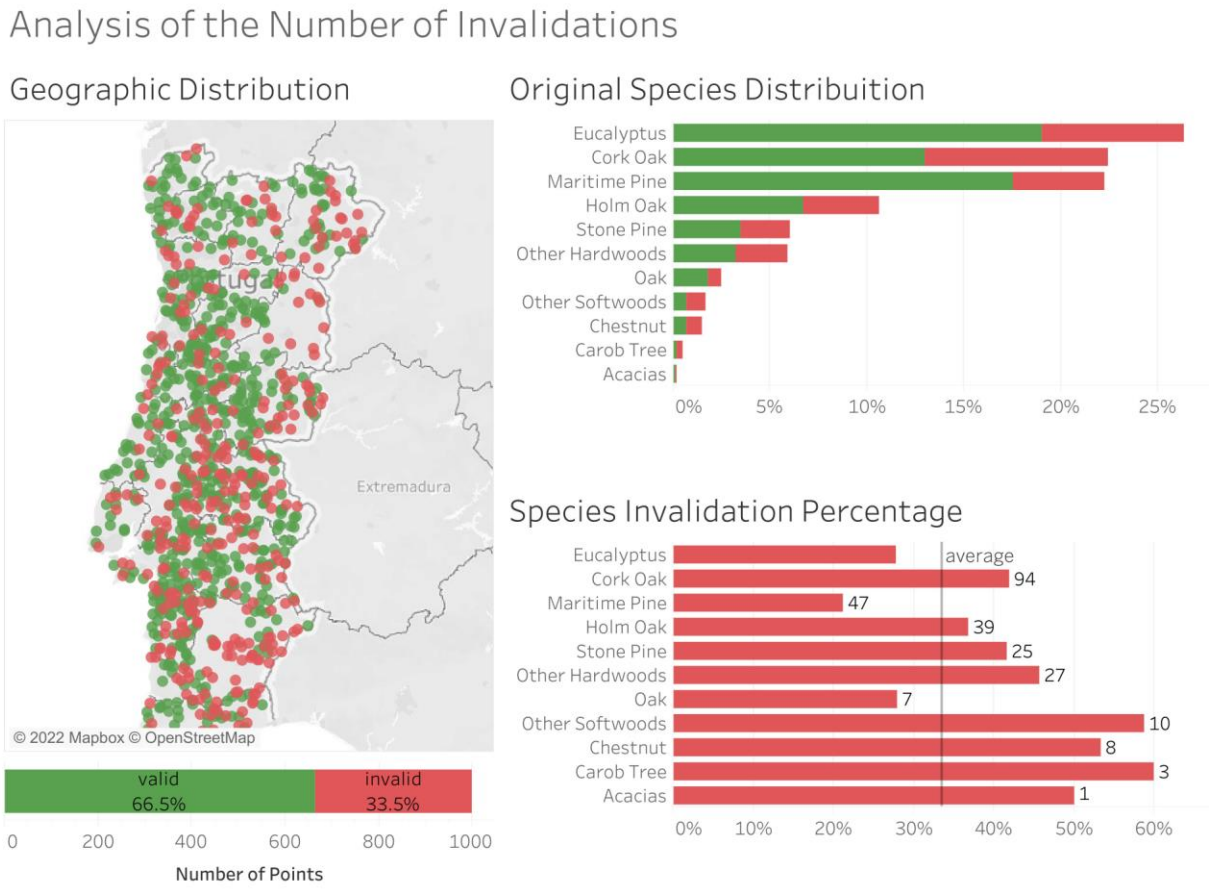

Figure 5 - Dashboard analysing the number of invalidations

3.2. Cause of invalidations

The primary cause for invalidation is low density closely followed by difficult analysis (see **Figure 6**). Once again there is a geographical asymmetry, with low density being predominant in the south and the interior of the country, this is the main reason these areas have a higher density of invalidated points, and consequently why cork oak has a relatively high number of invalidated points. These areas tend to be low density and populated by cork oak just as depicted in **Figure 3b**. We can see that the primary reasons species are invalidated are low density or other. Although this rule is hard to confirm or deny in species with small representation like acacias and carob trees. Additionally, eucalyptus has a high percentage of invalidations caused by complex plot limits.

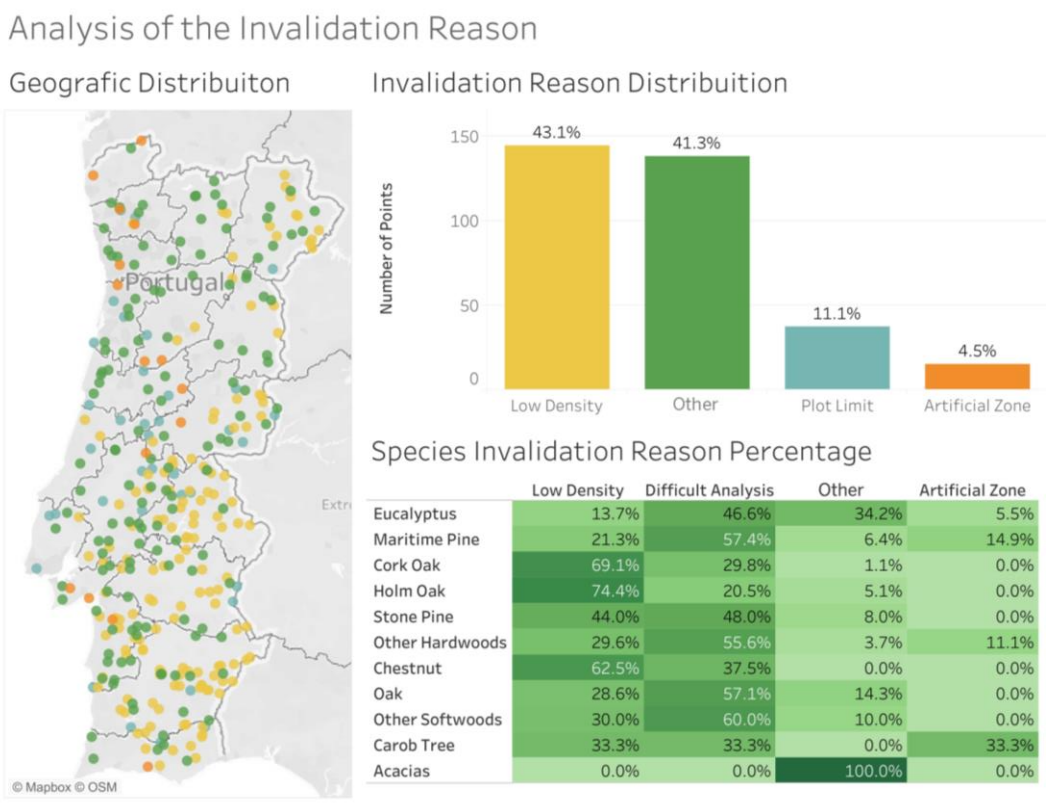

Figure 6 - Dashboard analysing the reason of the invalidation

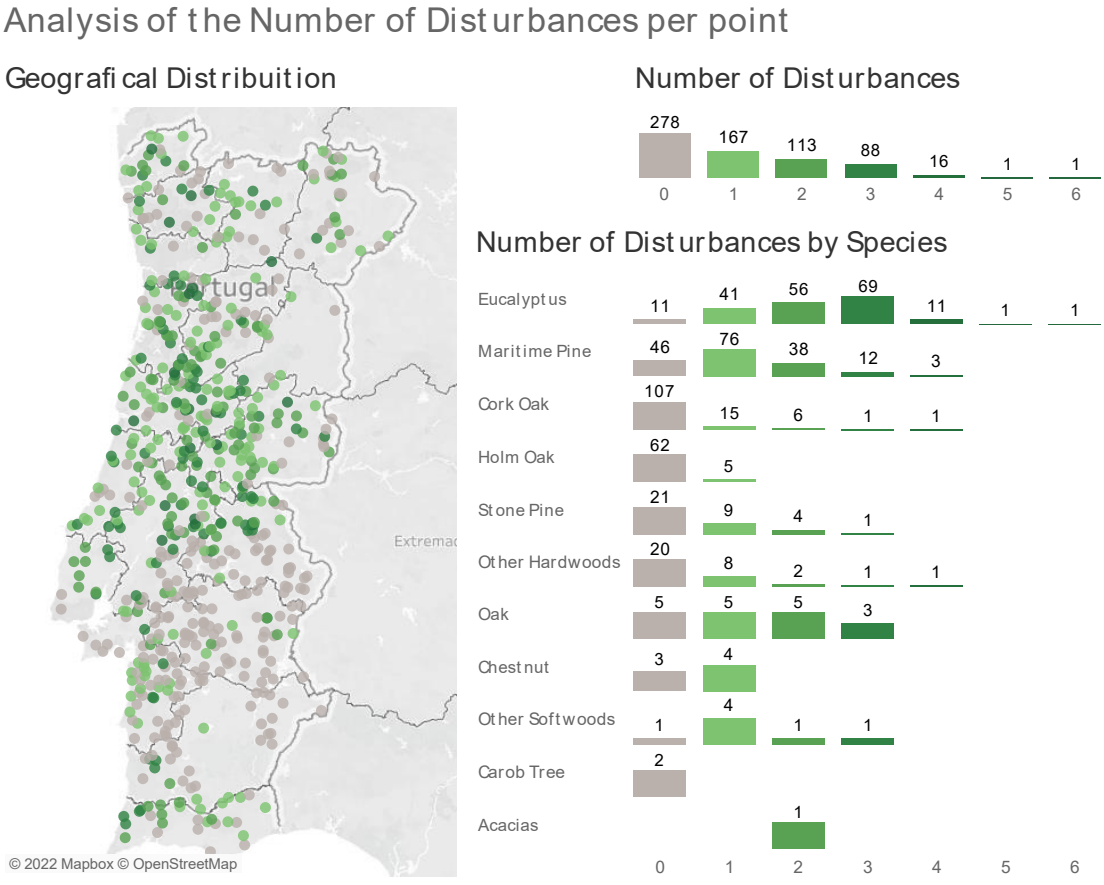

Figure 7 - Dashboard analysing the number of disturbances per point

3.3. Number of changepoints per point

The number of changepoints per point is summarized in **Figure 7,** showing that the mode of changepoints per point for the whole dataset is zero. However, the eucalyptus and the maritime pine classes have respectively a mode of 3 and 1 changepoints. This difference among species is reflected in the geographical distribution of the number of changepoints, the south has almost no changepoints while the center of the country is populated with points that have many disturbances, namely due to fire occurrences.

3.4. Cause of disturbance

Finally, the causes of the disturbances are reported in **Figure 8.** In our dataset, about 20% of the disturbances have an unknown origin, this makes it impossible to conclude if either fire or harvesting is the main cause of forest disturbances. Concerning the temporal distribution of causes, it can be concluded that unknown causes are predominant in the earlier years and tend to later disappear, while harvest cause has the exact opposite behavior. This is due to the lack of information about harvesting since the only way to validate this type of disturbance is either by a landcover change or by high-resolution satellite imagery. GEP only provides significant high-resolution photos after the year 2000. On the other hand, the fire records are in general complete throughout the years. For this reason, it can be assumed that many unknown causes may correspond to harvesting events.

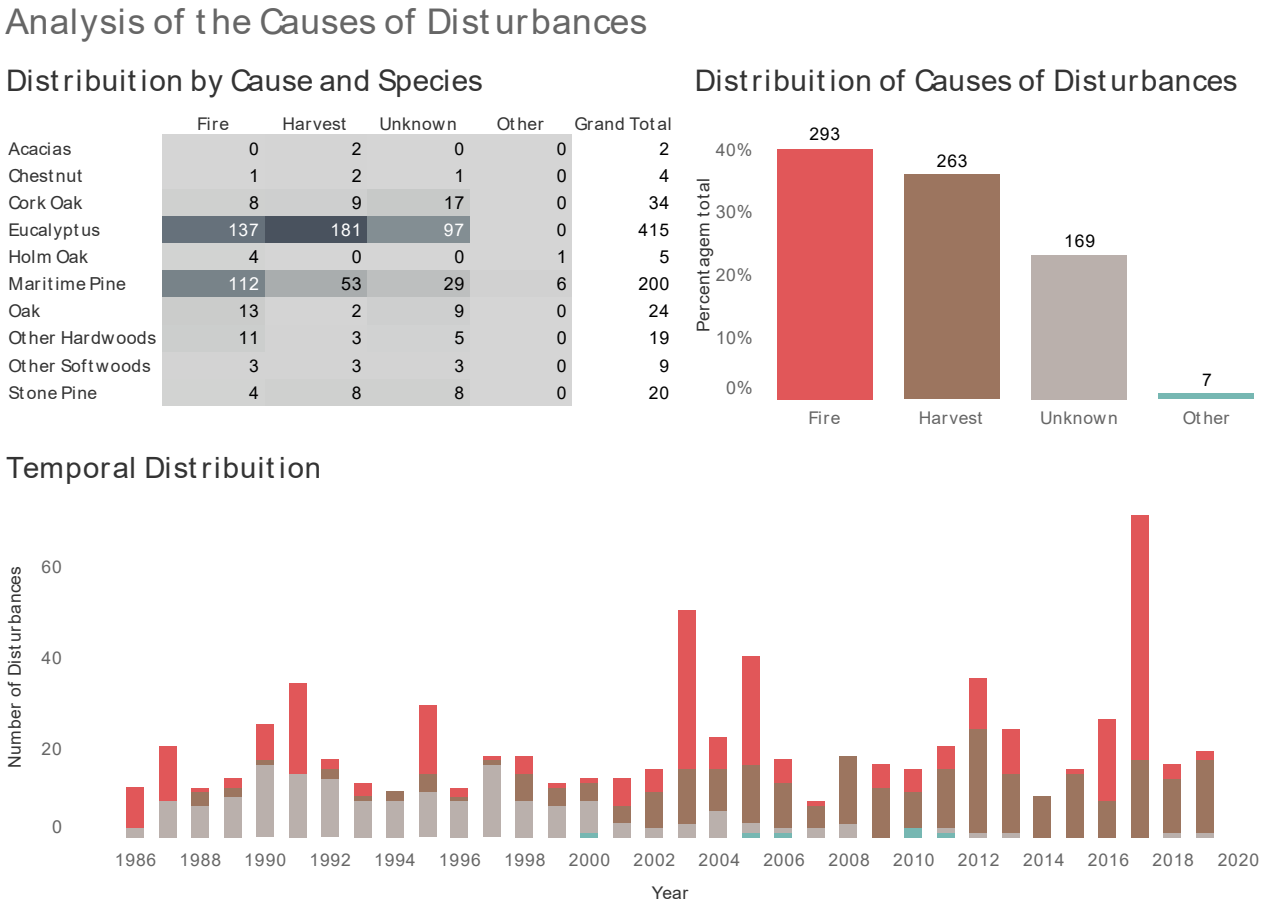

Figure 8 - Dashboard analysing the causes of disturbance

4. Discussion and Conclusions

In this paper, we described the creation of a curated dataset that contains 664 forest points generated from a stratified random sampling based on the tree species and climate zone that cover continental Portugal. Every point contains the auxiliary data used and a thorough list of all years where a disturbance occurs and the respective reason for the disturbance; the years span from 1986 until 2019.

While some of the breakpoints in the dataset can be obtained (with some work) from other sources, this dataset assures that if a breakpoint is not listed then almost certainly a disturbance has not occurred. Furthermore, due to the stratification, it is expected that the number and frequency and type of disturbances present are representative of real-world data for forest areas in Portugal. However, depending on the application, the number of geographic points may not be enough to provide full guarantees. Finally, this dataset only tracked severe disturbances, long term disturbances like droughts were not considered, and thus it may not meet the requirements of some applications.

This dataset can be used in several applications. First, and the main reason motivating the creation of the dataset, it can be used to evaluate algorithms that detect forest disturbances for example or a more generical use as a dataset for evaluating changepoint detection in time series. Finally, it may be employed for differentiating types of forest recovery.

Keywords:

Deep Learning, Fire Identification, Crowdsourcing

Abstract

Forest fires have become a global problem that affects large areas of the globe, and has received contributions from citizen science, namely the reporting of fire sighting by citizens with location and images, often using smartphones, which is becoming a frequent source of information to firefighting teams.

Nevertheless, such contributions need validation before resources are deployed and that is the focus of this work. This paper describes a novel approach to identify forest fires in real crowdsourced images using a deep learning (DL) approach.

The approach is based on YOLO networks to train optimized models that identify the real cases that need to be addressed, using a holistic methodology that considers all objects detected in each image before producing a decision. For our experiments, we used benchmark and real datasets of fire and smoke. In the experiments, the performance is compared under different experimental setups. Our approach results show that the proposed crowdsourcing holistic deep approach for fire identification can be successfully used in real scenarios.

1. Introduction

Fire is one of the leading hazards endangering human life, the economy, and the environment (Hall 2014), (Saponara et al. 2020). Identifying a forest fire in its early stages is essential for a faster and more effective response from fire and civil protection authorities. An effective initial response can decrease fire damage and, in certain cases, can prevent the loss of lives and property, e.g., houses and other belongings.

Crowdsourcing approaches (Zanca et al. 2020) involve the use of people to aid in solving problems that technology still struggles. For firefighting, crowdsourcing, or citizen science, can be extremely important in early detection, when communication systems are in place for such reporting. However, such contributions are sometimes malicious with the goal of diverting resources from real fires, often provoked by arsonists, and require validation before resources are deployed.

In this work, citizens are able to report ongoing fires through an app developed in the scope of the Fireloc project (https://fireloc.org), a system that enables the report of forest fires by identifying, locating, and reporting them, using crowdsourced data, i.e. geolocated images with a potential fire. The development of a contribution validation mechanism becomes imperative, allowing for faster and more accurate communication of the occurrence. With the increase of the volume of information received, processing by human visual analysis of each reported situation, even if done by an expert, becomes too time-consuming, and therefore not useful for a rapid response. Therefore, the development of an intelligent system that can automatically identify fire in the submitted images is proposed. This system can then be applied to each report made using the Fireloc application, assessing if there is a current fire or not and discarding false reports, which aims to improve firefighters' intervention. This system can enhance the process of analyzing crowdsourced data, ultimately enhancing firefighters' response.

We explore how the optimization of parameters in YOLO networks (Redmon and Farhadi 2018), (Redmon and Farhadi 2017), (Zhang et al. 2018), (Redmon et al. 2016), a deep architecture for object detection, can be used to allow a better performance in Fireloc project, i.e., to support the determination of validity of an image

obtained through crowdsourcing, a.k.a. citizen science. For this purpose, we construct a dataset with real images obtained in a simulacrum that result in a set of parameters to apply to real situations. We introduce a new concept in post-processing, proposing a holistic approach generalizing the YOLO object detection to an image classification system that fully supports the necessary validation before resources are deployed for firefighting.

In the following, Section 2 describes the related work in deep learning for fire identification. Section 3 describes the proposed holistic deep approach for fire identification, presents and analyses the experimental results. Finally, Section 4 shows the conclusions and future lines of research.

2. Fire Identification with Deep Learning

Fire identification and detection in images using deep learning (DL) (Lecun et al. 2015) have been source of much interest in the research community (Mao et al. 2018), (Qiang et al. 2014), (Lee et al. 2017), (Zhang et al. 2018), (Ayala et al, 2020). In (Mao et al. 2018), a novel fire recognition method based on multi-channel convolutional neural network is proposed, constructing 3 channel color images and using a CNN. The CNN can take as input videos or images and gives as output the probabilities of it belonging to each class considered. All videos are first converted to images frames and all images are then resized to fit the input size of the model. Each image is given to the model as a matrix with each RGB channel, and discriminating features are extracted. Parameter adjustment was achieved using backpropagation. The resulting model could be applied to both video and image inputs, classifying them as belonging the class fire or not.

In (Lee et al. 2017), the images are obtained using an Unmanned Aerial Vehicle (UAV) as a cost-effective means to provide high resolution images for wildfire detection. Results show that such images result in wide range of aerial photographs that can be used for object detection.

In (Zhang et al. 2018), given the difficulty of obtaining real images, a synthetic smoke dataset was constructed by inserting real smoke or simulated smoke into forest background to solve the lack of training data. The published results show that simulated smoke is the better choice, and the model is insensitive to thin smoke.

3. Holistic Deep Approach for Fire Identification

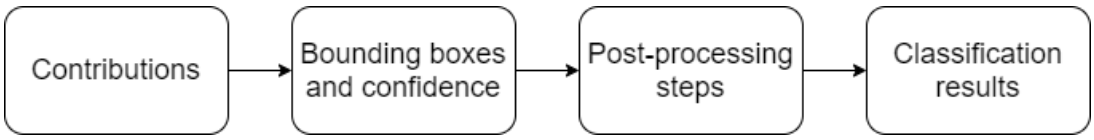

Figure 1- Holistic deep approach for fire identification system

In this work we propose a holistic deep approach for fire identification. Figure 1 shows the operating steps for smoke and fire detection in static images, integrated into the Fireloc project's system. Initially, using the mobile application and the camera of their smartphone or tablet, users can send photos of the forest fire or smoke they observe (contributions).

Then, for each contribution presented to the system, parameter tuning is performed, and the model identifies the parts of the image that contain smoke or fire with bounding boxes and an associated confidence score for each object detected.

Finally, given the specificity of the Fireloc project, a holistic post-processing mechanism is performed before the final classification results are presented to the firefighting team for decision making.

There are several challenges that must be tackled, namely the accurate predictions that avoid misuse of resources and the heterogeneity of submitted contributions in terms of different images formats, sizes, and quality.

The development of the object detection module focuses on the optimization of the parameters: the size of the initial anchors and confidence threshold. The main goal is hence to provide accurate prediction on crowdsourced images on the presence of fire (or smoke) in the given images.

3.1. Datasets

For the fire and smoke detection system implementation, custom datasets were used, manually annotated according to the YOLO format. Two independent sets of images were used to train and test the models, chosen according to the module real conditions of use.

The dataset chosen for the training step was an open source set of images. This dataset is publicly available at https://github.com/DeepQuestAI/Fire-Smoke-Dataset/releases/download and contains an equal number of images with fire and smoke, presenting fires in urban contexts with other objects present in the background and some overlapping objects to be detected (smoke and fire). Although the size of the images is smaller than the typical resolution of photos taken by smartphones and don't contain a high number of images, the variety of examples with smoke and fire makes it use feasible for training YOLO models.

To complement this set of training images, images of smoke and fire were collected in a forest fire context, with characteristics more similar to the actual use of the Fireloc system. These images are, therefore, more suitable for testing the performance of models and were collected in a simulacrum performed by firefighters on May 15, 2019, in tests carried out in Serra da Lousã by Association for Development and Industrial Aerodynamics (ADAI). The manual annotation of the proposed datasets for training and testing the models was carried and the distribution of examples of each class for training and testing datasets is presented in Table I.

Table I- Number of examples present in each dataset

	Total Fire examples	Total Smoke examples
Train dataset	2598	2348
Test dataset	460	421

3.2 Model evaluation

The approach followed to develop the object detection module went through an iterative process, optimizing selected parameters to improve the objects' detection results in the images. The mean Average Precision (mAP) and Average Precision (AP) values per class were analyzed for the evaluation of results. These can be considered standard metrics of YOLO models' performance since they allow an assessment of the relationship between false positives and detected false negatives (Everingham et al. 2010). An adaptation of (Everingham et al. 2010), from the (Cartucho et al. 2018) project, was used.

With the different parameters optimized, the process focused on analyzing the classification results of the images, using the confusion matrices obtained for the classification of the test images to evaluate the models after the application of the post-processing.

3.2. Experiments and results

In the experiments, the trained models were pre-trained with *Imagenet* and the following parameters were considered, defined in the configuration file of each model: (i) Number of classes = 2 (since the classes of objects considered for detection in the images are Smoke and Fire); (ii) Channels = 3 (RGB); (iii) Number of iterations = 6000 (number of iterations recommended by the author of YOLOv4 (Bochkovskiy et al. 2004) for training models with custom datasets).

3.2.1. Experiments and results for anchor adjustment

The definition of the initial anchors of the models can directly influence the detection results obtained. When adjusting the anchors initial size to approximate the bounding boxes sizes in the training dataset, it is possible to suit the boxes size that signals the detected fire and smoke objects in the images. It is to be expected that this approach, by improving the location of objects in the test images, will result in an improvement in the obtained mAP results. In the following experiments, the anchors are adjusted to the bounding boxes marked in the training dataset using the k-means algorithm and aim to improve object detection results.

Table II - Anchor Adjustment Performance Results – Average Precision (AP)

		EPOCHS					
		1000	2000	3000	4000	5000	6000
Fire Smoke	v4	23.08%	41.14%	40.69%	36.20%	46.00%	43.90%
	v4-anch	17.58%	32.53%	37.69%	**40.11%**	38.49%	38.65%
Fire	v4	4.83%	22.30%	15.52%	20.08%	**24.96%**	23.06%
	v4-anch	1.55%	5.92%	7.50%	11.74%	14.56%	13.28%
Smoke	v4	41.34%	59.98%	65.86%	52.32%	67.05%	64.74%
	v4-anch	33.61%	59.13%	67.89%	**68.67%**	64.42%	64.02%

Results show that the YOLOv4 model trained with the default values of anchor size presents better performance in detecting objects of the considered classes. The best result obtained with the model after performing the anchor adjustment is only 40.11% mAP, after 3000 training epochs, inferior to the best result achieved using the original anchors, 46% mAP obtained after 5000 training epochs.

When analyzing the AP results for each class of objects considered, the models present a significant difference in the fire detection performance, reaching a maximum of 24.96% AP/Fire with the model trained with default anchors. In the detection of objects of the Smoke class, both models present good results, reaching 68.47% of AP/Smoke.

3.2.2. Experiments and results for confidence threshold adjustment

This experiment aims to evaluate the effects of the variation of the confidence threshold defined not only on the results of object detection but also on the classification results of the images in the test dataset. In all previous experiments, the specified limit used for this confidence was the default value, used in the studies YOLOv3 (Redmon and Farhadi 2018) and YOLOv4 (Bochkovskiy et al. 2004).

To assess the effects of changing the confidence threshold on the object detections performed, the mAP results obtained after every 1000 iterations of training of the model were evaluated. Values 5%, 10%, 15%, 20%, and 25% were considered for changes in the confidence threshold. The experiment results can be seen in Figure 2, showing the increase of the defined confidence threshold, regardless of the number of training iterations of the model, results in a decrease of mAP results. These results indicate that the higher the defined confidence threshold, the lower the number of correct detections. When considering the results obtained, the confidence thresholds of 5% and 15% stand out positively.

4. Conclusions and future work

We have studied the problem of identifying fire and smoke in crowdsourced images that citizens submit to the Fireloc system to ultimately alert firefighters of ongoing fires. We have explored how the optimization of parameters in YOLO networks can be used to allow a better performance in fire identification. For this purpose, we have constructed a dataset with real images obtained in a simulacrum that result in a set of parameters to apply to real situations. We have additionally introduced a new concept in post-processing, proposing a holistic approach generalizing the YOLO object detection to an image classification system that fully supports the necessary validation before resources are deployed for firefighting.

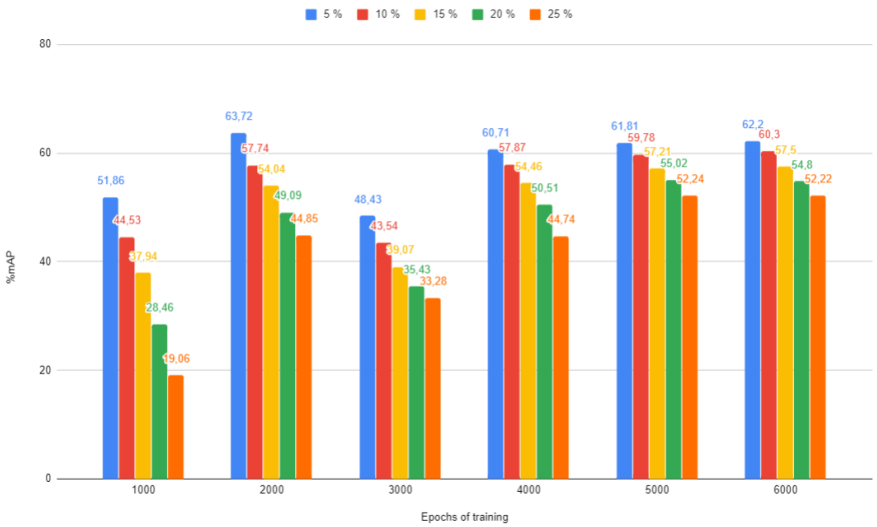

Figure 2 - Results obtained considering varying confidence threshold (5% to 25%)

Figure 3 shows the detection results for comparison of the two operating points. The results obtained with both thresholds are similar, although the image resulting from the detections carried out with 5% threshold shows a more significant number of repeated fire detection. The video is available at https://www.dropbox.com/s/fwtls664s5uukcy/fire_video demo.mp4?dl=0.

Figure 3 - Test results image detection comparison, example 2

Future work is foreseen in two paths. First, the augmentation of the dataset, as it has become clear that it is a potential source of improvement, e.g., through the use of Generative Adversarial Networks (GAN). Second, due to the recent interest in the image and video object recognition the generalization of the post-processing holistic approach to video sequences is also anticipated given that initial tests with video images suggest the viability of the proposed approach.

Deep learning, wildfire spread modelling, fire behavior

Abstract

We demonstrate the use of a deep learning (DL) approach for representing the behavior of a high-resolution physics-based wildland fire spread model. The ultimate objective is being able to efficiently use the DL model for intensive simulations of large fires while retaining fidelity to the fine-scale physical processes. We begin with a fire model that reduces the spatial domain of the fire spread problem to one dimension (1D). The 1D model explicitly resolves cm-scale fuel variations, heat transfer and heating/drying dynamics of individual fuel particles and burning behavior of the bed. We then ran the fire model for 78,125 factorial combinations of fuel, weather, and topographic conditions as training data for the DL algorithm. The results of the DL analysis show overall agreement of 96% of the variation in fire behavior as represented by steady state rate of spread, flame length and flame zone depth. Exceptions to the DL regression indicate areas where more work is required in refining the resolution in training cases and use of advanced methods of embedding the fire model inside the DL algorithm loop.

1. Introduction

A major challenge for wildfire modelling is the ability to span the range of scales of fire phenomena (Clark et al. 2003). Fuel particle heat transfer and ignition occur over millimetres but wildfires impact landscapes and communities across kilometres. Even if the fine-scale physical processes of fire spread were well known, it is impractical to resolve them computationally for large domains of real fires. Thus, physics-based modelling has been much slower than real time and has not yet become operational for wildfire management. Even for research purposes on relatively small fires (~10^3 m^2) using supercomputing clusters, physical models employing computational fluid dynamics in 3D must compromise spatial resolution to achieve performance and thus fidelity to the fine-scale fuel descriptions, and processes of heat transfer, ignition, and combustion.

An alternative approach, long used in fire spread modelling, is to limit the spatial domain to one-dimension (1D) (Fons 1946). A 1D formulation resolves the heat transfer and sequential ignition of discrete fuel particles at fine-scales and can be unambiguously compared with measured behaviours. In a reprise of this 1D approach, Finney et al. (2021) describe the new research required to understand fuel burning rates, convection heat transfer, and heating and ignition of fuel particles at the fine scales. The fine scale explicitly represents fuel heterogeneity and employs a 1D model for heating, drying, and pyrolysis of fuel particles. It solves a single 1D line spanning domains of about 50-100 m in less than a minute, but this is too slow to be implemented directly in simulations of large fires.

Here we describe the application of deep learning (DL) techniques to the problem of representing modelled fire behaviour. Assuming our high-resolution 1D fire model captures the system behaviour accurately, DL can be used to determine the relations between the resulting fire behaviour outputs and a large list of input variables. Rapid advances in the past decade in DL show it can represent complex and perhaps unknown relations among variables in the system.

A rigorous background on DL is outside the scope of this paper. We refer the interested reader to (Goodfellow et al. 2016). Briefly, DL is a branch of machine learning (ML) that relies on using neural networks with multiple

hidden layers of nodes that do not directly correspond to actual observations. These hidden layers allow DL models to build up rich latent representations of complex systems and are often distinguished from more traditional ML approaches in that they require less feature engineering to be successful, making them ideal candidates for complex domains in the geosciences.

There are many examples of traditional ML applications in wildfire modelling, but more modern DL applications are rare, particularly those modelling fire spread and growth (Piyush et al. 2020). Some examples include Hodges and Lattimer (2019) where a DL model was used to predict the structural evolution of wildfires in two dimensional simulations. Radke et al. (2019) used a DL model to predict how a single real-world fire evolves over the course of a 24-hour period. In a similar vein, we demonstrate that DL can be used to effectively model steady state variables predicted by the 1D fire spread model described below.

2. Methods

2.1. One Dimensional Fire Spread Model

The dynamical nonlinear 1D fire spread model is explained in detail by Finney et al. (2021) and in a companion paper that overviews a more recent version (Forthofer et al., *this conference*). Briefly, the model domain is a 1D transect through a fuel bed with resolution nominally of 1 cm. At these resolutions, variations in fuel structure, such as gaps and clumps can be explicitly resolved in contrast to bulk fuel descriptions (i.e., Scott and Burgan 2005). The simulation proceeds from a specified ignition at one end of the domain, calculating pyrolysis production and flame dimensions from fuel particles heated by radiation (flame and solid fuel) and convection. Convection heat flux to fuel particles from flames is calculated using a mean gas temperature profile and flame tip velocity (Finney et al. 2021). Fuel particle heating and drying response to steep heat flux gradients of an approaching fire (Cohen and Finney 2022a, b) are captured by a 1D conduction model for each size and material in each cell. Fire spread is an outcome of discrete particle ignition, which accelerates from the ignition state and achieves a steady rate of spread (ROS), flame length (FL), and flame zone depth (FZD).

To generate a dataset for training a DL model, the 1D fire spread model was run on a factorial combination of five values for each of the seven input variables, resulting in 78,125 distinct cases, see Table 1 and Table 2 for more details. For this demonstration, we chose only to represent steady state variables of fire spread rate, flame length, and flame zone depth from those data produced by the dynamical model. Others could include acceleration time and energy release from post-frontal combustion.

2.2. Pre-processing

The dataset is filtered to only keep data points where the 1D model reported realistic ROS values of no more than 10 m/s. The dataset is further normalized before model training such that all input variables are normalized into [0, 1] linearly between 0 and the max value of corresponding variable, and output variables are first square-rooted and then normalized in the same fashion as they're skewed and have a long tail. The dataset is randomly split into train (65%), validation (15%) and test datasets (20%) for model development before any filtering. The train dataset is used to learn the parameters of the DL model, while the validation dataset is used to select the best model to avoid overfitting the train dataset. The test dataset is never seen during model development and is reserved to measure the generalization quality of the DL model in the end.

Table 1. Descriptive statistics of input and output variables of the 78,125 full factorial combinations for training the DL model.

Category	Variable	Values (Full factorial design)	Train mean (std)	Validation mean (std)	Test mean (std)
Fuel	Particle Diameter (m)	{0.001, 0.002, 0.004, 0.005, 0.006}	0.0035 (0.0018)	0.0036 (0.0018)	0.0035 (0.0018)
	Moisture (%)	{5, 10, 15, 20, 25}	14.9 (7.0)	15.1 (7.0)	15 (7.0)
	Loading (kg/m3)	{0.1, 0.825, 1.55, 2.275, 3}	1.54 (1.02)	1.54 (1.02)	1.55 (1.02)
	Fuel Depth (m)	{0.01, 0.133, 0.255, 0.378, 0.5}	0.255 (0.173)	0.255 (0.173)	0.255 (0.172)
Weather	Wind Speed (m/s)	{0, 1.25, 2.5, 3.75, 5}	2.49 (1.76)	2.5 (1.77)	2.5 (1.77)
Topography	Terrain Slope (degree)	{0, 7.5, 15, 22.5, 30}	14.9 (10.5)	15.1 (10.6)	15 (10.5)

Fire	Bed Width (m)	{10, 20, 30, 40, 50}	30 (14.1)	29.7 (14.0)	29.9 (14.1)
Dependent variables	ROS (m/s)	N.A.	1.95 (10.11)	1.87 (8.29)	1.93 (10.38)
	Flame Length (m)		3.96 (2.57)	3.95 (2.59)	3.95 (2.56)
	Flame Zone Depth (m)		12.6 (12.0)	12.6 (12.1)	12.5 (12.0)

Table 2: Number of samples for the whole dataset (all) or each split (train, validation, and test). Each row corresponds to a different filtering, no filtering, valid ROSs or zero ROSs only.

Samples	All	Train	Validation	Test
All	78,125	50,681	11,712	15,732
Valid ROS	68,750	44,606	10,302	13,842
ROS == 0	6,666	4,307	1,020	1,339

2.3. Deep Learning Model

We use a two staged approach for predicting the steady-state variables. First, we use a binary classification model that predicts whether there is any fire at all (meaning the fire does not spread under the given conditions). If there is a prediction of *no fire*, then the ROS, FL and FZD are all zero. Otherwise, the regression model is used to perform the final prediction.

Given the relatively few inputs to the model, we chose the quintessential Feed-Forward Neural Network (Goodfellow et al. 2016, Chapter 6) (FFNNs) for both models. More specifically, we use a fully connected FFNN, which allows for a rich latent space that grows exponentially with the number of input features. As such, it is not appropriate for domains with large numbers of input features, but often works surprisingly well for smaller domains (Figure 1).

The DL models are trained on the training dataset such that the Mean Squared Error (MSE) (or binary cross-entropy, i.e., logistic loss) for the regression (or classification) model is minimized. L2 regularization was applied to avoid model overfitting. The learning rate and the learning rate decay rate were empirically determined by training multiple models and then selecting the models with the lowest loss on the *validation* dataset.

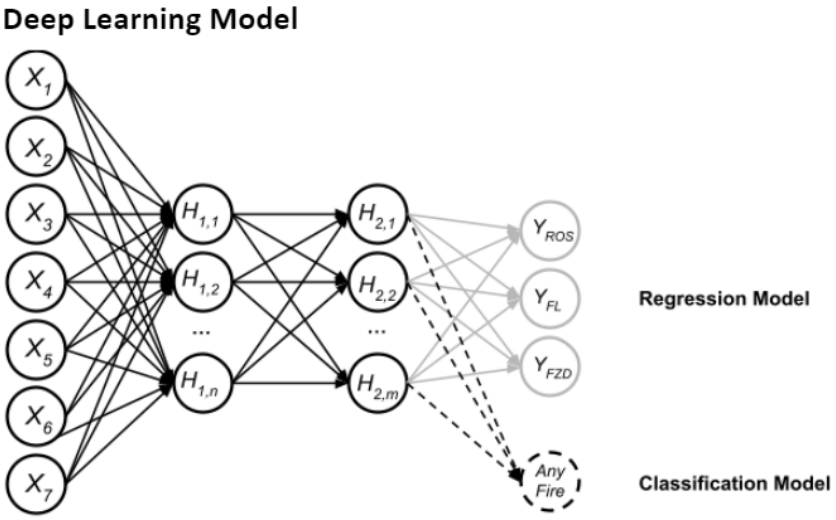

Figure 1. Architecture of feed-forward neural network used for classification and regression, consisting of two hidden layers. Common structures across both models are shown in solid black. The structure unique to the regression model is shown in solid gray. The structure unique to the classification model is shown in dashed-black. Both models take the same seven variables as input that feed into two hidden layers. The classification model requires fewer hidden nodes (n=8, m=8) whereas the regression model benefited from more nodes (n=32, m=8), and they had 145 and 547 parameters respectively. All nodes in the graph are perceptrons (the standard neural network unit) except for the Any Fire node, which also applies a final sigmoid transformation to facilitate binary classification.

3. Results

Use of the detailed 1D fire model as part of a large-scale wildfire simulation (2D or 3D) would provide the correct physics on combustion and steady state statistics but is infeasible due to the computational cost. Therefore, the primary goal for the DL model is to approximate the 1D model as accurately as possible at a dramatically reduced computational cost. For comparison, the average 1D model run time for the training data set was about 70 s for each of the 78,125 cases, whereas the DL model takes about 0.01 s for each case.

We show that the DL model captures the wildfire dynamics well (Figure 2). The scatter plots of the predicted dependent variables versus those from the underlying physical model for the test dataset show that most of the data points are quite close to the perfect reference orange (y = x) line. The mean (standard deviation) of the absolute errors for the dependent variables of ROS, FL, and FZD are 0.078 (0.17) m/s, 0.21 (0.29) m and 0.98 (1.53) m, respectively. Those numbers are close to that for the validation dataset, demonstrating that the DL model is capable of accurately reproducing the fire model's behaviour.

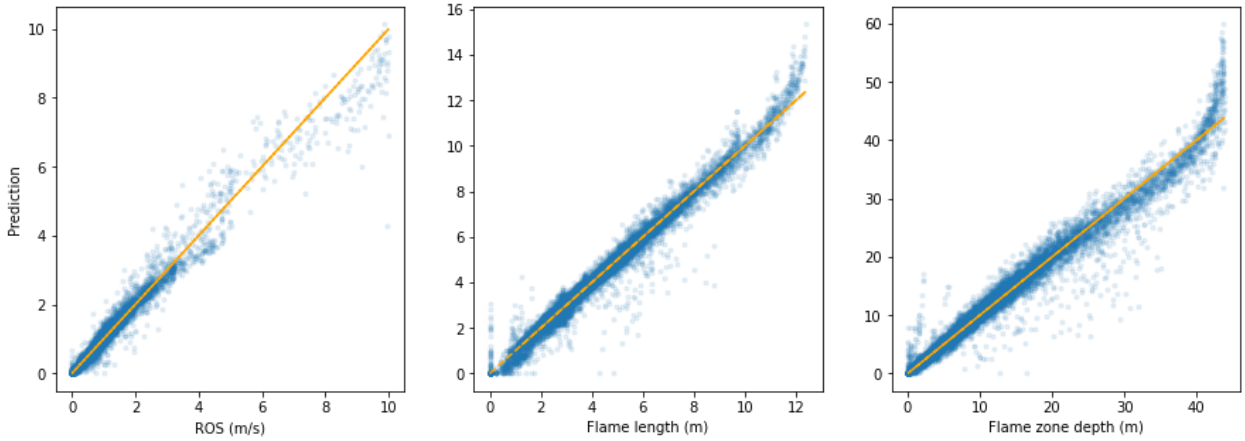

Figure 2: Scatter plot of predictions versus the values from the high-resolution physical model, for all three steady state variables, rate of spread, flame length and flame zone depth.

3.1. Qualitative Analysis

The example fire characteristics represented by ROS, FL and FZD are key descriptors of frontal fire behaviour. We found that errors made by the DL model are at the extremes of the input data. The error around zeros is an indicator that more work is required for the classification model in differentiating the no-fire cases correctly, which is an important problem in practical fire management. The overall underestimate for large ROSs and overestimate for large flames (Figure 2) might be related to dataset filtering, as the wind speed is at most 5 m/s, while we keep ROSs up to 10 m/s for cases with combined wind and high slope angle.

The DL model captured the monotonic dependence of fire behavior on the wind speed and terrain slope (Figure 3). It also and illustrates some extrapolation beyond the training data (recall that the whole dataset training data included only wind speeds up to 5 m/s), not only at the discrete wind speeds reported by the 1D model, but also over the continuous range. However, inevitably, at some point the models' limitations become apparent. Extending the models' accuracy to higher wind speeds can potentially be resolved by including training data at higher wind speeds or considering a probabilistic DL model, e.g. (Dillon et al. 2017), both of which are subjects of ongoing work.

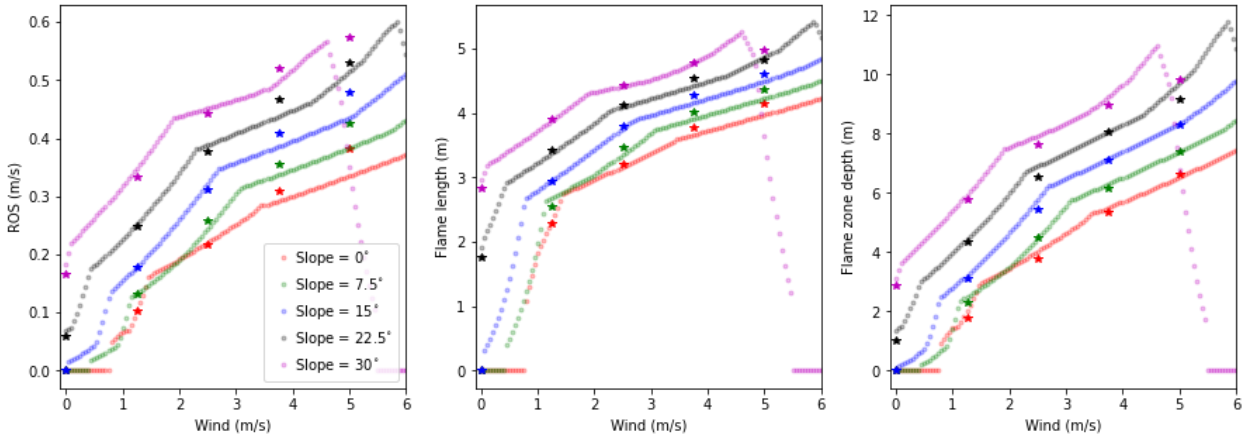

Figure 3: An example of the fit of the DL model (dots) to the 1D model outputs (stars with the same colour) for a range of wind speeds and slopes (0 to 30 degrees), with all other five input variables fixed at their corresponding median values. Extrapolated values are beyond the 5 m/s wind speeds.

4. Discussion

The current demonstration of DL modelling is limited to *homogeneous* fuel, weather, and terrain conditions, which is an oversimplification of the *heterogeneous* conditions where conditions include spatial varying fuels, time varying wind speed, etc. The physical 1D model can deal with this heterogeneity and future work involves investigating the neural network structure that would effectively model such conditions. FFNNs may no longer work as well, but it is likely that more advanced convolutional networks would suffice as demonstrated in Hodges and Lattimer (2019) and Radke et al. (2019).

5. Conclusions

We demonstrated an approach to wildfire modeling that relies on a physical fire spread model in reduced dimension (1D) to resolve the physical processes and DL modeling to produce a computationally efficient representation of the fire behavior. The DL model offers potential implementation in wildfire models at higher dimensions (2D) such as FARSITE (Finney 1998) or 3D where computationally cheap methods are strongly desired. In this capacity, our DL model would perform with low cost compared to the original and be able to address behaviors resulting from fine-scale processes. The DL model accurately associates these steady state variables to the range of input conditions for fuels, weather, and topography, with mean (std) absolute errors of 0.078 (0.17) m/s, 0.21 (0.29) m and 0.98 (1.53) m for ROS, FL and FZD respectively. DL modeling is thus demonstrated as a promising means to represent fine-scale fire behaviors for broad-scale application while maintaining adequate fidelity to the detailed physical processes and inputs. Future work includes modeling heterogeneous input variables and explicitly embedding the DL model in subsequent more sophisticated fire models.

6. Acknowledgements

We thank Zack Ontiveros, Jared Sisk and Carla Bromberg for their helpful discussions, and Lily Hu and Rif A. Saurous for reviewing and approving this manuscript. Isaac Grenfell and Bill Chatham contributed to the 1D model and training data.

Atmospheric modelling; wildfire; modelling of fire risk

Abstract

Over the last decades, several real-time air quality forecasting systems have been developed worldwide to support decision-making to control and manage anthropogenic pollution and its impacts. However, the current forecast systems do not, in general, integrate wildfire emissions. In Portugal, from 1996 to 2021, a cumulative area of 3 Mha burnt by rural fires was registered, accounting for roughly half of Portugal's continental area, causing damage to infrastructure and lives, and in particular impacting the quality of the air and human health. The ability of modelling tools to predict the behaviour of fire smoke is fundamental to effectively improve the accuracy of air quality forecasting and preventing public health consequences. There is a wide variety of models available to simulate fire-smoke phenomena. Nonetheless, it is necessary to consider computational aspects, resources, and goals to choose a suitable model to fit the purpose. In the ongoing FIRESMOKE project, the weather forecast model BRAMS-SFIRE version 5.0 is implemented to be part of the new version 5.6.2 of BRAMS. The BRAMS-SFIRE model was coupled to simulate a broad integration between the surface fire fluxes and the atmospheric environment and presented a good accuracy in terms of the physics of the atmosphere and fire interaction. FIRESMOKE also aims to improve the SFIRE model by including the crown fire behaviour. A predictive model for surface fire spread adapted for the timber litter and understory fire behaviour fuel model and conceptual predictions for the behaviour and size of crown fires, including conditions for the crown fire starting and spreading, were incorporated in the SFIRE model by linking these models with the existent surface fire spread and the numerical scheme of propagation. Furthermore, the smoke emitted by the fire, which spread is estimated with the new approach, was entered into the chemistry module of BRAMS. The goal of this paper is to present the BRAMS-SFIRE developments oriented toward the creation design of a FIRESMOKE system for forecasting and monitoring forest fire smoke emissions that also incorporate anthropogenic and biogenic sources of air pollution, to provide a public access service in the scope of air quality over the domain of continental mainland Portugal.

1. Introduction

Smoke integrated framework modelling systems have been implemented worldwide using a combination of independent models, generally providing smoke transport and pollutant concentrations, forecasting air quality, and producing alerts for the risk of high pollution caused by wildland fires. There are three main framework systems in the United States of America, the BlueSky (Wheeler et al., 2010), the United States National Oceanic and Atmospheric Administration smoke prediction system (Stein et al., 2009), and the ClearSky (Jain et al., 2007). Australia has implemented the Australian Bureau of Meteorology Smoke Prediction System for wildfires and prescribed burning (Peace et al, 2020). In Europe, the Copernicus Atmospheric Monitoring Service (CAMS, Akritidis et al., 2020) monitors emissions from fires and atmospheric composition using satellite observations

and numerical modelling. The Center for Weather Forecast and Climate Studies (CPTEC) at the National Institute for Space Research (INPE) in Brazil provides numerical air quality forecasts with the BRAMS modelling system, including emissions both from fires and urban/industrial sources (Freitas et al., 2017; Longo et al., 2013). In Portugal, modelling studies of air pollution from wildfires have been widely developed by the University of Aveiro (Miranda, 2004; Martins et al., 2012; Valente et al., 2007) which maintains the operational Portuguese air quality forecasting system. However, this system does not integrate wildfire emissions into the atmosphere.

Since Portugal is one of the Southern European countries with a higher number of forest ignitions (Rodrigues et al., 2013), the ability to predict the ignition and spread of forest fires, as well as the behaviour of emitted air pollutants, is important to improve resources management's effectiveness and efficiency, for operations of preventing, detecting and fighting forest fires and monitoring air quality, with repercussions on public health.

The application of a fire-smoke modelling system implies the selection of the models to be included that should take into account aspects, such as computational resources, the required accuracy, and physical phenomena representations. In many cases, the available models interact with each other through downscaling. Only a few models include a broad integration of the atmosphere's dynamic and thermodynamic concepts, comprising surface and soil phenomena interaction with the atmosphere's boundary layer. For high-resolution (meters) applications, this ability is limited to case-studies simulations and, still, with inefficient prognosis simulations of the weather state, and therefore, unsuitable for the fire-smoke forecast with high landscape resolution.

The BRAMS-SFIRE system (Menezes et al., 2016, 2021a; Freitas et al., 2017) aims at overcoming this challenge. BRAMS is continuously under development to better simulate atmospheric processes and the coupled SFIRE simultaneously simulates the interactions between the surface fire fluxes and the atmospheric environment, both on the mesoscale and micro-scale. The BRAMS-SFIRE system, which is the representation of fire spread, presented excellent results in terms of the physics of the atmosphere and fire interaction (Menezes, 2016, 2021a) promising a reliable performance for fire-smoke after the development of the crown fire spread model.

The ongoing FIRESMOKE project (Menezes et al., 2021b) aims to improve the meteorological weather forecast model BRAMS-SFIRE, which also integrates an atmospheric chemistry (CCATT - Eulerian Coupled Chemistry, Aerosol and Tracer Transport) model, with the development of a crown behaviour module. This modelling system operates from meso to local scale and in real-time conditions. The present work is part of this project and describes the incorporation in BRAMS, v5.6.2, of the crown fire propagation and fire smoke pollutants in the chemistry model CCATT.

2. Methodology

2.1. Overview of ongoing fire developments on BRAMS

The SFIRE model (Mandel et al., 2009, 2011) coupled to BRAMS (Freitas et al., 2017) by Menezes (2016, 2021a) allows the analysis of surface fire behaviour taking into account the type of fuel bed and its moisture, the topography and the atmospheric wind. Under the FIRESMOKE project, the developments of BRAMS-SFIRE comprise the up-grade for the last version of SFIRE, the introduction of a mathematical model for predicting surface fire spread (Rothermel, 1972) for fire behaviour fuel model 10 (timber litter and understory) (Anderson, 1982) and of the conceptual model for predicting behaviour and size of crown fires from Rothermel (1991), including conditions for the crown fire starting and spreading for coniferous forest fuel types (Van Wagner, 1977), based on the research of Scott and Reinhardt (2001). This new version of BRAMS-SFIRE, part of the current BRAMS model v5.6.2, would be suitable for the operational forecast of fire size and behaviour, weather, and air quality. This development was designed following the scheme in Figure 1. In this scheme, the crown behaviour introduced in the model is represented in the red boxes, in particular in: the "calculation of the fireline advance" and the "calculation of total fireline intensity".

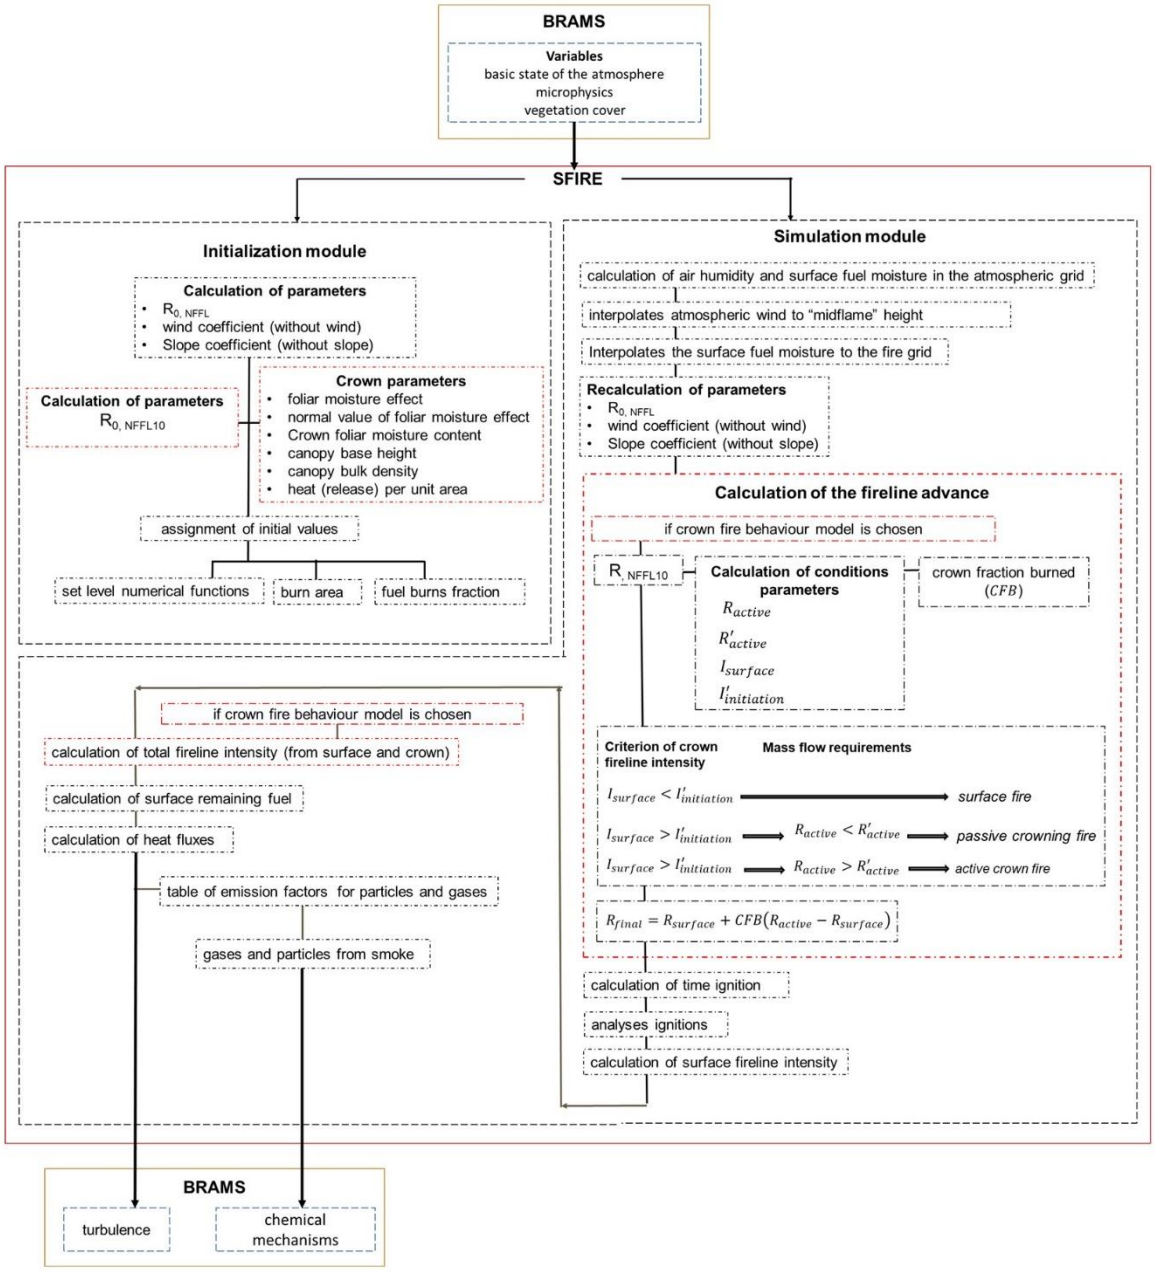

Figure 1- The framework of the BRAMS version 5.6.2 system, with the necessary developments for crown behaviour introduced in the SFIRE model. R is the rate of spread and I is the fireline intensity.

BRAMS-SFIRE, version 5.0, is a one-way coupled fire-atmosphere model. BRAMS injects data from variables of the basic state of the atmosphere, the microphysics, and vegetation cover into the SFIRE, which injects data from variables of sensible and latent heat fluxes from the fire into the boundary layer of the atmospheric model BRAMS, through the turbulence scheme, by carrying out a process of constant exchange during simulation. The SFIRE model uses as surface data high-resolution fuel data on a regular grid, generated using the Northern Forest Fire Laboratory (NFFL) fuel model (Anderson, 1982), and a table with physical and mineral properties, and dendometric measures of the thirteen NFFL fuel models. A new module was built to include the propagation of fire in crown trees by creating new routines and adapting the code of SFIRE's original routines. In this module, the parameters referring to no wind forward rate of spread for a surface fire for NFFL fuel model 10, and the forward rate of spread for NFFL fuel model 10 were programmed. Some considerations were implemented, namely for the crown ignition criteria of Byram's fireline intensity and critical fireline intensity for initiating a crown fire, and the requirements of mass flow, namely, the forward rate of spread for a fully active crown fire

and a critical forward rate of spread for sustaining an active crown fire. Depending on the criteria met, a forward rate of spread for any type of fire - surface, passive crown, or active crown - was associated with the level set numerical method from the SFIRE model, which is the numeric propagation scheme (Osher and Fedkiw, 2003). The assessment of crown fire in SFIRE, requires other estimates of canopy fuel characteristics, namely, canopy bulk density (CBD), canopy base height (CBH), and crown foliar moisture content per cent (FMC) and foliar moisture effect (FME) data. The CBD and FME was programmed from a alometric equation and FMC trough read of data in a "namelist.fire" table, and CBH trough read of a map created from Forest Inventory data from 7964 field plots in Portugal, available from Portuguese Institute for Nature Conservation and Forests (ICNF).With the module "sfclyr_sfire", is made the interaction between BRAMS and SFIRE.

2.2. BRAMS and smoke modelling

Atmospheric emissions during fire events were estimated using the most suitable emission factors ($g.kg^{-1}$), the burning efficiency, the fuel load ($kg.m^{-2}$), and the burned area (m^2). Most of the studies reported in the literature include emission factors for American fuels (e.g. McMeeking et al. 2009; Akagi et al. 2011), savannas/pastures, tropical and extratropical forests (Van Der Werf et al. 2017). For this work, emission factors for Mediterranean conditions were chosen based on a bibliographic review considering values selected by previous studies (Miranda 2004; Alves et al. 2011; Van Der Werf et al. 2017; Vicente et al. 2017, 2012). For Eucalyptus, Acacia and Pinus pinaster species the emission factors were expressed as the average of the emission factors obtained experimentally by Alves et al. (2011) and Vicente et al. (2012, 2017). For the other hardwoods species, the emission factors reported by Van Der Werf et al. (2017) were used. For other resinous, Oak, Chestnut, Cork Oak and Stone pine species the emission factors were obtained by Miranda (2004). Finally, the emission factors obtained for each species were adapted to the NFFL classification considered by the model to update the emission factors parameterization for the Mediterranean conditions.

Within BRAMS concentrations of smoke pollutants are estimated using the species mass released by a fraction of biomass burned (emission factors) dispersed as fluxes, through buoyancy convection and vertical and horizontal advection in dry air along the vertical column in the BRAMS simulated boundary layer, and resolved by chemical mechanisms in the domain of simulation. The selected emission factors of gases and particulate matter from fires, in the domain of simulation, are included in the modelling system through an emission table.

Fire weather index, fire burned area, attribution, causality, pseudo transfer entropy (pTE)

Abstract

Understanding the current fire-climate relationships is of utmost importance in order to assess the potential impacts that projected climate may exert in the near future. However, the many factors involved in fire activity often prevent a proper attribution of the observed variability. Unlike the many previous correlative studies, here we address this problem using a 'causality' measure known as “pseudo transfer entropy” (pTE), relating three widely used fire danger indices to the global observed burned areas (namely the Canadian Fire Weather Index, the Fire Danger Index from the Australian McArthur Mark 5 Rating System and the Burning Index from the U.S. Forest Service National Fire-Danger Rating System). The study has been performed at an spatial aggregation level defined by the RESOLVE ecoregions, attending to their homogeneous fuel and climatic properties, and considering different spatial and temporal aggregation statistics (mean, 90th percentile, 95th percentile and sum).

We present an open, web-based interactive tool to explore and compare the results derived from the causality of these different fire danger indices with the observed burned area. Our results unveil some consistent patterns and three main conclusions can be drawn: 1) in the overall, all indices exhibit a similar performance in explaining observed burned areas, although regional differences may justify the selection of one index over another in regional studies, 2) the aggregation method used at the ecoregion level affects the causality results, with higher percentiles being better explained by pTE than the mean state and 3) the interactive tool designed may serve as a valuable method of intercomparison and analysis for the vulnerability and impact assessment community involved in fire research.

1. Introduction

Fire is an integral earth system process whose causes are complex (Pausas 2021), often difficult to disentangle, and largely dependent on the scale of analysis. Climate is one of the most important factors affecting fire regimes globally (Bedia 2015; Abatzoglou 2018). Understanding the current fire-climate relationships is of utmost importance in order to assess the potential impacts that projected climate may exert in the near future. However, the many factors involved in fire activity often prevent a proper attribution of the observed variability. Unlike the many previous correlative studies, here we address this problem using a 'causality' measure, in particular “pseudo transfer entropy” (pTE), relating three widely used fire danger indices (the Fire Weather Index from the Canadian Forest Service Fire Weather Index Rating System, the Fire Danger Index from the Australian McArthur Mark 5 Rating System and the Burning Index from the U.S. Forest Service National Fire-Danger Rating System) with global observed burned area records at a monthly scale in the last 20 years. Furthermore, we perform an intercomparison of these fire danger indices taking as spatial reference for the analysis the main terrestrial ecoregions.

2. Data collection

To perform this study, three different datasets have been taken into consideration.

2.1. Fire danger indices

The Copernicus Climate Data Store (CDS) catalogue entry named as "Fire danger indices historical data from the Copernicus Emergency Management Service" [ECMWF 2019] offers historical –1979 to present– information for a set of indices related to fire danger. These indicators are retrieved in a regular latitude-longitude grid which covers the entire globe (180ºW to 180ºE, 90ºS to 90ºN) with a spatial resolution of 0.25º and a daily temporal resolution. From this CDS catalogue entry, data for 3 variables was downloaded: the Fire Weather Index (FWI) from the Canadian Forest Service Fire Weather Index Rating System, the Fire Danger Index (FDI) from the Australian McArthur Mark 5 Rating System and the Burning Index (BI) from the U.S. Forest Service National Fire-Danger Rating System.

2.2. Fire burned area from satellite observations

We have used monthly data of Burned Area (BA) at 0.25◦ resolution from the "Fire burned area from 2001 to present derived from satellite observations" database (C3S 2019a; C3S 2019b) which is publicly available through the Copernicus Climate Data Store (https://cds.climate.copernicus.eu/cdsapp#!/home) as part of Copernicus, the European Union's Earth Observation Programme managed by the European Commission (https://www.copernicus.eu/en). The BA data used are derived through the analysis of reflectance changes from the medium resolution sensors Terra MODIS and Sentinel-3 OLCI, helped by the use of MODIS thermal information. The algorithms used are adapted to the native data from these sensors to produce an homogeneous gridded dataset of global coverage containing monthly data of BA at the grid scale, extending the database to the present.

2.3. RESOLVE Ecoregions dataset (2017)

RESOLVE Biodiversity and Wildlife Solutions provides access to this dataset containing information about 846 in-land ecoregions which depict an overall representation of our living planet (Dinerstein 2017). There is an online visor showing the above mentioned ecoregions: https://ecoregions.appspot.com/

3. Data pre-processing

The process to clean and homogenise the raw data –described in section 2– can be divided in the following tasks (schematized in Figure 1):

Despite having the same spatial resolution (0.25º), the fire danger indices data needed to be regridded to the burned area observations grid due to the fact that their meshes presented some differences. Afterwards, the data is temporally aggregated to the same temporal resolution: 1 Month. Therefore, the fire danger indicators are converted from daily to monthly data and the burned area observations remain in a monthly resolution.

As a last step, the ecoregion's metadata is used to perform a spatial aggregation on both the fire danger indices and the burned area observations.

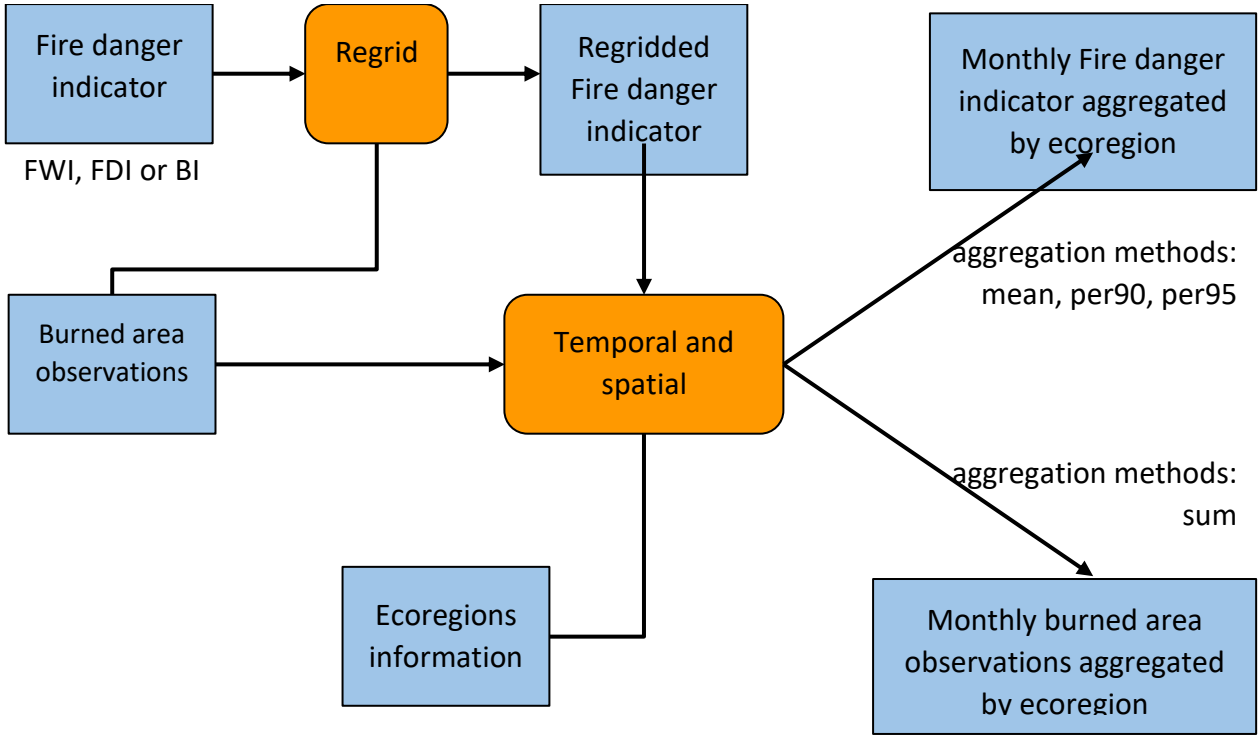

Figure 1- Data pre-processing scheme where the orange boxes represent tasks guided by an algorithm and blue boxes represent data that is used as input/output for the orange boxes.

The aggregation methods used remain constant in both temporal and spatial aggregation algorithms. As established in Table 1, the observed burned area was computed by the sum in order to have the total amount of area burned on time and space. However, the fire danger indices had a different approach and were computed using several statistical options such as the mean, the 90th percentile and the 95th percentile. Other aggregation methods such as the 99th percentile and the maximum were considered, but they presented a lower number of ecoregions with significant results on the causality measure.

Table 1. Combination of variable - aggregation method which were taken into consideration (green).

	MEAN	PERCENTILE 90	PERCENTILE 95	SUM
FWI				
FDI				
BI				
BURNED AREA				

As a consequence, there will be 10 different variables after the preprocessing task (+10 significance test results) for a total number of 693 ecoregions. This number is lower than the total number defined by the RESOLVE dataset due to the following specific facts: 1) some ecoregions do not have enough extent to perform the temporal and spatial aggregation over them –no grid points inside them–, 2) only terrestrial information was provided by both the fire danger indices and the burned area observations, and 3) there are ecoregions with no presence of fire in their surface.

4. Methodology

Once the monthly data is computed, an analysis of the causality from fire danger indices to the fire burned area is performed using a recent fast and effective metric called pseudo transfer entropy (pTE) (Silini 2021). Given

two time series X and Y, we say that X causes Y, if the information contained in the past X, in conjunction with the information contained in the past of Y, can predict the future values of Y, better than the past of Y alone. This means that a fire danger index contains predictive skill on the observed burned area, if a significant pTE from the former to the latter is found. We compute the pTE between the monthly indices, using an embedding size of 2 and a time lag of 1. The embedding size is found by modelling the burned area time series as an autoregressive model.

Once the pTE between fire danger indices and burned area are computed, we have to account for their significance. From the original series we create 100 Iterative Amplitude Adjusted Fourier Transform (IAAFT) surrogates, preserving both the spectra and amplitude distributions, and we compute the pTE between them. The quantiles of the resulting pTE distribution, allow to define significance thresholds. In this study we consider a pTE value above the quantile 90 as significant.

5. Results and discussion

In the context of the research project, a web-app has been designed as a framework to visualise the causality measurement by means of pTE of the different combinations between the set of fire danger indices and the chosen aggregation methods with the total burned area: https://showcase.predictia.es/global-fwi-causality. The aggregation method –as well as the fire danger index– can be chosen on the right side panel. This tool allows the user to browse both the spatial and temporal characteristics of the different types of data. In this way, the user can study the spatial distribution of the causality of the different fire indices (Figure 2), but can also carry out much more in-depth investigations at the ecoregion level (for instance, the Italian Sclerophyllous And Semi-Deciduous Forests), having access to other features such as static data (Figure 3) the analysis of aggregated time series (Figure 4), scatter plot relating the value of the index to the burned area (Figure 5), and a heatmap which compares the index-aggregation method combinations with the burned area on an annual basis (Figure 6).

Some important conclusions can be derived from the web application. Overall, there is not a fire danger index (FWI, FDI or BI) that works globally better since all of them exhibit a similar performance. However, it makes really sense to use some of them over others depending on the ecoregion of interest when performing a local study. Moreover, all three indices follow similar patterns on how the significant ecoregions are distributed because most of them are located in three different main areas: over the boreal strip (Canada, Rusia, Greenland, among others), East-Asia and the Oceanic region, and the centre of Africa –where most of the worldwide area burned is located–.

The use of various aggregation methods allows the analysis of causality depending on whether more intermediate values of fire danger indices or more characteristic values of the extremes of these variables have been taken for the ecoregions of interest. Although there are more ecoregions with significant results when considering the mean value of the fire danger metric (FWI: 298, FDI: 281 and BI: 260) rather than, for instance, the 95th percentile (FWI: 269, FDI: 225 and BI: 240), it seems –as shown in the web-app– that the larger ecoregions are more affected by the extremes than ecoregions with a lower surface area.

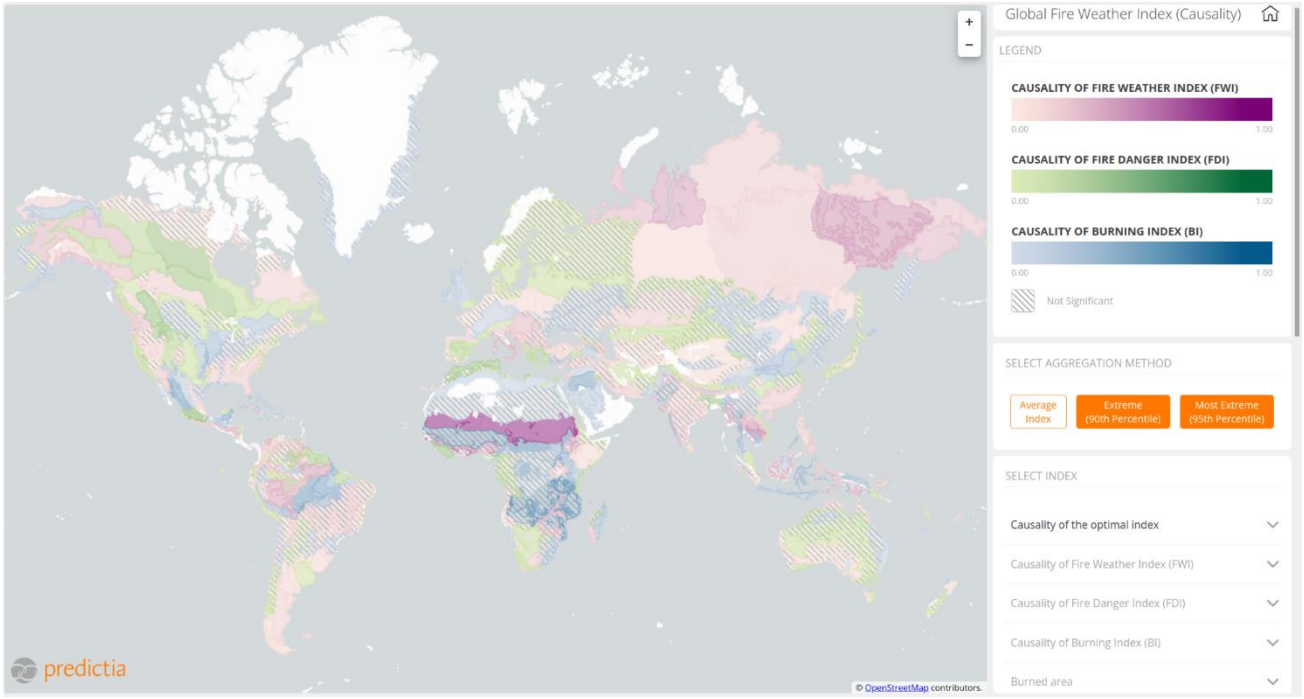

Figure 2- Home page of the web application designed to facilitate access to the processed data. At the left side, the ecoregion map with the 693 ecoregions available during the study. At the right side, there is a panel that acts as a selector to choose the different variables and aggregation methods available.

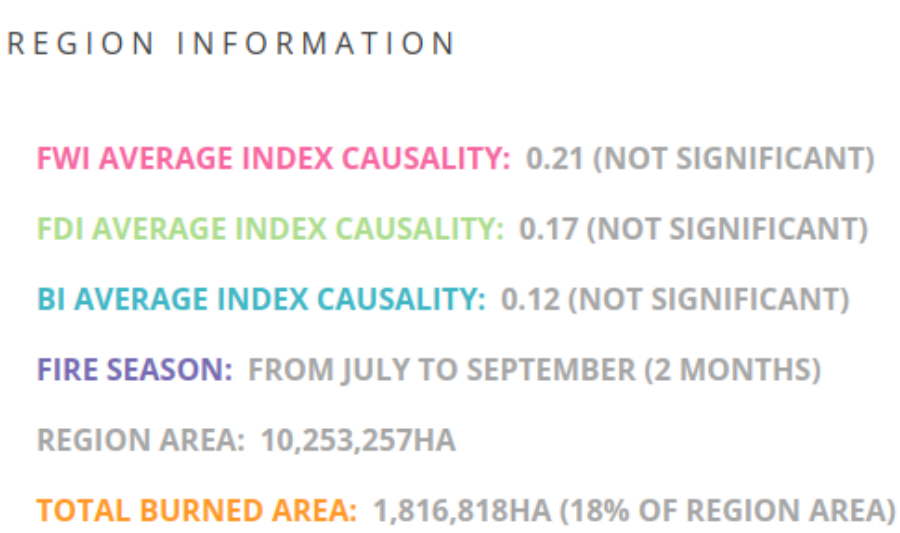

Figure 3- Example of ecoregion static information for the "Italian Sclerophyllous And Semi-Deciduous Forests" ecoregion. This static information contains: the causality of the different indices (FWI, FDI and BI) aggregated by a given aggregation method (95th percentile in this case), the fire season and its length, the ecoregion area and the corresponding total area burned.

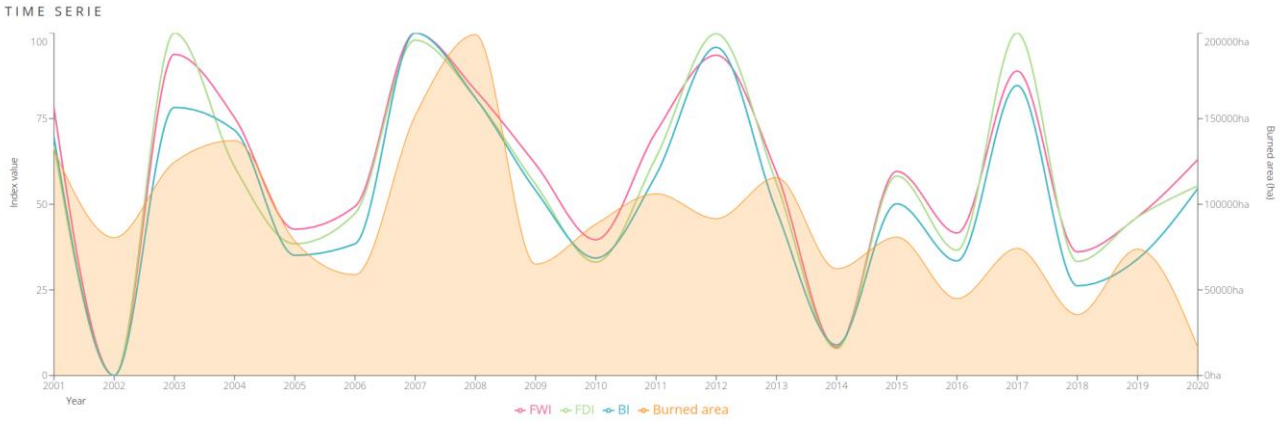

Figure 4- Example of time-serie showing the annual data for different indices (FWI, FDI and BI) aggregated by a given aggregation method (95th percentile in this case) and the total burned area for the "Italian Sclerophyllous And Semi-Deciduous Forests" ecoregion.

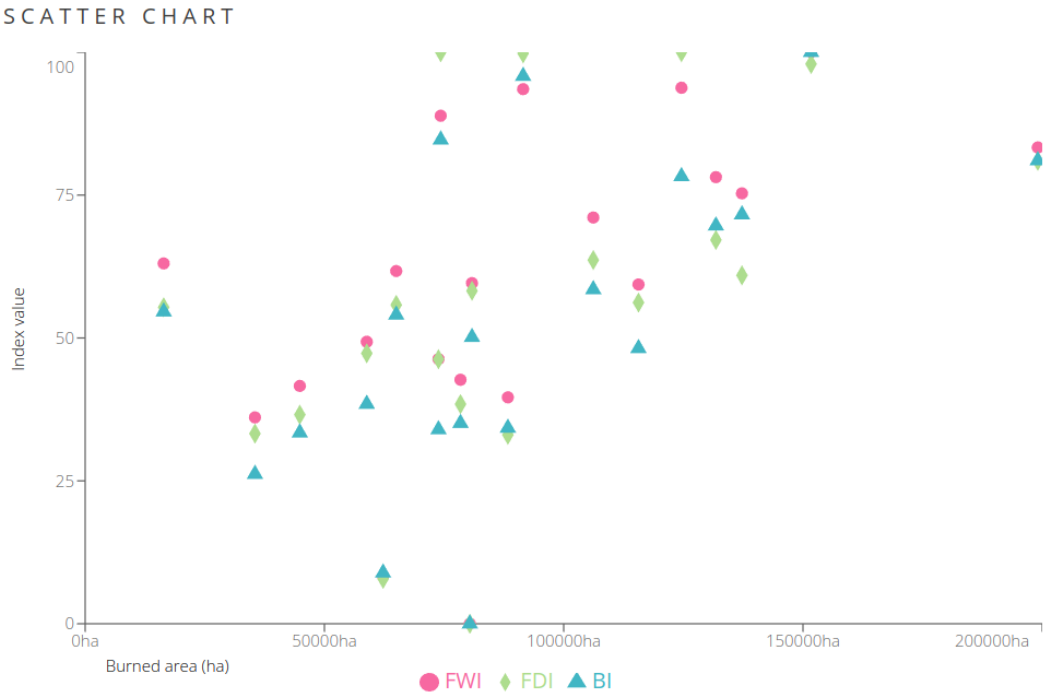

Figure 5- Example of scatter chart showing the relation between the different indices (FWI, FDI and BI) aggregated by a given aggregation method (95th percentile in this case) and the total burned area for the "Italian Sclerophyllous And Semi-Deciduous Forests" ecoregion.

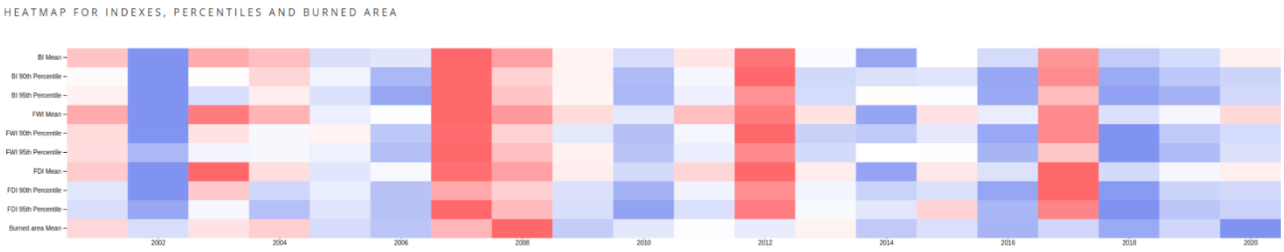

Figure 6- Example of quantile based stripes showing the annual characterisation in comparison with the entire period for all the different combinations of indices (FWI, FDI and BI) and aggregation methods (mean, per90, per95) and the total burned area for the "Italian Sclerophyllous And Semi-Deciduous Forests" ecoregion. From blue to red, it indicates the quantile to which the data belongs: lower, mid-lower, mid-upper, upper.

Wildland fires, Rate of Spread, Prediction Models, Wind, Laboratory experiments

Abstract

In this work, a collection of ten wildland fire rate of spread prediction models that take into account the effects of wind are reviewed and tested against 166 individual laboratory fire tests, available in the open literature. The investigated models include the well-known semi-empirical models of Rothermel, Wilson and Catchpole et al., the empirical models of Rossa and Fernandes, developed using laboratory fire tests and the empirical models of Burrows et al., Anderson et al., Fernandes et al. and the Canadian Forest Fire Behavior Prediction System, developed using field measurements. The performance of the ten models is evaluated, both qualitatively and quantitatively, by employing a range of statistical error metrics. It is shown that the performance of each model is affected by their specific characteristics, in conjunction with the characteristics of the experiments against which the models were evaluated. It is found that the model of Catchpole et al. yields the lowest statistical error metric values in the specific measurement data set employed here. The empirical models that have been developed using field measurements exhibit significant discrepancies against the experimental data, due to the use of specific parameters regarding fuel type, scale and wind speed. Increasing wind velocities up to 3 m/s result, in the majority of the investigated models, in decreasing discrepancies with the experimental data.

1. Introduction

Prediction of the wildland fire Rate of Spread (ROS) is consistently one significant aim of the fire science community, since knowledge of the spatial-temporal evolution of a wildland fire event provides valuable information for a broad range of activities, ranging from fire defence to civilian evacuation. However, a single, catholic model that can accurately predict any potential wildland fire ROS has yet to be presented. This is, partially, due to the complexity of the involved physical phenomena, comprising a synergy of several interacting physical and chemical processes, e.g. combustion, turbulence, kinetics, heat, mass, and momentum transfer. Moreover, a wildland fire is a multi-scale phenomenon, which can manifest in various types of landscapes with potentially different horizontal (continuous-discontinuous) and/or vertical (surface, understory, over-story) fuel configurations. In this frame, a plethora of models has been developed to predict the ROS in various types of wildland fires, each with its own characteristics and limitations.

Wildland fire ROS prediction models are commonly categorized based on their corresponding level of physical foundation. For instance, a ROS model can be developed based on physical-chemical foundational principles and assumptions (physical model), or using statistical correlations stemmed from experimental data (empirical models), or even a combination of both (semi-empirical models) (Pastor et al., 2003). Experimental measurements, necessary for the development of empirical and semi-empirical models, are provided either from laboratory fire tests, which mainly focus on small-scale surface fires, or from large-scale field experimentation (or field observational studies) that, based on the specific characteristics of the landscape, may potentially account for multiple-scale phenomena.

Among the various parameters that influence the behaviour of a wildland fire, atmospheric wind velocity is of particular interest. Early studies recognized the impact of wind as one of the most influential parameters

affecting the rate of spread and the evolution of a fire front (Rothermel and Anderson, 1966). The majority of the empirical and semi-empirical ROS models is able to incorporate the effects of atmospheric wind, either directly or through a model supplement. More specifically, models developed from field experiments seldom account for the case of a "quiescent" wind environment due to its rarity, as well as the fact that quiescent fires are generally characterised by relatively low ROS values, thus representing a "best case scenario".

In this work, ten different wildland fire ROS prediction models of empirical or semi-empirical nature are being reviewed and validated against 166 individual laboratory fire tests, aiming to quantify their prediction accuracy, by means of various statistical error metrics. Their performance is then discussed in detail, taking into account the specific characteristics and limitations of each model.

2. Investigated ROS models

A collection of ten models has been selected to be evaluated. The investigated models include a first group of the well-known "semi-empirical" models of Rothermel (1972), Wilson (1990) and Catchpole et al. (1998), a second group of the "empirical" models of Rossa and Fernandes (2018a, 2018b) developed using laboratory tests and a third group of the "empirical" models of Burrows et al. (2019), Anderson et al. (2015), Fernandes et al. (2009) and also the Canadian Forest Fire Behavior Prediction System (Forest Canada Fire Danger Group, 1992), which are fuel-specific and have been developed using field measurements.

All three semi-empirical models are based in the theoretical work of Frandsen (1971), where the steady state rate of spread, R (m/s) of an advancing flaming front is expressed as the ratio of thermal power per unit area (called the propagating heat flux) received by a fuel element from the flame, I_p (W/m^2) over the energy density required from the fuel element to reach ignition conditions, L (J/m^3). Rothermel (1972) modified Frandsen's ratio, employing theoretical reasoning as well as laboratory experiments, resulting in a semi-empirical model that is considered to be a "benchmark". In this model, the effects of wind and slope were decoupled from I_p, resulting in a "basic propagating heat flux", $I_{p,0}$ that in turn is assumed to be a fraction, ξ of the energy generated by the flame front, I_R (W/m^3). Through laboratory experiments, Rothermel statistically related the model's theoretical properties with specific measurable properties of the fuel, as well as the wind velocity and the slope angle. Later, Wilson (1990), based on empirical evidence as well as statistical data from a broader range of additional laboratory experiments on quiescent conditions, re-examined the model of Rothermel. One of the main modifications proposed by Wilson is the hypothesis that the energy generated from the flame front contributing to the propagating heat flux, stems only from the heat content of the pyrolyzed gases. Finally, the Catchpole et al. (1998) model was based on laboratory experiments on a wind tunnel as well as on the two previously cited models. One of the main ideas of this model was the re-coupling of the propagating heat flux with the effect of wind.

The empirical work of Rossa and Fernandes (2018a, 2018b) comprises two models that statistically relate the quiescent rate of spread, R_0 (m/s) with fuel related properties, whereas a complementary model that accounts for the effect of wind is used. Their work is based on laboratory experiments and, despite being of empirical nature, selection of some of the related properties is based on theoretical reasoning.

The remaining four empirical models are based on field experiments or observational studies of actual wildland fires on specific flora environments. Burrows et al. (2019) modeled the flame ROS on spinifex grassland (a horizontally discontinuous surface fuel) yielding a "parsimonious" three-parameter model. Anderson et al. (2015) presented a group of empirical models based on a large database of shrubland fires. Fernandes et al. (2009) developed a model for predicting the flame ROS on maritime pine stands. Lastly, the Forestry Canada Fire Danger Group (1992) developed the Fire Behavior Prediction System (FBP) from various types of field experiments and observational studies. This model has been developed to accept fuel specific parameters from various fuel models of Canadian flora environments.

The general form of the ten models investigated in this work are presented in Table 1, where σ (m^{-1}) is the surface-to-volume ratio, β (-) is the packing ratio, m_d'' and m_n'' (kg/m^2) are the dry and net fuel load, respectively, h and h_v (kJ/kg) are the heat content of the fuel and the fuel pyrolysis gas, respectively, M (%) is the fuel moisture content, Q_p (kJ/kg) is the heat of pyrolysis, Q_w (kJ/kg) is the latent heat of evaporation of water, s (m^2/kg) is the particle specific surface, c (%) is the fuel cover (for a discontinuous, horizontal fuel geometry), U (m/s) is the laboratory wind tunnel velocity and U_z (m/s) is the field wind velocity measured at a height z (m

or ft). The rest of the parameters, represented by capital letters, namely A to K, represent specific model constants (different for each model), while the parameters represented by lower case letters, e.g. a, b, and c, represent fuel specific constants for the CFFBPS model.

Table 1 – General form of the main equations corresponding to the investigated ROS models.

Rothermel (1972)	$R = \frac{I_{R,1}(\sigma,\beta,h,M,\eta_S,m_n'')*\xi_1(\sigma,\beta)}{L_1(\sigma,\mathrm{M},\rho_b)}(1+\mathrm{A}(\sigma,\beta)*U^{B(\sigma)})$
Wilson (1990)	$R = \frac{I_{R,2}(\sigma,\beta,\delta,h_v,M,Q_p,Q_w,m_d'')*\xi_2(\sigma,\beta)}{L_2(\sigma,\mathrm{M},\rho_b,Q_p,Q_w)}(1+\mathrm{A}(\sigma,\beta)*U^{B(\sigma)})$
Catchpole et al. (1998)	$R = \frac{I_P(U,\sigma,\beta,\mathrm{M})}{L_2(\sigma,\mathrm{M},\rho_b,Q_p,Q_w)}$
Rossa and Fernandes (2018a, 2018b)	$R = R_0 * K * [1 + E * U^F (R_0 * m'')^G (H + M * I)^J]$, $R_0 = A * M^B * \delta^C$ (1) or $R_0 = A * M^B * \delta^C * \ln(D * s)$ (2)
Burrows et al. (2019)	$R = A * \frac{U_z^B * c^C}{M^D}$
Anderson et al. (2015)	$R = A * U_z^B * \delta^C * e^{D*M}$ or $R = A * U_z^B * \left(\frac{m''}{\delta}\right)^C * e^{D*M}$
Fernandes et al. (2009)	$R = A * U_z^B * e^{C*M} * \delta^D$
CFFBPS (1992)	$R = a * (1 - e^{-b*ISI})^c$, where $ISI = A * e^{B*U_z} * \{C * e^{D*M} * [1 + E * M^F]\}$

3. Methodology

Aiming to evaluate the prediction accuracy of the ten investigated ROS models, a set of 166 individual laboratory fire tests, performed on surface fuels, was collected from the open literature. All the experiments were conducted in wind tunnels, where fuel beds were linearly ignited. The fire tests set includes experiments with various kinds of fuels, namely pine needles, excelsior and wood sticks, which results in a high variety of the fuel parameters. A summary of the experimental studies used in this work is presented in Table 2.

Table 2 – Summary of the experimental studies used for validation.

Reference	**Number of fire tests**	**Fuel**
Lozano et al. (2008)	6	Bamboo sticks
Anderson et al. (2010)	133	Pine Needles (Pinus Ponderosa) / Excelsior
Mendes-Lopez et al. (2003)	7	Pine Needles (Pinus Pinaster)

Korobeinichev et al. (2021)	14	Pine Needles (Pinus Sibirica)

In the Atmospheric Boundary Layer, the axial wind velocity decreases with decreasing height, therefore the wind velocity measured at a given height above the flame can be much higher than the wind velocity close to the flame. In order to use the ROS models developed using large-scale field measurements, i.e., Burrows et al., Anderson et al., Fernandes et al., and CFFBPS , the actual "field" wind velocity, U_z, measured at a height *z*, usually in a meteorological station, is required. However, since all fire tests employed in this study were performed in a wind tunnel, there is a need to determine an "equivalent" velocity U_z, using the (usually constant) velocity measured in the wind tunnel, *U*. This wind velocity "adjustment" is performed using the methodology of Albini and Baughman (1979), where the Wind Adjustment Factor (WAF), which corresponds to the ratio of the "mid-flame windspeed" $\overline{\overline{U}}$ to U_z, was introduced. Under the assumption made by Baughman and Albini (1980) that the flame height (above the fuel bed) is considered to be approximately equal to the height of the

fuel bed, the WAF can be estimated using Equation (1), where z and δ are expressed in "ft" (Andrews, 2012). The adjustment of the wind tunnel velocity, U to U_z is based on the additional assumption that the wind tunnel nominal speed (U), due to the small scale of the laboratory fires, is approximately equal to $\overline{\overline{U}}$, an assumption that is commonly made in studies of similar nature (Weise and Biging, 1997).

$$WAF = \frac{\overline{\overline{U}}}{U_z} = \frac{1.83}{\ln\left(\frac{z + 0.36\delta}{0.13\delta}\right)} \tag{1}$$

4. Results and Discussion

The ten ROS models are used to estimate the ROS values in all 166 individual fire tests considered here. Each "predicted" ROS value, R_p (mm/s), is compared against the respective "observed" ROS value, R_o (mm/s); the results are presented both qualitatively, e.g., Figure 1, and quantitatively, by estimating the values of several statistical error metrics. The error metrics selected to evaluate each model's performance are the Mean Absolute Percentage Error (MAPE), the Mean Biased Error (MBE) and the Root Mean Square Error (RMSE), defined in Equations (2), (3) and (4), respectively, where n is the total number of experiments (166 in this case).

$$\text{MAPE} = \frac{\sum_{1}^{n} \frac{\left|R_p - R_o\right|}{R_o}}{n} 100\% \tag{2}$$

$$\text{MBE} = \frac{\sum_{1}^{n} \left(R_p - R_o\right)}{n} \tag{3}$$

$$\text{RMSE} = \left(\frac{\sum_{1}^{n} \left(R_p - R_o\right)^2}{n} \right)^{\frac{1}{2}} \tag{4}$$

The investigated models are evaluated based on their accuracy, i.e., their overall ability to yield predicted values close to the observed ones. The obtained results are graphically presented in Figure 1; the evaluation is assisted by depicting the 10%, 20% and 30% error thresholds, as well.

In Figure 1 (left), results of the semi-empirical and the laboratory-developed empirical models are presented. The models of Catchpole et al. and of Rossa and Fernandes seem to perform well exhibiting, generally, errors lower than ± 30%. The model of Rothermel shows a tendency to under-predict the measured values, thus yielding non-conservative values, a fact that may present an enhanced risk when this model is used in actual operational environments. The model of Wilson, on the other hand, is exhibiting a tendency for over-prediction. Overall, the model of Catchpole et al. seems to yield the most accurate results.

In Figure 1 (right), the performance of the field-developed empirical ROS models is depicted. In general, in this case the results are more sparsely distributed compared to those of the laboratory-developed models. The model of Burrows et al. is found to strongly under-predict the measured values, while the models of Anderson et al. seem to perform slightly better, while still under-predicting the experimental data. The model of Fernandes et al. exhibits the best performance among the five models, while the CFFBPS model predictions are broadly distributed, both over and above the 45 degree slope "line of perfect agreement".

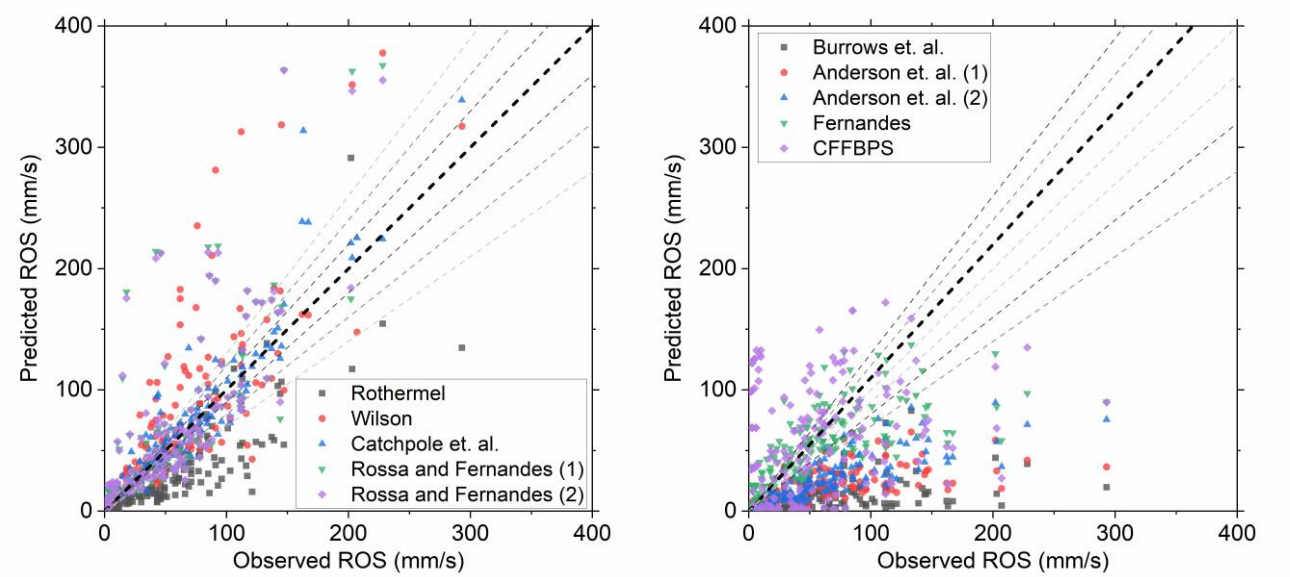

Figure 1 - Comparison of predicted and measured ROS values for the 166 investigated experimental test cases.

The respective values of all calculated statistical error metrics are presented in Table 3. The relative performance of each model may be explained based on their corresponding specific characteristics. For instance, the model of Catchpole et al. exhibits the lowest discrepancies in two out of three error metrics. This may be attributed to the fact that the majority of the experimental data used here (80%, c.f. Table 2) stems from the work of Anderson et al. (2010), who employed the same experimental apparatus used for the development of the Catchpole et al. model. As far as the field-developed models are concerned, their performance mainly depends on four characteristics. Firstly, these models are fuel specific, which means that few fuel-related parameters are required as an input, while the rest of the parameters are integrated in various constants, e.g., statistically fitted coefficient values. For example, the model of Burrows et al. was developed using measurements in fires of spinifex grasslands, a fuel that exhibits horizontal discontinuity. In addition, the only fuel parameter included in the Burrows et al. model is the fuel moisture content. These observations can be related to the fact that the Burrows et al. model exhibited the highest, in absolute terms, MBPE values.

Table 3 - Statistical error metrics for the ten models, validated against the 166 individual fire tests.

Model	**MAPE**	**MBE**	**RMSE**
Rothermel	46 %	-25	40
Wilson	59 %	15	51
Catchpole et al.	**35** %	4	**20**
Rossa and Fernandes (1)	95 %	34	131
Rossa and Fernandes (2)	90 %	33	125
Burrows et al.	79 %	-49	66
Anderson et al. (1)	65 %	-40	58
Anderson et al. (2)	58 %	-35	50
Fernandes et al.	74 %	-6	37
CFFBPS	381 %	**3**	59

Secondly, the fact that field experiments employ live as well as dead fuels may not allow to properly consider the effects of FMC. Thirdly, field experiments usually employ fuel areas exhibiting at least one order of magnitude higher fuel bed width, compared to laboratory tests. Under external wind conditions, the potential ROS depends on the flame front's effective length, which can significantly change during the fire due to the large dimensions of the fuel area as well as the nature of the ever-changing wind (in both magnitude and direction) (Cheney et al., 1993; Cheney and Gould, 1995). Finally, the assumption used to determine the WAF,

i.e. that the height of the flame above the fuel bed is considered to be equal to the height of the fuel bed, is usually not valid in small-scale fires, a fact that might induce further deviations from the observed values.

Figure 2 depicts values of each model's prediction MAPE as a function of wind velocity; the experimentally imposed wind velocities are "clustered" in 4 groups. In the case of ROS models developed using laboratory measurements (Figure 2, left), MAPE is generally decreasing with increasing wind velocity, up to 3 m/s; MAPE values of the Burrows et al. and Anderson et al. models, are not significantly affected by the wind (Figure 2, right).

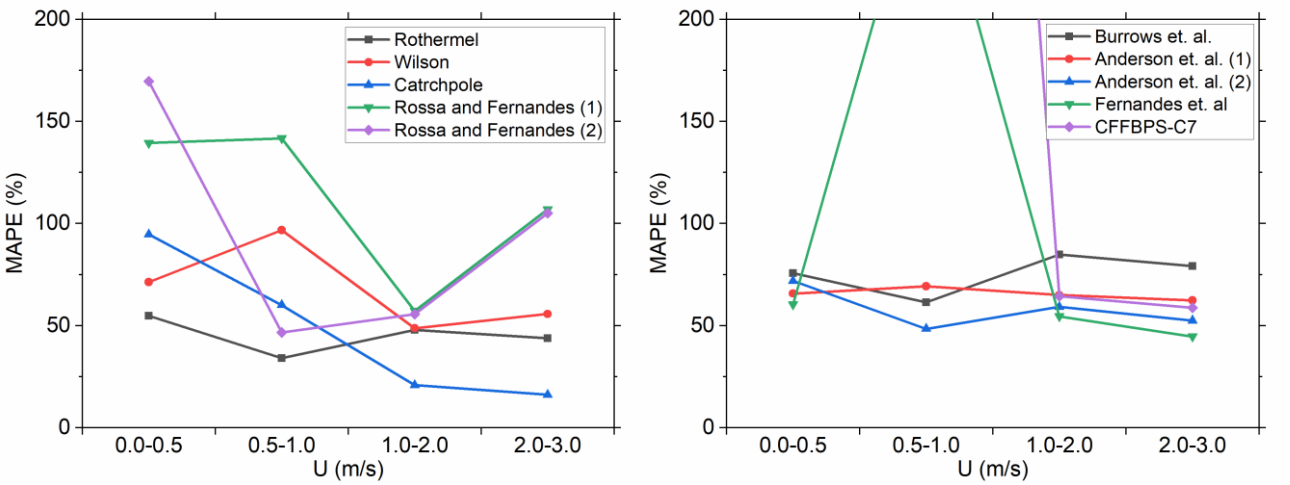

Figure 2 – Effect of wind velocity on the Mean Absolute Percentage Error (MAPE) of each model's predictions.

5. Concluding Remarks

Ten wildland fire rate of spread prediction models were evaluated against laboratory experiments of surface fires. As expected, models that were developed using laboratory data exhibit higher levels of agreement compared to models developed using field data. The field developed models may not be able to accurately predict fires from laboratory experiment due to their fuel specific development (that might differ from the laboratory fuel beds), the fact that field cases are of different scale and are comprised of both live and dead vegetation and, finally, due to the use of severe assumptions in adjusting the laboratory wind speed to the wind velocity. In addition, increasing wind velocities up to 3 m/s result, in the majority of the investigated ROS models, in decreasing discrepancies with the experimental data.

Abstract

In order to assess fire and wildfire risk one must address various features and analyse the danger and vulnerability aspects. Besides fire ignition probability, one of the most important variables for addressing fire danger is fire propagation potential. Fire propagation potential (FPP) can be described as a quantitative description of the circumstances under which, if fire ignites, it leads towards propagation of fire. This means that not all ignitions cause propagation of significant fires. Some ignitions are easily extinguished and pose no danger to vulnerable assets. On the other hand, some ignitions result in large and mega fires, causing large, burned areas and huge casualties. Fire propagation potential (FPP) provides quantitative distinction between these two different circumstances.

Machine learning techniques are more and more applied in fire management tools as they provide us with techniques for learning from the past data and predicting the future outcomes. Majority of previous work is focused on analysis of the large fire events, their causes and development. However, when modelling the FPP, we should consider situations on both ends of the outcome spectrum - situations when fire ignites and propagates and situations when fire ignites and does not propagate. If one uses only data on fires that propagate, without considering the alternative situations data, results that are achieved can be incomplete.

In this paper we propose a novel and more full approach to fire danger assessment by analysing situations of both cases - high and low fire danger. We simplify the value of FPP and consider that in cases the fire propagates the value of FPP is one, and zero otherwise. We used data collected from the events of both cases. We obtained a balanced dataset and trained machine learning model with a data set having representatives of both ends of the FPP spectrum.

The research is demonstrated in the study area of Split and Dalmatia County. We consider past fires that are sensed by satellite and recorded in the EFFIS system as situations when FPP had value 1. To assess the situations when FPP was 0 we analysed the fire intervention database maintained by fire departments. We filtered fire interventions related to forest fires that lasted less than 2 hours and engaged 2 or less firefighters since these records represent time and place of the fire that did not propagate.

For these two cases of events, we collected Sentinel-2 imagery and weather data that consists of temperature and wind speed. Sentinel-2 imagery pixels were extracted for the area associated with both types of events. The dataset was split into train and test datasets, where classifiers were trained by using 80% of data and 20% of remaining data was used for testing the classifier performance. Experiments were conducted by training classifiers using commonly used classifiers - Decision Tree Classifier, K-Nearest Neighbors, Multi-layer perceptron, Random Forest Classifier, Naive Bayes Classifier and Logistic regression. The best performance, according to the R2 score and RMSE is measured on Decision Tree Classifier.

1. Introduction

Assessment of fire danger is done by assessing the probability of occurrence of hazardous fire event. It is obvious that fire poses a hazard or threat in case it ignites, but not all ignitions result in a hazard. In case the fire does not propagate it is not considered dangerous. That is the reason to study the fire propagation potential (FPP) as a limiting factor for fire danger assessment.

Fire danger is studied in literature and various approaches, among which physics-based methods, statistical methods, and machine-learning methods for fire danger predictions are proposed (Pourghasemi 2020). Machine learning methods have shown itself useful for analysis of past events and predicting the future events when

appropriate data is collected (Pham, 2020). Thus, in order to apply Machine learning methods we must obtain a dataset that will be used in the training phase of building the machine learning based model and select the appropriate learning algorithm.

Previous attempts of building a machine learning based model for fire danger prediction mostly relied on data of high fire danger from historical fires (Dimuccio,2011;Tehrany 2019; Pourghasemi 2020) but are neglecting the cases with low fire danger.

In this research we created a balanced dataset covering both cases - fires with burned areas and fire ignitions that did not result in spread. This dataset is used for building a machine learning classifier that distinguishes between situations with high and low FPP.

2. Materials and methods

2.1. Study area

Study area of this research is Split and Dalmatia county, a central-southern county in Croatia with the population of 455,242 (2011) and the land area 4,540 km2.

This region often suffers from large fires especially during the summer season.

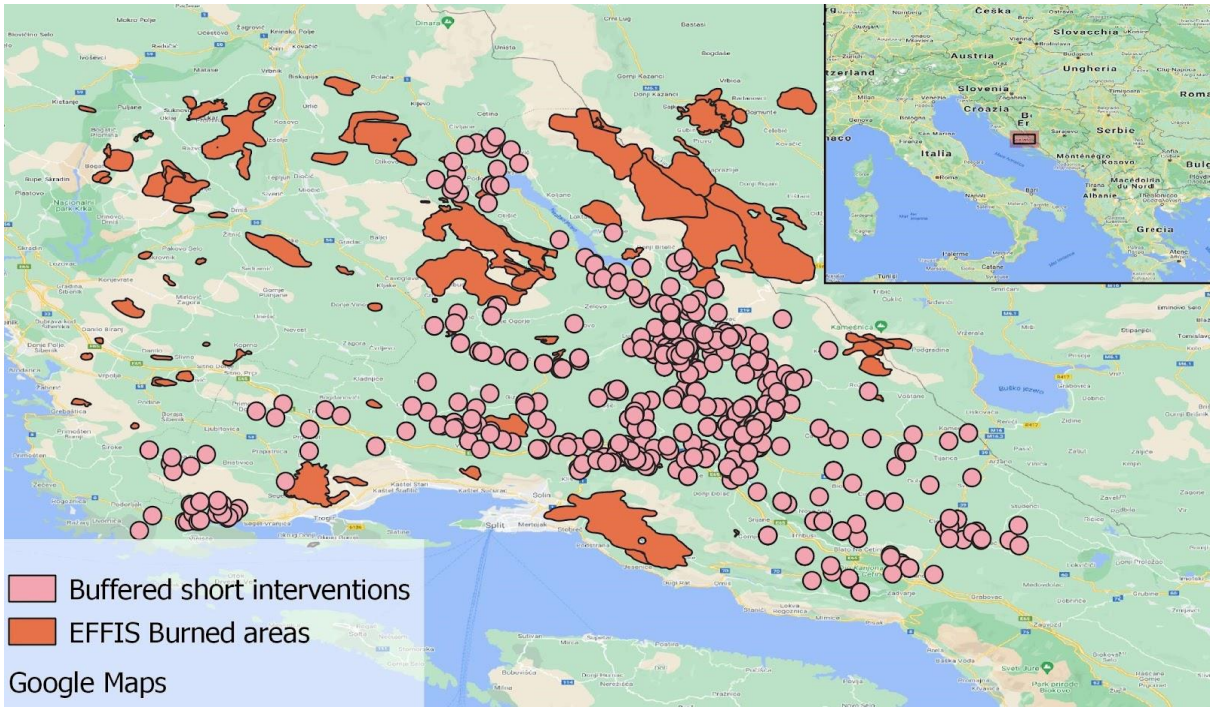

Figure 1- Study area -Split and Dalmatia County with burned areas and locations of interventions without fire spread we used in our research.

2.2. Dataset

In order to observe two cases on both ends of fire propagation potential values we collected data from two different sources.

First, we collected burned area data from the European forest Fire information system (EFFIS) that described burned areas in the study area from 2015 till the end of 2021.

Second dataset was fire departments intervention records from the 2017 till the end of 2021.

These two datasets were used to observe two cases:

Case 1: fire that ignites and propagates to the surrounding area. We observed such situations resulting in burned area noticed by EFFIS system.

Case 2 fire that ignites but is easily extinguished. We observed fire interventions with the description of forest fire, where intervention lasted less than 2 hour and less than 3 firefighters were engaged.

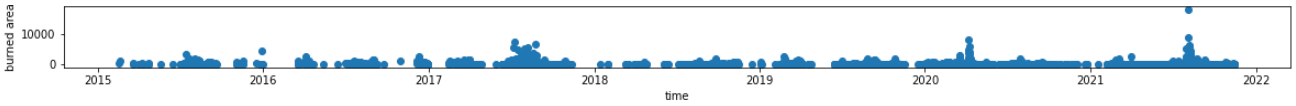

Figure 2- Temporal distribution of burned areas during the period 2015-2022

Reflecting on the fire triangle, the mostly used tool for fire behaviour understanding, propagation of fire is limited by the presence of three variables: fuel, heat, and oxygen. If ignition has happened, heat is present, thus we must determine the presence of fuel and oxygen to enable fire propagation. In our research we used two sources of data that we use as a proxy for quantifying the presence of fuel and oxygen - Sentinel-2 imagery and weather data. Sentinel-2 imagery is collected as Level-2A reflectances in 12 available wavelength bands for the study area. We also collected weather archived data for the period of interest. For each burned area we collected Sentinel-2-L2A pixels value with 60m resolution for each of the 12 bands, representing atmospherically corrected surface reflectances of the 12 wavelength bands, from the imagery taken between 1 and 3 days before the fire.

For the Case 2 events, interventions were described not as an area but as the single point. We collected the same Sentinel-2-L2A pixel values with 60m resolution for the 1 km buffer area surrounding the ignition incident.

This resulted with a dataset each row representing a 60x60m pixel described with 12 values of reflectances for each of the Sentinel-2 band at the time of the event, air temperature for the date of the event, wind speed at the time of the event and value 0 or 1 indicating whether the pixel is burned or not burned.

48604 data items representing burned pixels, and 216376 pixels representing non burned pixels, with a total of 264980 items. However, this dataset is not balanced. We used a common balancing method - down sampling to create a balanced dataset that has a similar number of representatives of both classes. We randomly selected only 25% of majority class samples and created a balanced dataset that consists of total 102698 data items.

Figure 3- A sample of the balanced dataset used for classification

2.3. Classification Algorithms

The dataset described in the previous section was randomly splitted into two subsets - train dataset consisting of 80% of the data and test dataset consisting of the remaining 20% of the data. We used the train set to train a classifier that would predict which case the pixel belongs to - case 1 - the pixel will burn if fire ignites, or case 2 the fire will not propagate over the pixel.

The following machine learning algorithm were tested for classifying Case 1 and Case 2 pixels

- Logistic regression
- Naive Bayes Classifier
- K-Nearest Neighbours with 3 neighbours
- Decision Tree Classifier
- Random Forest Classifier with maximum tree depth 5
- Multilayer perceptron with 10 hidden layers

For each classifier we calculated two evaluation measures - R-squared - R^2 score (Chicco, 2021) and Root Mean Square Error (RMSE) (Jierula, 2021). The R^2 and RMSE were calculated both on train and test set in order to check for overfitting.

3. Results

The selected classifiers were trained to predict two classes of propagation potential based on Sentinel 2 imagery and weather features. The classifiers performance measures, as measured on our dataset are shown in Table 1.

Table 1. Performance evaluation measures of classifiers used in the experiment

ML ALGORITHM	TRAIN R^2 SCORE	TEST R^2 SCORE	TRAIN RMSE	TEST RMSE
K-Nearest Neighbors	0.999528	0.999056	0.021728	0.030727
Decision Tree Classifier	1.000000	0.999056	0.000000	0.030727
Multi Layer Perceptron	0.990676	0.990244	0.096559	0.098773
Random Forest Classifier	0.943704	0.938159	0.237269	0.248679
Logistic Regression	0.835045	0.828639	0.406147	0.413958
Gaussian Naive Bayes	0.839293	0.828009	0.400882	0.414717

Ideal value of R^2 measure should be 1. The closer the R^2 value to 1, better the performance of the classifier. We can see that tested algorithms predict the propagation potential that is corelated with our label. The RMSE value should be as small as possible. All tested classifiers have small value of RMSE.

4. Conclusion

From the results shown in Table 1 we can observe that non-linear classifiers result in better performance on our data set. Thus, we can conclude that the relationship between fire propagation potential and land surface reflectances and weather is not linear and straightforward, but rather complex. This was expected since we did not consider different types of land cover, vegetation, and roads, but merely used Sentinel-2 imagery as raw input of low-level land cover features. The resulting empirical propagation potential classifier gives promising results and performs well on test dataset. In future work we will investigate the results on larger study area and cross compare the results on areas with different climate and topographic features. Also, in future work we will investigate the usage of semantic data about the land and weather features to obtain a more general model.

Rothermel spread model, fuel sensitivity, remote sensing

Abstract

Fire behavior models ingest a variety of inputs such as weather, topography, and fuel maps to generate predictions of how a fire will behave. Model prediction accuracy is thus to some degree dependent on the fidelity of the input data sources. For many widely used fire models, however, the exact relationship between fuel input quality and model performance is not well understood. This paper seeks to quantify the relationship between input fuel data and output prediction accuracy in popular fire models based on the Rothermel fire spread equation. In particular, it examines how granularity of fuel classes and spatial resolution affect the accuracy of fire behavior predictions. Fuel maps used in the study are generated from remote sensing images using machine learning to map between satellite and ground conditions. Prediction accuracy is evaluated with multiple metrics including rate of spread (ROS) and fire front shape. The outcomes of this study will provide important guidance as to the benefit of producing high fidelity fuel maps when utilizing the Rothermel spread equation to predict fire behavior.

1. Introduction

Fire behavior models use several input data layers such as fuel type (defined as fuel class), moisture content, surface-to-volume ratio, heat content of fuel, bulk density of vegetation, wind velocity and topography of the terrain for predicting rate of fire spread (ROS), flame length (FL) and fire perimeter. All of the aforementioned parameters are subject to spatial and temporal changes by natural occurrences (landslides, change in weather pattern, wildfires, etc.) and human activity (prescribed burns). Therefore, the accuracy of the fire behavior model relies on the accuracy of these input layers data. It is both time-consuming and costly for land managers to keep track of the changes in the fuel type distribution and properties. The use of satellite data can quicky reciprocate the changes (in a matter of days) in fuel type and weather conditions to generate accurate input data (when coupled with machine learning algorithms) for existing fire behavior models.

In this work, an external pre-trained machine learning model will be used to label updated Sentinel-2 MSI data with coarse land cover labels, having a spatial resolution of 10 meters. These labels will be compared pixel-by-pixel, with top-level Scott & Burgan classes (Scott & Burgan, 2005) from the most recent LANDFIRE (LF) fuel product available (resampled to 10-meter resolution, Fig.1). For all pixels, if the land cover model disagrees with the LF Scott & Burgan classification that pixel will be reclassified with the updated derived classification. For example, the most recent LANDFIRE 2020 product may label a pixel as “Timber Litter 1” (TL1) while the updated land cover model – called the Lockheed Martin (LM) land cover model – labels the same pixel with current Sentinel-2 as “Shrub & Scrub” at that same point. Subsequently, this new classification will be stored with this pixel reclassification as, “Shrub 1” (SH1). The output of the LM fuel model will be a raster map of Scott & Burgan classes. This LM fuel model will be validated by predicting the rate of spread and fire perimeter of the Cameron peak fire (for which significant data points are available) which is the largest recorded wildfire in Colorado history.

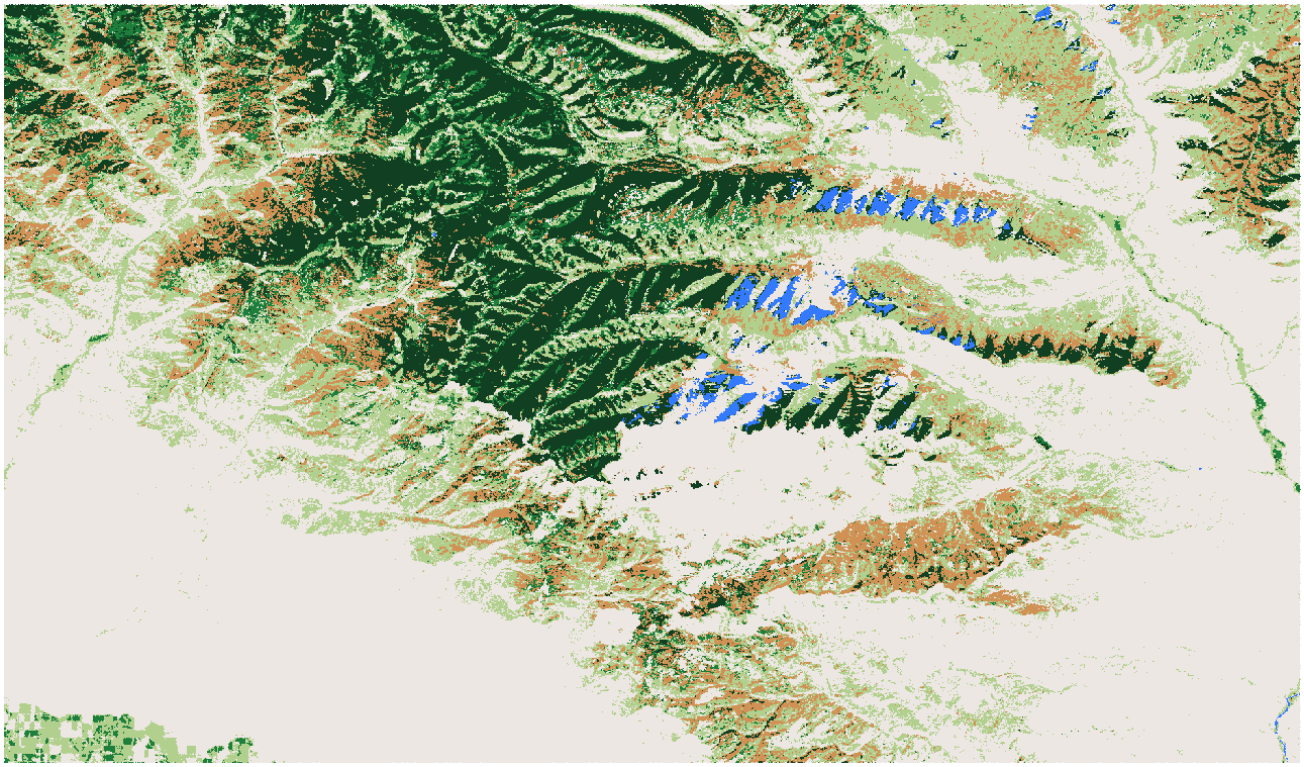

Figure 1 - Sample fuel map generated at 10m pixel resolution using Scott & Burgan fuel classes.

2. Fire Behavior Models in the Field

The most accepted fire prediction models in the United States, the Rothermel-based fire behavior model (Rothermel, 1972) will be used for predicting the rate of spread, flame length and fire perimeter for the LM fuel models.

3. Methods of Evaluation

The fire spread rate and fire perimeter at different times will be used for evaluating the LM fuel model.

4. Sensitivity to Fuel

This section will describe how various fuel map attributes were examined and observations of how each attribute affected prediction accuracy.

4.1. Granularity of Classes

Fuel class granularity will be examined through the comparison of Anderson and Scott & Burgan fuel classes (Scott & Burgan, 2005). Similar maps will be generated with the different fuel models and will be evaluated on how they influence the resulting fire shapes.

4.2. Spatial Resolution

Spatial resolution will be evaluated by generating a high-resolution fuel map and then down sampling it multiple times and comparing with prediction accuracies after each down sampling. Similar procedure will be followed for predicting the influence on fire spread through fire shapes at different times. A sensitivity analysis will also be carried out.

5. Conclusions

Based on the work reported here, recommendations will be made for generating accurate fuel maps to produce optimal prediction results with the Rothermel-based fire behavior models.

Evaporative demand, fire danger, wildfire, prescribed fire

Abstract

Evaporative demand, the upper limit of actual evapotranspiration (ET) that could occur given unlimited surface water supply, has a strong connection to drought and wildfire potential in the western United States and globally. A physically based evaporative demand formulation incorporates temperature, wind speed, humidity, and incoming shortwave radiation – components that drive land surface-atmosphere interactions and drying. These are also the primary physically based components in the U.S. National Fire Danger Rating System – some combination of temperature, humidity, and wind speed are also common inputs to other fire danger systems. Thus, association between evaporative demand and fire danger can be expected and this has previously been demonstrated such as via the Evaporative Demand Drought Index (EDDI) indicator. For example, EDDI can be decomposed to examine the weighted physical factors over time leading up to a fire event. Utilizing evaporative demand for monitoring and prediction can serve as an early warning of fire potential depending on climatological persistence patterns for weeks to possibly months in advance though rapid onset anomalies may yield a similar result. Evaporative demand can also inform prescribed burn planning. Based on the exploration of EDDI indicators prior to fire events, this presentation will discuss analyses of evaporative demand in the context of both wildfire and prescribed fire to better understand if and how evaporative demand can be used to inform wildland fire management decisions.

1. Discussion

Evaporative demand (E_0), the upper limit of actual evapotranspiration that could occur given unlimited surface water supply, has a strong connection to drought and wildfire potential globally. Plant water cycle processes including soil water uptake, plant water storage, and water loss through transpiration all influence plant water availability. Extensive transpiration can dominate the plant water cycle leading to increased fuel flammability. A physically based E_0 formulation incorporates temperature, wind speed, humidity, and incoming shortwave radiation (Allen et al. 2005) – components that drive land surface-atmosphere interactions and drying. These are also the primary physically based components in the U.S. National Fire Danger Rating System as well as inputs to other fire danger systems (e.g., temperature, humidity, and wind are primary inputs for the Australia Forest Fire Danger Index).

The Evaporative Demand Drought Index (EDDI; Hobbins et al. 2016; McEvoy et al. 2016) is based only on E_0, which has been shown to signal the onset of rapid drying and flash drought before other indicators such as precipitation, soil moisture, and actual ET. EDDI may better capture short- and long-time scale dry dynamics and provide early warning for fire activity. McEvoy et al. (2019) showed that EDDI generally had higher correlations to fire danger outputs than other commonly used drought indicators.

Figure 1 shows EDDI for three 2018 fire events in California – the Mendocino and Carr fires in July and the Camp fire in November. Colors denote the EDDI percentiles with red colors signifying higher percentiles. In this example these three major fires occurred when EDDI averaged above the 95th percentile for the two months leading up to the fires.

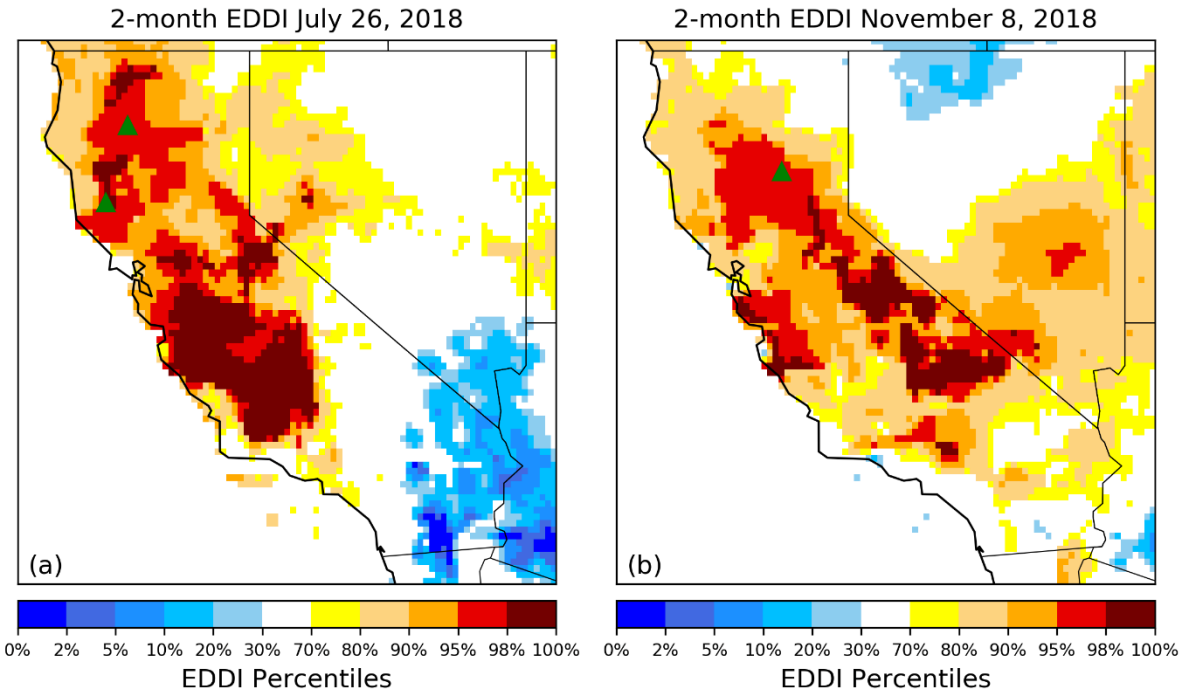

Figure 1 EDDI 2-month percentile categories for (a) 26 Jul 2018, and (b) 8 Nov 2018. Triangles represent the Mendocino (lower) and Carr (upper) fires in(a) and the Camp fire in (b). From Brown et al. (2020).

EDDI can be decomposed to examine the weighted physical factors over time leading up to a fire event. Figure 2 shows the E_0 anomaly and the contributions from each of its drivers aggregated over a two-week window moving forward daily across Sonoma County, California from mid-August through the end of October 2018, a period of eight weeks prior to and three weeks following the ignition of the Tubbs Fire. E_0 is elevated above its climatological median (50^{th} percentile) throughout the period. A notable spike of much above-normal temperatures occurred prior to the fire outbreak from 31 August until 5 September. During the first two weeks of September a positive E_0 anomaly remains but becomes near normal for the second half of September due to the mitigating effects of above-normal humidity and below-normal wind speeds and solar radiation. In early October temperature remains near normal but the combined effects of now-below-normal humidity and above-normal wind speed and solar radiation dominate the E_0 anomaly, which climbs again through the day of the fire ignition (8 October) and afterwards. On the day of ignition, E_0 reaches its second spike when it exceeds its 95th percentile. This indicates that near-surface moisture was decreasing and a drying of the air mass was taking place even during a period of near-normal temperatures. It is also worth noting that wind speed had the largest contributions during the onset of the second spike from 29 September through 2 October. These patterns are suggestive of an important role of rapid (flash) meteorological impacts on fuels. Autumn in California is climatologically dry; an E_0 indicator such as EDDI highlights factors besides soil moisture drought that contributes significantly to drying of fuel moisture. E_0 should work suitably well in other fire prone regions.

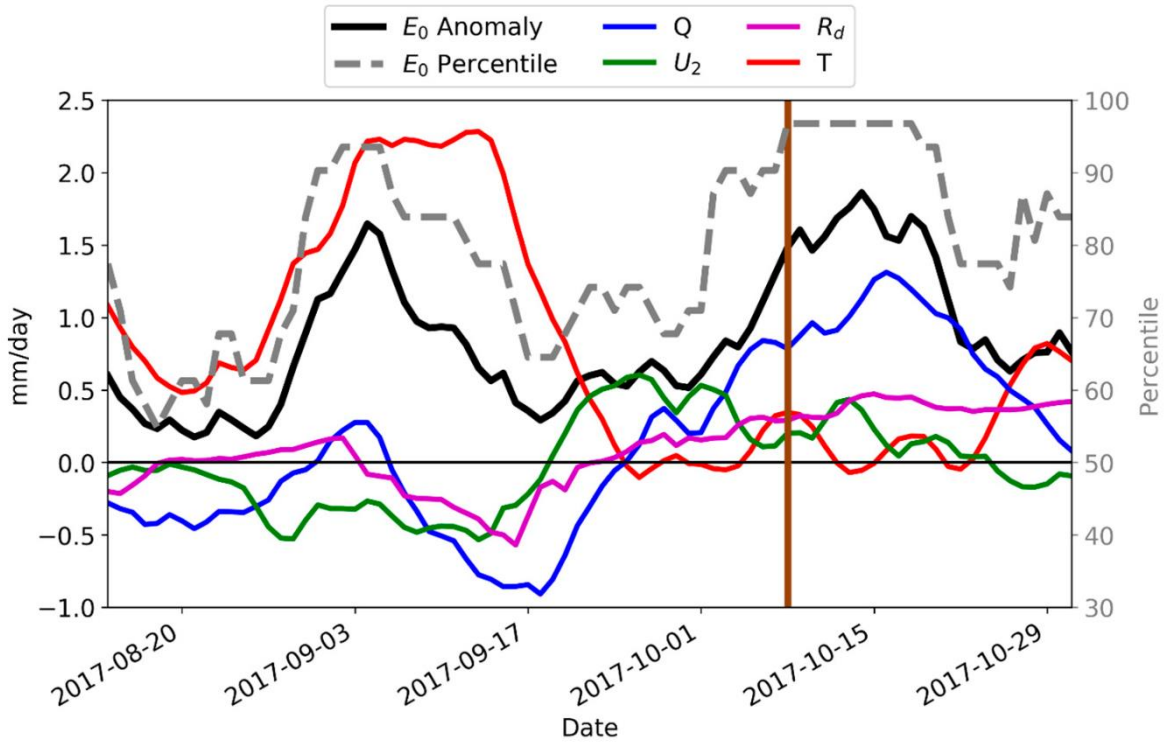

Figure 2 Evaporative demand (E_0) anomaly prior to and during the October 2017 Tubbs fire in Sonoma County, California. The 2-week E_0 anomaly (black line) is spatially averaged across Sonoma County. The contributions from each of its drivers are shown as colored lines (temperature (T) in red, specific humidity (Q) in blue, downwelling shortwave radiation (Rd) in purple, wind speed (U2) in green); percentiles of 2-week E0 are shown in dashed grey (right-hand axis); and the ignition date of the Tubbs fire is shown as a vertical brown line. From McEvoy et al. (2019).

Utilizing E_0 for monitoring and prediction can serve as an early warning of significant fire potential weeks to possibly months in advance especially given persistent climatological patterns though rapid onset anomalies may yield a similar result. The scope of this project is to determine the extent that E_0 can be used as an early warning for significant wildfire potential. Soil moisture drought alone is not always a sufficient indicator of fire potential. Cases of large fires with normal soil moisture conditions but high E_0 have been observed. Short time (e.g., weekly scale) periods of anomalous high E_0 may be sufficient to allow for periods of increased fuel flammability, though this likely will vary depending on vegetation type. Persistence of high E_0 can serve as one indicator of fire potential. That is, while weekly-scale anomalous E_0 can serve as an indicator of increased fire potential, monthly to seasonal scales that are persistent with anomalous E_0 can also serve as an indicator. E_0 could also be used for prescribed burning. For example, if E_0 was calibrated to fuel flammability, then observed E_0 could help inform the potential success of a burn given a specific management goal or serve as indicator of a potential burn escape.

E_0 is already being utilized for some fire activities, especially in California. Examples include successful integration of EDDI into fire management operations with California Predictive Services such as submitting Severity Funding Requests, daily fire weather briefings, seasonal fire potential outlooks, and incorporated into the Fire Behavior Field Reference guide and wildland fire fighter training curriculum (Brent Wachter, *pers. comm.*).

Keywords

Extreme fires, fire risk scales, Canadian Fire Weather Index, Fuzzy c-means, decision tree

Abstract

With climate change, large, unpredictable, and difficult to suppress forest fires are increasingly frequent. To increase the ability to anticipate and respond to these extreme events it is necessary to characterize the meteorological conditions associated with the risk levels of these events. The main objective of this work is to automatically identify those severity conditions and extract classification rules to characterize extreme forest fires with at least 100ha of burned area (90% percentile) in mainland Portugal for the period 2001-2020.

The conditions characterizing the extreme fires are elicited by applying fuzzy clustering and predictive methods to forest fire data and corresponding fire risk indices, namely the Canadian Forest Fire Risk Index (FWI), and subindices, as well as the Continuous Haines Index (CHI), provided by the Portuguese Institute of Sea and Atmosphere (IPMA). The dates and localization of fires are obtained from the shapefiles provided by the Portuguese Institute for Nature Conservation and Forests (ICNF), and complemented with data from the MODIS Global Burned Area Product MCD64A1 downloaded from the University of Maryland repository.

The popular fuzzy c-means (FCM) algorithm is applied to group fires into five and seven clusters, with no pre-specified ground-truth severity. Then each cluster is labelled with the fire risk scale class assigned to the cluster's prototype considering the EEFIS scale (European-Forest-Fire Information System) for five clusters and IPMA fire risk scale for seven clusters, respectively. Fuzzy Sammon mapping has been used to visualize and validate the fuzzy partitions.

Using the data from 2001-2018, decision trees (DT) were induced in order to obtain the conditions and thresholds that characterize the obtained clusters, and tested with the data from 2019 and 2020. To ensure the quality of the classification results robust validation techniques such as cross-validation and bootstrapping as well as evaluation metrics are applied.

The DT rules described by conjunctions of the fire risk indices and thresholds, were not always in agreement with the reference forest fire risk prediction scales, revealing the importance of adapting the indices values according to the region in question and taking into account several factors (forest fire risk indices) in the analysis of the conditions associated with the level of risk of an extreme forest fire. The proposed approach shown to be a proof of concept to derive an empirical fire severity risk scale for the collection of used indices and to compare the results with the two fire risk scales used by IPMA and EEFIS.

1. Introduction

With climate change, those large, unpredictable, and difficult to suppress forest fires will become increasingly frequent (Petroliagkis et al., 2015). In Portugal, wildfires continue to be one of the most serious natural catastrophes, due to their high frequency and intensity, and with climate change they will become more frequent. To increase our ability to anticipate and respond to these phenomena, it is necessary to study and characterize the meteorological conditions that favor them.

There is no generally accepted definition of what an extreme fire is. This difficulty in defining what an extreme fire is clearly explained by (Viegas, 2012) and (Tedim et al., 2018). However, there is consensus (Tedim et al., 2018; Fernandes, 2005) that three descriptive parameters, burned area (BA), rate of spread (ROS) and fire line intensity (FLI), are necessary indicators to assess what an extreme fire is, as they characterize three essential

aspects of fires: damage caused, unpredictability and suppression capacity, respectively. Table 1 presents the limits used by the authors Tedim et al. (2018) and Fernandes (2005) to define an extreme fire.

Table 1. Adapted from (Tedim et al., 2018; Fernandes, 2005)

Aspects	Parameter	Reference Values
Damage	BA	>= 100 ha
Unpredictability	ROS	>= 50m/min (in forests)
Suppression Capacity	FLI	10000-30000kW/m

Although these descriptive parameters are important to define an extreme fire, in practice, only the burned area (BA) will be used, due to the lack of other data and compatibility problems between them. More specifically, we will use the 90% percentile of the size of fires in Mainland Portugal from 2001 to 2020, which corresponds to about 100 ha, which is in accordance with the criteria in Table 1.

To characterize the meteorological conditions for the occurrence of forest fires, it is used the values of the Continuous Haines Index (CHI) (Mills and McCaw, 2010) and the Fire Weather Index (FWI) (Turner and Lawson, 1978; Van Wagner and Pickett, 1985), and their subindices (FFMC, DMC, DC, BUI and ISI). To characterize the level of risk, the ordinal risk scales based on the Fire Weather Index (FWI) defined by IPMA (IPMA-FWI, 2022) and by the European-Forest-Fire Information System (EEFIS) (Joint Research Centre, 2020) will be adopted in our study.

The objective of this work is to explore fuzzy clustering (Ruspini et al., 2019) to unsupervisedly group fire risk data into distinct fire risk classes, such that a fire may have a positive degree of belongingness to more than one risk class. After the data is clustered, decision tree based methods are used (Quinlan, 1986) to derive if-then classification rules characterizing the meteorological conditions associated with the different classes of risk of fire occurrences.

2. Materials and Methods

The shapefiles of forest fires in Portugal in the period 2001-2020 were obtained from the available geocatalog provided by ICNF (https://geocatalogo.icnf.pt/metadados/area_ardida.html). The data was filtered by burned area in QGIS, and the fires with area >= 100ha were retained (of which 113 are in years 2019 and 2020). When not available, the date of the fire ignition data was obtained from the burned area MODIS Global Burned Area Product MCD64A1 (https://modis.gsfc.nasa.gov/data/dataprod/mod45.php).

The data regarding the FWI, FFMC, DMC, DC, BUI, ISI and CHI indexes were provided by IPMA. The data for the FWI are daily and for the CHI are data every 3 hours, for the period 2001 to 2020, calculated from the operational model analysis data of the European Center for Medium-Term Weather Forecasts (ECMWF), with a regular geographic grid of 0.125º latitude and 0.125º longitude, covering the territory of Mainland Portugal. For each fire, the fire risk indexes corresponding to the ignition date of the network with the largest area of intersection were considered.

There were built two data samples considering fires with burned area greater than to 100ha: one taking the five indices (FWI, CHI, ISI, DC, FFMC), and the other one with seven indices (FWI, CHI, ISI, DC, FFMC, BUI and DMC).

The conducted experimental study comprises three stages: (i) pre-processing and exploratory pre-analysis of fire data and risk indicators; (ii) application of the fuzzy c-means algorithm (FCM) (Bezdek, 1981) to generate fuzzy partitions of fires; and (iii) induction of decision trees (Quinlan, 1986) from the fuzzy clusters.

For each data sample the FCM was run looking for five and seven clusters. The clusters prototypes (centroids) of the obtained fuzzy partitions with five clusters (FCM-5) were labelled according to the EEFIS severity risk scale while the ones of the fuzzy partitioning with seven clusters (FCM-7) use the IPMA scale for the classification. Then, the fire fuzzy partitions, originally in a 5/7-dimensional data space, were projected in 2D with fuzzy Sammon mappings (FUZZYSAM) (Feil et al., 2007) for visual inspection and validation. Finally,

the data fires were assigned to the cluster with highest belongingness and labeled with the classification of the corresponding cluster prototype.

With all observations thus labeled with a certain fire risk class, there were generated decision trees to extract if-then rules that associate meteorological and terrain conditions with a certain level of extreme fire risk.

To avoid overfitting, a decision tree was induced from the data of period 2001-2018 with depth between 1 and 9, with the hyperparameters tuned using stratified shuffle splitting (using a 50%/50% for training and validation). Finally, the data of 2019 and 2020 fires was classified with respect to the FCM prototypes and used to evaluate the performance of the induced trees, namely with the standard precision, recall and F1 metrics.

3. Results

In this Section we discuss the main results of our approach and summarize the assessment of DT classification with the evaluation metrics.

3.1. Phase 1 – Fuzzy Clustering

Figures 2 and 3 show the FUZZYSAM mappings for the four fuzzy partitions resulting from the four combinations of parameters: **some** - five indices (FWI, CHI, ISI, DC, FFMC) or **all** – seven indices (FWI, CHI, ISI, DC, FFMC, BUI and DMC), and **C5** - five clusters or **C7**- seven clusters, hereafter designated as **someC5/C7**, **allC5/C7**, respectively. The projected clustered fires are represented as blue dot points, the colored star points represent the clusters prototypes labelled according to the EEFIS/IPMA severity risk scales, while the iso-lines represent degrees of belongingness (from closest prototypes values of 0.9, 0.8, 0.7 etc) derived from the FCM membership function. This projection guarantees the interpoint fuzzy weighted distances of the projected data approximating the corresponding weighted distance in the original (5D/7D) space. It is useful for interpretation of the clustering results since it is based on the Euclidean distance between the clusters prototypes (representative fires with average indices values) and the data fires.

It is interesting to observe that for the two partitions with five clusters, only the fire risk class labels “Very Low / Low”, “High” and “Very High” are used to classify the clusters. In case of fuzzy partitions with seven clusters, the situation depends on the used data sample with all/some indices. Anyway, the fuzzy partition derived from the configuration someC7 has a continuum of the risk class labels “Very Low”, “Low”, “Moderate”, “High”, and “Extreme”, being the best partition.

3.2. Phase 2 – Induced trees

The decision trees induced from the FCM clustered data (configuration someC7), at depths 3 and 4, are presented in Figures 4 and 5. The obtained trees are human interpretable and show that most fire occurrences are concentrated in three (four) leaves, one for each class, indicating that the result can be quite robust. It is interesting to observe that in both situations are used indices for fuel modelling and fire behaviour, and indices modelling the instability and dryness of the atmosphere. It is clear also that some of the leaves could be pruned, getting the same classification. For the case of seven clusters (someC7) all depth 3 or greater present good quality trees for use (Table 2).

3.3. Evaluation Metrics

The evaluation of the classification results from DT with depths 1 to 9, derived from the fuzzy partition someC7, are presented in Table 2. For DTs with depth above 2 the results appear to be very robust, with score values of recall, precision and F1 above 0.8. However, the metric values for depths above 6 are very close indicating that the deeper trees are overfitted. Furthermore, the shallower depth 3 tree obtains a good performance being very effective at separating the “Very Low’’ and “Extreme’’ fire classes from the others. The confusion occurs essentially in the middle classes and all the risk indices are used except the FWI. So, the decision tree with depth 3 is a good compromise between correct classification and rules simplicity presenting a classification F1 score value above 0.80, which is considered very reliable for real data.

Table 2. Evaluation metrics of the induced trees for configuration some C7

Metric (weighted)	DT depth 1	DT depth 2	DT depth 3	DT depth 4	DT depth 5	DT depth 6	DT depth 7	DT depth 8	DT depth 9
Recall	0.458	0.703	0.838	0.867	0.875	0.919	0.931	0.928	0.928
Precision	0.609	0.736	0.836	0.864	0.873	0.918	0.927	0.927	0.927
F1	0.520	0.712	0.832	0.860	0.873	0.917	0.926	0.926	0.926

4. Discussion and Conclusion

This work consisted of a comparative experimental study between the rules that associate meteorological conditions with extreme forest fire risk levels, generated from data mining and machine learning techniques, with the two ordinal scales of fire risk prediction of reference, the EEFIS scale and the IPMA scale. Specifically, the fuzzy clustering algorithm FCM was explored for the grouping of extreme forest fire data, occurred between 2001 and 2018, into severity fire risk classes, and subsequent visualization in 2D FUZZYSAM maps. Then a classification model was induced by decision tree algorithm for the characterization and extraction of rules, that is, to highlight the meteorological conditions associated with different levels of extreme fire risk. The applicability of these algorithms was tested for this purpose.

The FCM algorithm shown to be effective in the segmentation and classification of extreme fires, for the number of clusters five and seven, providing flexibility to the clustering effort with degrees of membership that may distinguish and rank the fires occurrences with respect to their severity. The partition with seven clusters was chosen with some of the indices (FWI, CHI, ISI, DC, FFMC) because the clusters recognize the "Low''/"Very Low'', "High''/"Very High'' and "Extreme" classes of the classification used in the IPMA. The decision tree classification model, once its hyperparameters have been trained and tuned, through hyper-parameterization and validation techniques, stratified shuffle split, also proved to be effective in extracting the meteorological conditions associated with different levels of extreme fire risk. The decision trees induced from the fire data with 5 indices labelled with the FCM-7 cluster prototypes, presented promising results, with classification validity scores higher than 0.8. The rules generated by these trees were used to determine the meteorological conditions associated with different levels of extreme fire risk, having been analyzed and compared with the EEFIS and IPMA scales, showing that the thresholds do not correspond exactly. This is expected since the EEFIS and IPMA scales were obtained from a single index, while our approach combines conditions of several indices: FWI, subindices and Continuous Haines Index. The generated rules clearly separate "Low'', "High'' and "Extreme''. However, while the rules for "Low'' and "Extreme'' are well defined, for high risk there are several sets of rules that define it. It is also interesting that the danger index CHI, linked to the instability and humidity of the lower atmosphere, is considered as important in the classification of danger (especially extreme) for both rules, with depth 3 (Figure4) and rules with depth 4 (Figure5). In the first case, depth 3, the extreme classification is given for the case of CHI>5.172 and FWI>46.9. Other indices are used to define the low, moderate or high classification rules, always having CHI as the first classification division. In the second case, depth 4, the extreme classification is achieved by two rules: 1) FWI>46.9 and CHI>4.103 or 2) If CHI≤4.103 and FWI>57.02 (extremely high value of FWI), Figure 5. Rules for depth 4 are more complex than those for depth 3, especially for the definition of "Low'', "Moderate'' and "High'' classes.

In the future, the same approach will be applied to particular edaphoclimatic regions of Portugal mainland in order to understand if the results are consistently obtained, as well the expected differences among regions. Furthermore, vegetation and topographic indices will be added in order to be able to induce risk level conditions for wildfires.

5. Acknowledgments

This work was supported by Fundação para a Ciência e a Tecnologia (FCT.IP) through project Floresta Limpa (PCIF/MOG/0161/2019) and NOVA LINCS (UIDB/04516/2020). The authors are indebted to the reviewers for their helpful comments that allowed to improve the paper.

Abstract

The large fires that have occurred in recent years around the World have shown that the management of these events becomes much more difficult when the extension of the burnt area or the location of the fire fronts, among other fundamental information for those managing operations in theatre, is not known. In addition, the large involvement of firefighting resources often challenges the operability of the communications system, sometimes making it dysfunctional or with limited operability. This was a reality seen in several large fires, from which we highlight the Fire of Pedrógão Grande that occurred in Portugal in June 2017.

Aware of the need to improve operational technology for fire monitoring, the Eye in the Sky Project has been developed. Our approach within this project is to design and develop an easy to deploy kit that can be launched from anywhere and fulfil these needs, providing quality real-time aerial imagery of the wildfires and guaranteeing emergency communications. The proposed solution consists of a HAB that will carry a flying wing UAV with two different high-value types of payloads that meet these two specific functions of imagery collection in the visible and infrared ranges and communications repeater. The authors like to refer to the Eye in the Sky solution as a satellite dedicated to a specific fire.

Naturally, the development of such solution raises several challenges, particularly in terms of the operational functioning of this solution, the optimised use of the balloon/glider pair with the associated payload, the capture, automatic detection of the fire images and their georeferencing, and the communications system between the payload, the ground station and the users in the command centre. The several challenges that have arisen in the development of this solution, as well as the way found to solve them are hereby exposed.

1. Introduction

The recent increasing number of large wildfires leads to new challenges in the response operations. Involving larger areas and periods of extreme fire behaviour with high fire spread rates, the monitoring of the fire perimeter and the knowledge of the evolution of the fire front is not always possible with the conventional terrestrial means. Thus, drones have been increasingly used to meet this challenge. However, although very useful and versatile in terms of manoeuvrability, drones have some limitations, such as the short autonomy or safety issues due to the sharing of flight height with fire-fighting aircrafts. Another challenge posed by larger fires is associated with the greater number of agents involved in the theatre of operations and consequently the greater number of telecommunications carried out, which sometimes causes the operational communications system to collapse or requires its reinforcement with complementary communications antennas.

The project Eye in the Sky - Using High-Altitude Balloons for Decision Support in Wildfire Operations develops a solution (Figure 1) of a high-altitude balloon (HAB) that transports a flying-wing unmanned aerial vehicle (UAV) carrying a payload with equipment considered of interest for the operation, such as a combination of RGB and IR cameras, which allow monitoring the progress of the fire, or/and a communications link and repeater. Thus, the high-altitude balloon can be seen as an on-demand mini satellite specifically dedicated to the fire event. After being released from the ground, the balloon rises rapidly, leaving the firefighting aircraft operating height in some seconds, so no longer interfering with their activity. The balloon continues to rise until, by decision of the operator or because it has reached the limit of the pressure conditions, it releases the glider which begins its descending phase autonomously or commanded by the operator. This solution allows a continuous operation time that can exceed ten hours.

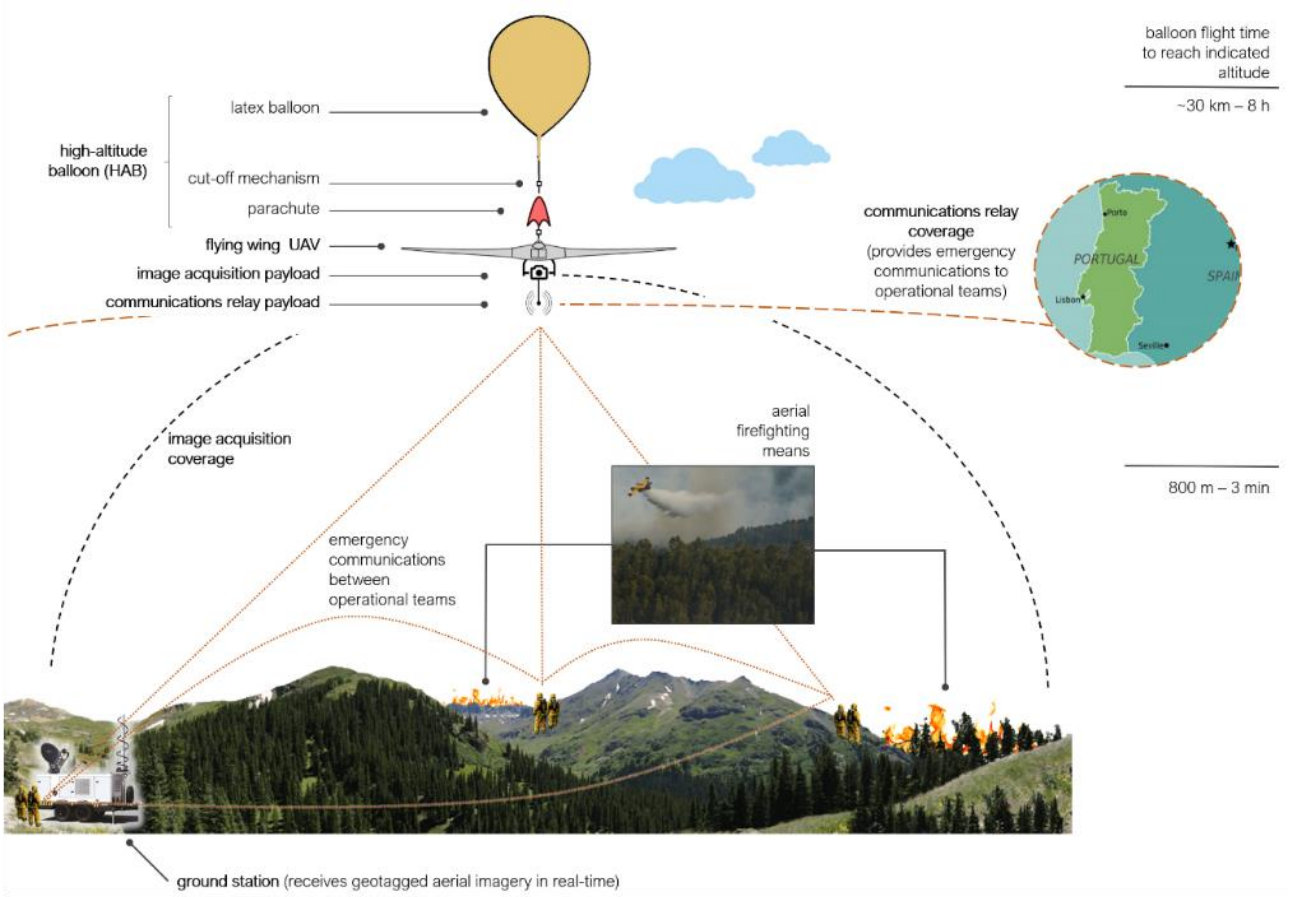

Figure 1 - Representation of the concept of using a high-altitude balloon in fire-fighting operations developed in the Eye in the Sky project (www.adai.pt/eyeinthesky).

In the Eye in the Sky project the described solution is being developed working on three main fronts, namely: a) high-altitude balloon payload stabilization, altitude control and mission prediction, and flying wing mission definition and control, b) automatic detection of fire and hot areas and respective image georeferencing before sending to ground station; and c) ground-to-ground transmission system to establish remote contact with the payload to transmit control orders and to access captured images, as well as to reinforce operational communications in theatre of operations. These topics are described in the following sections.

2. High-altitude balloon in fire-fighting operations

The HAB + UAV hybrid platform proposed incorporates the high cargo capabilities of an aerostat that travels passively through the atmosphere to reach targeted areas, but with low positional accuracy, and the navigation and positioning capabilities of an UAV glider with limited autonomy. These two elements, HAB and UAV together, significantly expand the working envelope of each independent solution, increasing the mission

autonomy when compared with UAV-only-based solutions, making them particularly useful in fire monitoring applications.

A wildfire monitoring test was carried out in the context of the fire event that started in Conqueiros/Proença-a-Nova (Portugal) on the morning of September 13th, 2020. In this test, a balloon equipped with three cameras operating in the visible range was launched from Montalvão, in the municipality of Nisa, at 7 p.m. on 14th September. The balloon reached altitudes greater than 12km, covering the path shown in Figure 2.

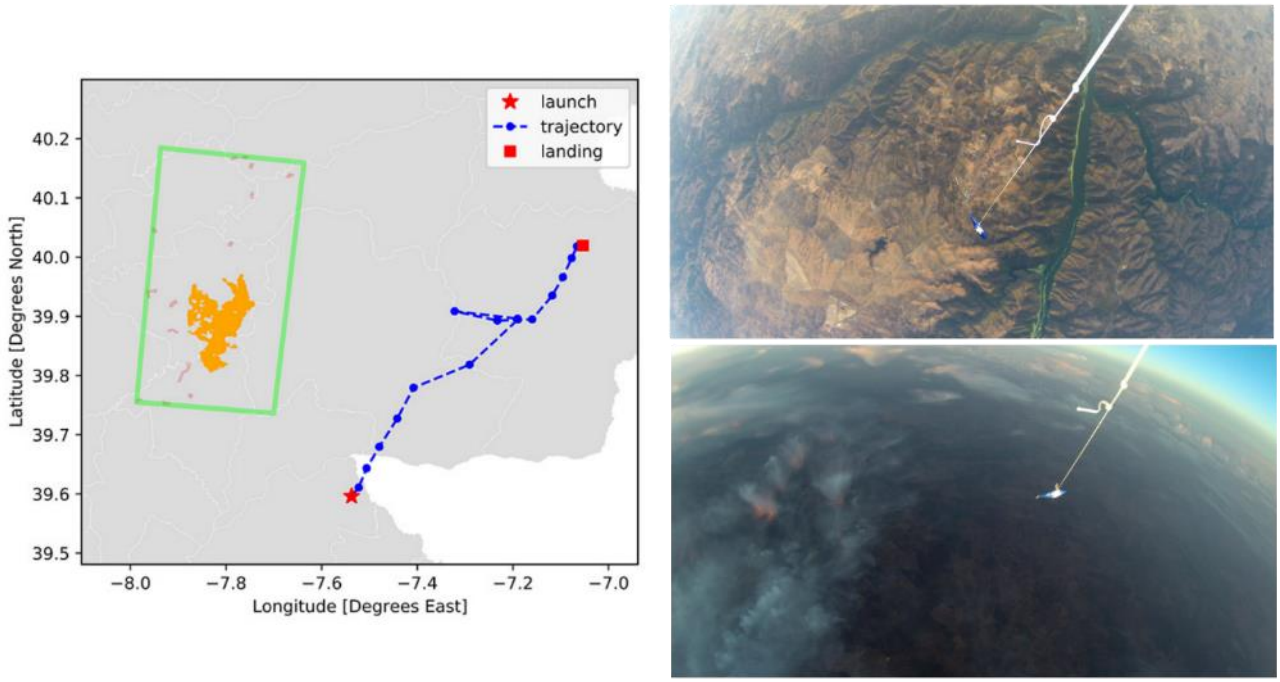

Figure 2 – Left: Balloon trajectory (in blue 'o', launch site '⋆', payload landing site '■') and fire event region (outlined in green) that led to the burned area (in yellow) in Conqueiros/Proença-a-Nova (Portugal). Right: Some images acquired in the same balloon launch at different altitudes by one of the cameras.

This launch had as main objective to test image acquisition at unset, with several cameras operating in the visible range. Although the results were limited by the balloon trajectory that did not pass directly over the fire due to the limitation in the definition of the launch zone and the direction of the existing winds, and the disturbance caused by the smoke column and the excess of artificial lights existing in the captured area, it is still possible to verify the large coverage of the balloon acquired imagery and the potential of the proposed solution.

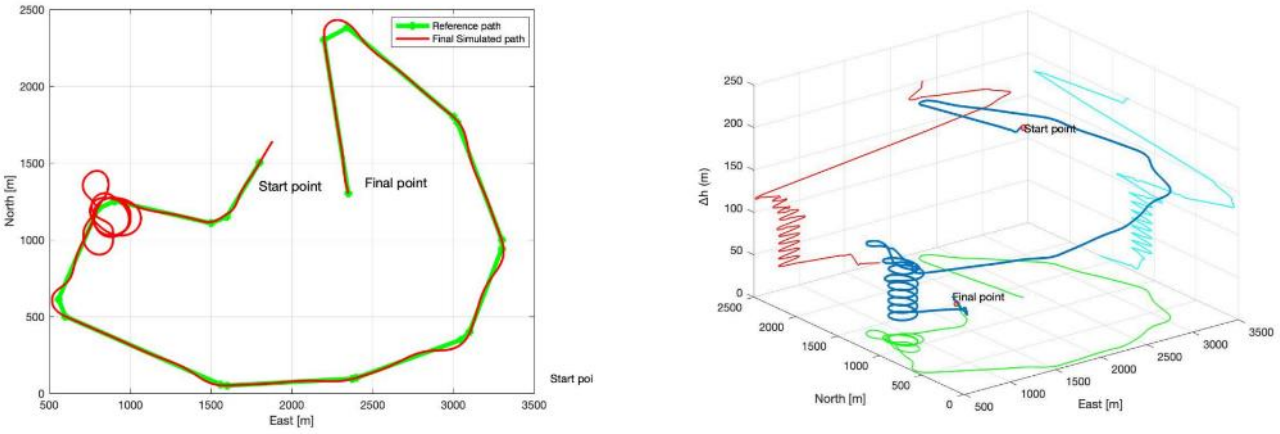

Figure 3 – Example of mission to be executed by the flying wing (reference) and its simulated performance. Vertical range was reduced to limit the loitering turns. (a) North-East visualization; (b) 3D visualization. (Yu (2021))

To guarantee the precision of the aerial imagery coverage, the mission definition of the flying wing UAV after remote cut-off from the HAB, and respective trajectory control, is essential. The implementation of nonlinear control solutions robust to wind disturbances and model uncertainties take gain from its gliding flight capabilities, guaranteeing the mission execution while maximizing flight time (Cordeiro et al. (2021)). An example of a UAV mission after deployment from HAB and stabilization, and simulated execution, is presented in Figure 3, where several points of interest are surveyed (vertical range was greatly reduced to limit the resulting loitering turns on descent).

3. Images

For the image acquisition system, a multimodal payload was developed encompassing thermal and visible range sensors. These two modes have complementary characteristics and enable developing fire detection algorithms that work separately on each of the modalities (Sousa et al. (2019), Sousa et al. (2020a)) or in tandem, allowing for better detection redundancy and robustness to occlusions in the data acquired by each sensor. Extensive field tests have been developed towards the characterization of the sensors, comprising flights with different altitude and horizontal profiles, varying different fire intensity, fire perimeter geometry and different ignition arrangements. These tests enabled identifying the best low-level image processing algorithms for encoding thermal data (Sousa et al. (2020b)). Figure 4 showcases an instance of data acquired including the different approaches taken that are made available in the dataset proposed in (Sousa et al. (2022)). Subsequently, the next steps involve improving the developed off-board automatic data annotation pipelines (Messias et al. (2021)) and applying intelligent system approaches to handle the image processing needs on-board the UAV.

Figure 4 – Examples of aerial images captured in the tests. Left: Tests setup; Middle: Visible range image in RGB color space. Top-Right: Thermal image processed with a linear automatic gain control algorithm, encoded with the GrayRed color palette. Bottom-Right: Thermal image processed with a plateau equalization automatic gain control algorithm, encoded with the Grayscale color palette.

4. Communications

During a fire event, the existence of alternative telecommunication relay systems is of extreme importance. In extreme events, the potential disruption of the communications service can cause severe damage to the firefighting operations. The main goal here is the research and implementation of an autonomous UAV-borne telecommunications service and the respective ground control system. The airborne system is responsible for transmitting all the telemetry data, images, and voice relay, while the ground system will receive these data and send mission controls back to the UAV/HAB. Another goal is the improvement of communications Quality of Service (QoS) between the local forces and the national entities to define adequate firefighting measures.

The image acquisition and respective analysis has an important role. To guarantee the quality of image transmission and reception, a communications relay system is deployed with the aerial platform, equipped with an omnidirectional antenna. This system provides the fire scene information across a high throughput

transmission via radio frequency using the UHF band. The scenes go for an image conversion procedure before transmission like MPEG4, MPEG5, JPEG200, and others. The management of the entire aerial communication system is performed in an SDR device that is responsible to maintain a communication channel with different modulations schemes (AX.25, SARATOGA, DVB-T and others) and properly encrypted. To guarantee the voice relay, a TETRA radio channel is added to comply with the common technology used by the firefighters (SIRESP).

The ground platform includes a fully automated motorized antenna, with high directivity and gain, equipped with a high sensitivity receiver. The system will use the telemetry data of the aerial platform to point the antenna accurately and improve the communication channel characteristics (RSSI, BER, image quality). The images are decompressed and shared with the national entities (CDOS and CNOS) through a satellite internet service.

Figure 5 represents the block diagram of the entire communications system.

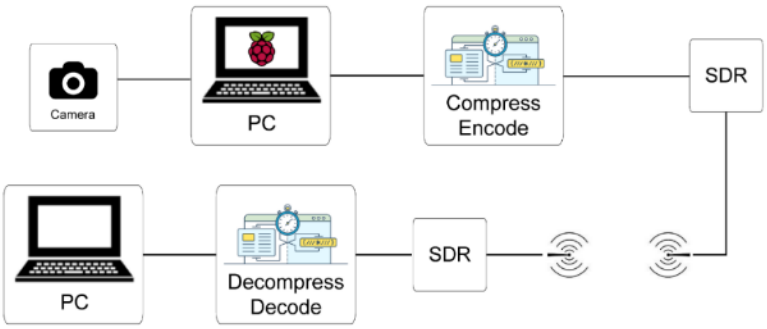

Figure 5 - Block diagram of the communications system.

5. Final Remarks

A solution was presented that is intended to become an important support tool for firefighting operations. This solution involves a high-altitude balloon carrying a glider plane and a payload that can be adapted to each situation. The payload is conceived to have a set of IR and RGB cameras for monitoring the fire and a communications repeater which will reinforce the communications system within the theatre of operations. This is a solution that allows a continuous operation that can exceed ten hours.

Although its main focus is the firefighting phase, as previously described, this solution can also be used in ignition detection operations or even in the aftermath phase in the search for hot spots that deserve greater attention by the forces remaining on the ground to avoid reignitions.

Abstract

The increased number of extreme wildfires due to climate change generates new challenges in wildfire modelling and prevention actions. One important aspect is to provide current forest fire spread simulation tools with the capability of being faster and more accurate preserving their forecast abilities. In this paper, we propose an alternative forest fire front reconstruction algorithm that could easily be incorporated in the well-known FARSITE fire spread simulator without affecting its functionality. The fire front reconstruction core part in FARSITE represents up to 60% of its total execution time. The proposal alternative algorithm is based on the α-shape algorithm but including some adaptation considering the particular case of forest fire. Meanwhile, the current FARSITE fire front reconstruction algorithm has a complexity of $O(n^4)$, the adapted α-shape algorithm has a complexity of $O(n\,log(n))$. This new approach has the benefit of being parallelizable using a divide and conquer strategy what will allow to significalty reduce the FARSITE's execution time without modifying its forecat results.

1. Introduction

Climate change is affecting the face of the world. One of the critical aspects of this change is the increase of the average temperature generating long periods of drought in areas that areas not used to. Consequently, in the last decades, one can found extreme wildfires in regions such as Finland, eastern Australia, UK that were typically places with a low rate of huge forest fire (United Nations Environment Programme, 2022-02; Perry et al., 2022). Due to this disrupt new events, there appear new ways of evaluating fire risk indexes according to changing weather conditions such as, for example. the Extreme-Fire Behaviour Index (EFBI) (Artes et al., 2021). These indexes allow to determine whether an ongoing wildfire have the potential to become an extreme forest fire or not. However, once a given wildfire is labelled as potential extreme fire, the next useful step would be to determine the severity of the fire in terms of potential burn area, principal propagation direction and the rate of spread. For that purpose, several forest fire spread simulator have been developed such as FARSITE (Finney, 1998), QUIC-Fire (Linn et al., 2020), Wildfire analyst (Artes et al., 2015) WRF-SFIRE (Mandel et al., 2014) with the aim to be used during an ongoing wildland fire. However, to be useful a forest fire forecast system should provide accurate results faster than real fire propagation, especially when dealing with extreme wildfires. This trade-off has been shown to be difficult to achieve because having higher precision results typically is penalized with higher execution times. This feature is quite relevant in FARSITE when forecasting large forest fires that take place in complex terrain. In particular, the part of the code that consumes most of the computing time is the one devoted to reconstructing the fire perimeter at each time step (Finney, 1998). FARSITE's algorithm has a complexity of $O(n^4)$, that prevents it to be used at real time. In this paper, an alternative algorithm for forest fire perimeter reconstruction is presented, which has a complexity of $O(n\,log(n))$, opening the possibility of turning FARSITE into an operational tool.

The original FARISTE's algorithm for fire front reconstruction is described in section 2. Section 3 introduces the proposal strategy. The experimental study is explained in section 4 and, finally, the main conclusions are reported in section 5.

2. FARSITE: Crossover

FARSITE is a forest fire simulator designed by Finney in 1994 (Finney, 1998). It is an iterative model to construct the evolution of a fire front over a time step. To do that, FARSITE defines a forest fire perimeter as a set of points, whose position in the area is evaluated at each time step applying the so called Rothermel's Model (Rothermel, 1972). In particular, FARSITE has two main steps to evaluate forest fire evolution: the propagation step (step 1) and the fire front reconstruction (step 2).

Step 1 consists of applying Huygens' principal approach for elliptical wave-front modelling. The fire is represented by a set of vertices (points) and for each vertice, the propagation equations of the Rothermel's model (Rothermel, 1972) are applied to evaluate their new positions. Once all vertices have been evaluated, then step 2 is carried out. The fire front reconstruction (called *Crossover* in the FARSITE's code) consists of finding an ordering on the boundary vertices (points) such that there are no intersections between the edges given by any two consecutive points. This is currently done by iteratively comparing all possible combinations of vertices composed by any two edges against each other, in a naïve algorithm. The main objective of such a process is to detect burnt areas and prevent the reconstruction process of generating complex loops and knots without any meaningful. Figure 1 shows this kind of situations. The figures referred as *Before* correspond to fire front obtained once FARSITE' step 1 has finished, and no extra corrections has been performed. Meanwhile the images referred as *After* are the final correct burnt areas (preserving or not preserving an enclave) once FARSITE's step 2 has finished,

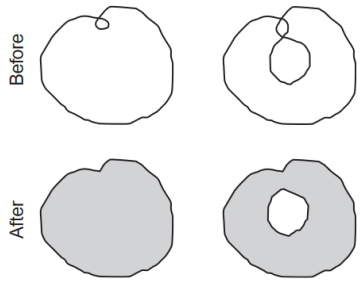

Figure 1- Example of a fire front reconstruction from (Finney, 1998).

As it is stated in the FARSITE's documentation (Finney, 1998), this process could be extremely expensive in terms of execution time. In particular, the *Crossover* routine has a complexity of $\boldsymbol{O(n^4)}$, what clearly penalize the total FARSITE's execution time. In the next section, an alternative algorithm for fire front reconstruction is described, which exhibits a high potential degree of parallelization and, therefore, it arises as a good alternative to accelerate FARSITE's simulations.

3. The boundary α-shape algorithm

The proposal described in this section is based on the α-shape algorithm, which is a generalization of the convex-hull and a subgraph of the Delaunay triangulation (Delaunay, 1934). In a roughly way, given a set of points, the α-shape algorithm could generate different shapes from the Delaunay triangulation of those points, according to the α value selected. This value will control the precision degree of the generated shapes.

A conformal α-shape (Cazals et al., 2005) is very similar to an α-shape but instead of a global parameter α, it uses a local scale parameter. Even so, α-shapes and conformal α-shapes share most of their properties, but the conformal α-shapes are very useful when the data is non-uniformly sampled. In this section, we outline the proposed conformal α-shape algorithm that is designed to substitute the current fire front reconstruction algorithm included in FARSITE.

3.1. Algorithm description

The alternative algorithm that we propose, is based on an α-shape but is adapted to the needs of the problem, making it more akin to a conformal α-shape. In the new algorithm, the inner edges of the Delaunay triangulation will use $\alpha = \infty$, making them irrelevant, while the boundary of the triangulation will use a meaningful α value.

This approach, in addition to saving computation time, allows us to work with a data distribution with which the α-shape might not give us the expected results.

3.2. Inputs & Outputs

The FARSITE fire front reconstruction process starts from a vector of points and returns another vector of ordered points, not necessarily of the same size. Since we want that the new algorithm could be used in an easy plug&play scheme being transparent to the FARSITE's user, we must adapt the inputs and outputs of the alternative algorithm to match those of FARSITE to be able to use it in an interchangeable way.

The desired input for the α shape is a vector of unordered points, but the alternative algorithm previously requires a Delaunay triangulation. As such, the first step to be carried out should be to obtain the Delaunay triangulation by means of an unordered vector of points. Obtaining the Delaunay triangulation is the most time-consuming part of the proposal; however, it exhibits a complexity of $O(n\,log(n))$, what supposes a great improvement considering the original complexity of the current FARSITE algorithm.

The adaptation of the output data of the new proposal algorithm is simple since we already have identified the border of the concave hull.

3.3. Parameter selection

In the *boundary* α-shape algorithm, as in the basic α-shape, it is necessary to choose an α value that will determine the shape obtained. From the context of the problem, the most logical thing to do is to use FARSITE's perimeter resolution parameter, since it is a parameter that the user decides. However, a deeper study of this point should be performed.

4. Experimental results

In this section, we provide the preliminary results obtained in terms of execution time and accuracy of the prediction results when using the original FARSITE fire front reconstruction method and when using the proposal boundary **α**-shape algorithm to generate the new fire perimeter. The performance results reported in this section, are based on running the fire front reconstruction component of FARSITE in an isolated way and compared to the proposed *boundary* α-shape algorithm. Therefore, in order to be fair, the comparison has been done by feeding both programs with the same format of data and generating both the same output data format. Those formats are conformal with the ones used in FARSITE.

4.1. Execution time

The main contribution of the alternative proposal to reconstruct the fire front is the algorithm's complexity reduction. One the one hand, the original naïve FARSITE *Crossover* procedure exhibits a complexity of $\boldsymbol{O(n^4)}$, meanwhile the *boundary* α-shape approach has a complexity of $\boldsymbol{O(n\,log(n))}$ what implies a significant reduction of the execution time of this component of the simulator, which currently represents 60% of the total execution time of FARSITE. In figure 2, one can observe the time spent in executing both reconstruction algorithms when using different numbers of points for the fire perimeter. As we can observe, as the number of points increases, the execution time spent by the new algorithm decreases compared to the time spent by FARSITE approach. This performance improvement is more significative when dealing with a huge number of points being able to achieve a performance improvement of twenty time when using 100000 points. This result could lead to a FARSITE total time execution time of 50%. Describing the fire front with a huge number of points implies to describe the forest fire behavior with better precision but, typically this improvement in the fire front resolution has a direct impact in the execution time. Our proposal has the ability of provide accurate results without penalizing the total execution time.

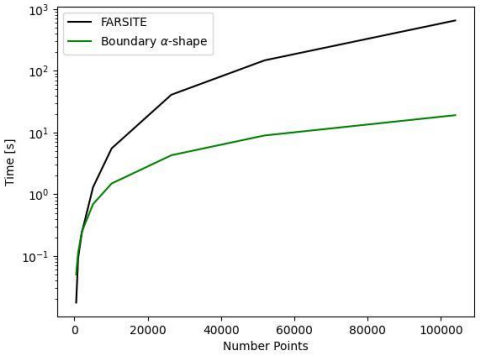

Figure 2 - Execution times of FARSITE Crossover and boundary α-shape with different numbers of points

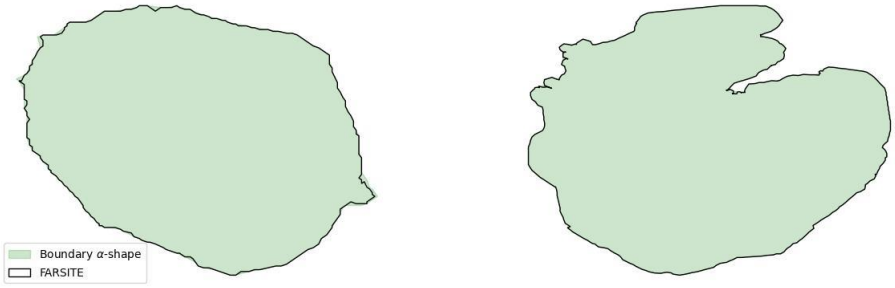
4.2. Propagation results

The modification of the fire front reconstruction process could lead to different fire behaviour, that is, the output shapes of the simulation tool could be slightly different. However, this substitution should provide similar enough not to modify the overall behavior of the fire. As it is well known, the α-shape algorithm generates quite different results depending on the value of the α parameter. The experimental results shown in this section has been obtained using as α value the resolution of the perimeter, which, in this case, has been set to 30 meters. Figure 3 shows the output provided by the original fire front reconstruction made by FARSITE (black line) and the output provided by the new strategy (green shape). In particular, the two cases depicted in this figure corresponds to two real fires, figure 3(a) is a fire that took place in Pendilhe (Portugal) in 2013 and figure 3(b) was an event that happened in Arkadia (Greece) in 2011. As we can observe, the results are almost the same, however, if we analyze the shape and the line in detail, one can found certain regions where the green shape overpass the black line. Nevertheless, those difference are not significant enough to affect the global behavior of the wildfire,



a b

Figure 3- The fire front reconstruction obtained when applying the FARSITE Crossover algorithm and the boundary α-shape proposal to two real wildfires.

5. Conclusions

Climate change generates an increasing number of wildfires, which are growing in intensity and area affected. To tackle such events, current available tools must be enhanced to be faster without loosing their forecast abilities. In this work, an alternative algorithm for FARSITE fire front reconstruction algorithm is presented. The proposal strategy does not affect the simulations results provided by FARSITE but, the preliminary studies show promising results with a reduction of the execution time of 20 times. The initial validation has been done only with the part of the code associated to the fire front reconstruction and the next step is to integrate the new algorithm within FARSITE.

Abstract

Wildfires and forest fires have devastated millions of hectares of forest across the world over the years. Computer vision-based fire classification, which classifies fire pixels from non-fire pixels in image or video datasets, has gained popularity as a result of recent innovations. A conventional machine learning-based approach or a deep learning-based approach can be used to distinguish fire pixels from an image or video. Deep learning is currently the most prominent method for detecting forest fires. Although deep learning algorithms can handle large volumes of data, typically ignore the differences in complexity among training samples, limiting the performance of training models. Moreover, in real-world fire scenarios, deep learning techniques with little data and features underperform. The present study utilizes a machine learning-based approach for extracting features of higher-order statistical methods from pre-processed images from publicly available datasets: Corsican and FLAME, and a private dataset: Firefront Gestosa. It should be noted that handling multidimensional data to train a classifier in machine learning applications is complex. This issue is addressed through feature selection, which eliminates duplicate or irrelevant data that has an effect on the model's performance. A greedy feature selection criterion is adopted in this study to select the most significant features for classification while reducing computational costs. The Support Vector Machine (SVM) is a conventional machine classifier that works on discriminative features input obtained using the MIFS, feature selection technique. The SVM uses a Radial Basis Function (RBF) kernel to classify fire and non-fire pixels, and the model's performance is assessed using assessment metrics like overall accuracy, sensitivity, specificity, precision, recall, F-measure, and G-mean.

1. Introduction

Millions of hectares of forest have been destroyed by wildfires in recent years (Bhujel, Maskey-Byanju et al. 2017, Mannan, Feng et al. 2017, Nolan, Boer et al. 2020). Nature's balance is protected by forests. Forest fires are usually identified after they have spread across a large area, making management and extinguishment difficult, if not impossible (Alkhatib 2014). Computer vision-based fire detection is gaining active research attention in categorizing surface and crown fires (Guan, Min et al. 2022). Surface fires in the forest can be easily identified with smoke sensors, making classification difficult. Crown fires occur when a surface fire is not controlled immediately. No sensor can withstand the tremendous heat produced by a crown fire, making sensing difficult (Chowdary, Gupta et al. 2018). To detect crown fires early, satellites or unmanned aerial vehicles must continuously monitor the forest landscape. Vision-based techniques also help firefighting teams locate their destination by classifying video or picture information. Apart from preventing flames from spreading, this strategy aims to minimize economic and financial losses to human and forest life. The classification of fire pixels in an image or video can be done using either standard machine learning or deep learning (Bot and Borges 2022, Bouguettaya, Zarzour et al. 2022, Majid, Alenezi et al. 2022).

The conventional machine learning paradigm necessitates feature extraction and selection. Alternatively, deep learning can be used to automatically extract and select features for classification (Farhana Thariq Ahmed, Ahmad et al. 2019). Manual feature extraction is inefficient at capturing discriminative feature information in large data sets. Handcrafted approaches also perform inefficiently and are unreliable as data size increases. While deep learning methods may handle enormous data volumes, they could not account for the variation in complexity across samples. Thus reducing the efficiency of their training models and increasing misclassification (Guan, Min et al. 2022). Moreover, in complex fire scenarios, deep learning with minimal data and features underperforms.

Thus, the current study employed machine learning to extract higher order features (Swami, Mendel et al. 1998) from the image dataset for fire pixel classification. Higher order cumulant features were used since they are resistant to Gaussian noise in the original data. In remote sensing applications like fire monitoring and detection, higher-order statistical features are rarely used (Vijithananda, Jayatilake et al. 2022). The present study evaluates higher order cumulants (order 3) that extract the cumulant coefficients from images using an unbiased approach. Handling multidimensional data to train a model is difficult in machine learning. Through removing redundant or irrelevant data, the model's performance can be improved. To lower the computational cost, information theoretic feature selection approaches have been used in this work with a predefined set of significant feature inputs. Later, the discriminative features are fed into the SVM classifier. To assess the model's performance, the images are classified as either fire or non-fire using an SVM classifier with a Radial Basis Function (RBF) kernel. The current approach uses fire photos from publicly available datasets, notably the Corsican (Toulouse, Rossi et al. 2017) and FLAME (Shamsoshoara, Afghah et al. 2021) datasets. Fire detection was indeed conducted using images from the, Firefront Gestosa , a private dataset.

2. Proposed framework

Figure 1 depicts the current work's process for categorizing fire pixels with handcrafted feature extraction and selection. Three publicly available image datasets have been used in this study: Corsican (Toulouse, Rossi et al. 2017), FLAME (Shamsoshoara, Afghah et al. 2021), and Firefront Gestosa. Furthermore, the present work, combined the three distinct datasets to increase the number of training examples for the presently proposed machine learning model. In this work, the pictures of the adopted datasets are manually labelled and annotated using the data partitioning technique. Prior to the classification task, the images in the image dataset are pre-processed using mask creation and flame localization. Cropping and resizing the photos to 300*300 pixels is then performed using the patch creation approach. Following that, the resized images are divided into training, testing, and validation test sets. The downsized images are then modified using the Radon transform, which reduces the image's dimensionality from two dimensions to one dimension.

The present work applied a projection angle of 0^0 to 360^0 and a step size of 10^0, for performing the Radon transform. As a result, each image is formed contributes to 37 angles. The current study extracts HOS cumulant features from each angle and then concatenates all 37 angles' extracted features into a single feature vector. Since it is impractical to input a larger feature vector to the learning algorithm, the present work incorporates a feature selection approach to reduce computational complexity. The current work examined the extracted features experimentally using a greedy feature selection criterion - Mutual Information Feature Selection (MIFS), with a predefined set of optimal features (30, 50 and 80). Finally, the reduced set of optimal features is sent into the SVM classifier, which performs fire pixel classification. Finally, the machine learning model is used to localize the fire pixels and the classification performance of SVM is evaluated using the following metrics: overall accuracy, sensitivity, specificity, precision, recall, f-measure, and g-mean.

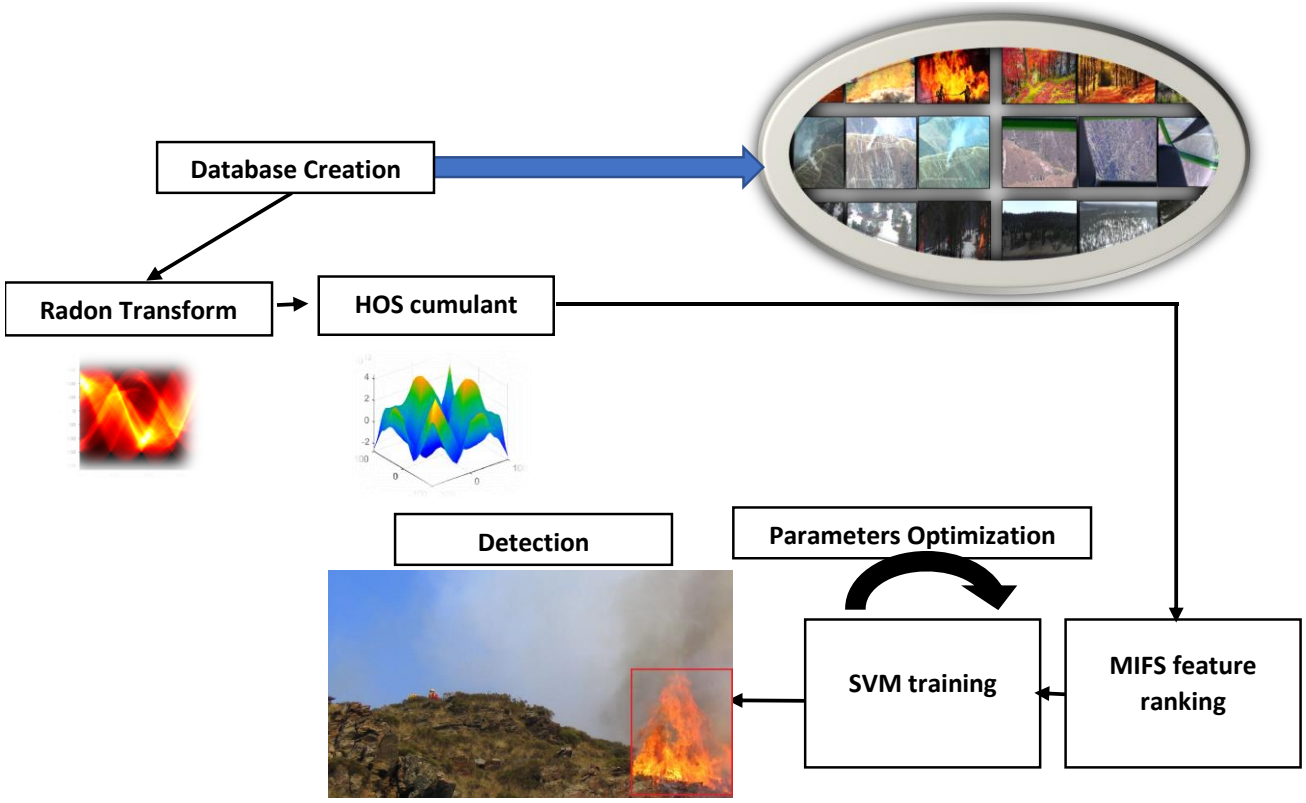

Figure 1- The proposed framework for fire classification adopting a handcrafted approach.

3. Material and methods

3.1. High order cumulants features

The present work, extract higher order statistical features from the pre-processed image. In specific, higher order cumulant features (Mendel 1991, Swami, Mendel et al. 1998) of order three is extracted from the image in an unbiased fashion. By removing the sample mean from the pre-processed image, radon transform (Stanley 1983) was performed to reduce the dimension of the image to a single dimension. Afterwards, cross-cumulant estimates were computed. The third order cumulant represent the normalized skewness and it can recover the cumulant information even in the presence of coloured Gaussian noise present in the image. For a random variable y the cumulant generating function can be expressed as $K(n)$,

$$K(n) = logE[e^{nY}] \qquad (1)$$

The higher order cumulants can further expressed as the central moments with polynomial functions as

$$K_1(\mathrm{Y}) = \mathrm{E}(\mathrm{Y}) \qquad (2)$$

$$K_2(\mathrm{Y}) = \mathrm{var}(\mathrm{Y}) = \mathrm{E}(\big(\mathrm{Y} - \mathrm{E}(\mathrm{Y})\big)^2) \qquad (3)$$

$$K_3(\mathrm{Y}) = \mathrm{var}(\mathrm{Y}) = \mathrm{E}(\big(\mathrm{Y} - \mathrm{E}(\mathrm{Y})\big)^3) \qquad (4)$$

Where, equation 2,3,4 represents the mean (first order), variance (second order), and skewness (third order) respectively.

3.2. Mutual information ranking technique

MIFS (Battiti 1994), a greedy feature selection method, guarantees the selection of highly informative features using mutual information as a metric. This selection paradigm uses a regularisation parameter, β, to identify the

non-linear relationship between selected features and output class. This value β reduces the level of uncertainty among the optimal feature subsets by eliminating duplicate features. Finally, for classification, the ideal feature subset with pre-defined feature information will be fed into machine learning classifier.

MIFS has an advantage over other linear transformation-dependent approaches in that it considers the non-linear relationship between features and the output class labels. As a result, MIFS delivers strong generalisation for training while also reducing computing time.

The MIFS algorithm uses the following approach to ensure that every feature chosen is informative (Battiti 1994):

1. Feature set (empty) $\hat{S}$ initialized with initial features, as $\hat{S} \leftarrow f_0 \ldots, f_n$ features.
2. Mutual information among the feature variables, f to be computed between the feature variables and the class labels (output: O), as I (O: f) in the extracted feature set $\hat{S}_f$
3. Select the features that are highly mutually informative with the output, O and add them to the empty feature set based on the increasing order mutual information as, $\hat{S} \leftarrow \hat{S} \backslash \{f\}$ and $\hat{S} \leftarrow \{f\}$
4. Implement a "greedy" selection of features for a set of pre-determined numbers such as 30, 50 and 80
    a. For every set of feature pair in the set $\hat{S}$, calculate $I(f, \hat{s})$, $\hat{s} \in \hat{S}$, if not calculated already.
    b. The features that are highly related to each other are chosen to satisfy the criteria of mutual information as,

$$I(0 : f) - \beta \sum_{\hat{s} \in \hat{S}} I(f, \hat{s})$$

5. Finally, the set $\hat{S}$ is treated as an ideal feature subset as it contains highly informative features.

4. Results and discussion

The experiments were conducted over a dataset of 8036 pictures, where 4016 represent fire and 4020 are non-fire images. One hundred and twenty-five sun pictures are injected on the database to simulate high intensity pictures that could be misleading to the classifier. The exact contribution of every set of data (Corsican, FLAME and Firefront_Gestosa) into the final dataset is given in table 1. The final dataset was partitioned to training, validation, and test sets with the following ratio: 60%, 20% and 20% respectively. The SVM model, with gaussian kernel, was trained in a loop with varied parameters configurations to find the optimal Gamma and cost parameters.

Table 1- The corresponding parameters of the conducted experiments

Dataset	Corsican Dataset	FLAME Dataset	Firefront_Gestosa Dataset	Sun Pictures
Fire	1775	2003	238	**0**
Non-Fire	0	2782	1113	**125**

Table 3. represent the experimental results by varying the selected features as 30, 50 and 80 from the total set of extracted feature vector. The MIFS paradigm performs the feature selection with regularisation parameter β set to three different values as 0.1, 0.5 and 0.8. The parameters of the conducted experiments are given in table 2., while the corresponding results are given in table 3. The model's performance was measured with overall accuracy, sensitivity, specificity, precision, recall, f-measure and g-mean metrics. The results observed to be better with increasing number of features irrespective of β. Overall performance reported high with set of 80 selected cumulant features with no significant difference in the reported values with β.

Table 2- The corresponding parameters of the conducted experiments

Experiment Nº	*Number of Features*	*Other Parameters*
Experiment 1	30	The regularization parameter β = 0.8
Experiment 2	50	
Experiment 3	80	
Experiment 4	30	The regularization parameter β = 0.5
Experiment 5	50	
Experiment 6	80	
Experiment 7	30	The regularization parameter β = 0.1
Experiment 8	50	
Experiment 9	80	

Table 3- The given results of every experiment

5. Conclusions and outlooks

Fire detection is a task that require high precision to localize the exact position of flames. Hence, an accurate and well-trained model need to be developed to make the intervention of the firefighters faster. The current paper divulgates the results of an SVM model trained with 3rd high order cumulant feature set reduced with a mutual information algorithm. The given results are very promising. However, more experiments need to be run using other feature ranking techniques to observes the fluctuation of different parameters and the performance of the classification technique.

Abstract

Global change is raising the occurrence and simultaneity of large wildfires. However, increasing the number of suppression resources is not necessarily the way to manage it and even less if suppression resource assignment is determined based on the experience of the incident commander or incident management team.

This research focuses on the estimation of fireline production rate in wildfires of different size under Mediterranean conditions. Fireline production rate was defined as the expected length of fireline that can be built by a firefighting crew in a period. Their most important explanatory variables were fuel model type, attack type, fire size, working time and support of aerial resources. Fuel models with the highest fireline production rate are those corresponding to grassland. Fireline production rate in indirect attack is lower than in direct attack regardless of fuel model. Fireline production rate decreased with increasing wildfire size. Firefighter production rate was decreased by 41.79% after three hours of work, due to fatigue in stress conditions next to the fire front. Aerial support increased fireline production rate between 8.14% and 20.63%. Finally, according to the findings obtained, the most efficient crew is made up of 7-9 firefighters.

The assessment of the average firefighter production rates based on easily identifiable variables from an incident command post, provides objective information for decision making about the type and number of resources required in wildfires suppression activities. An efficient allocation of suppression resources would reduce crew fatigue and increase the effectiveness of operational plans.

1. Introduction

Although large wildfires constitute less than 2% of the total forest fires (Donovan and Brown, 2005), they are the most severe causing the greatest ecological and socio-economic impacts. Due to their greater virulence and suppression difficulty, large wildfires require the highest suppression costs (Rodríguez y Silva et al., 2020). Moreover, Holmes and Calkin (2013) have indicated that in large wildfires, differences between the standard fireline production rates and estimated rates could be observed.

Fireline production rate was defined as the expected length of fireline that can be built by a firefighting crew in a period (Broyles, 2011). There is a lack of information regarding the productivity and efficiency of wildfires suppression resources (Thompson et al., 2018). Katuwal et al. (2016) used a Stochastic Frontier Analysis to model the production of the suppression resources, including the variability and inefficiency in suppression operations. Rodríguez y Silva (2017) and Rodríguez y Silva and Hand (2018) have generated productivity models based on the combination of suppression resources using econometric techniques.

The main goal of this research is to assess the fireline production rate developed by firefighters in wildfires of different size in Mediterranean ecosystems. Despite difficulties in generating the dataset (Plucinski, 2019a), this research was created through direct observations on active fires. In contrast, other studies estimated rates in firefighter trainings and burn areas and over-estimate fireline production rate (Plucinski, 2019b). Although some studies (Chico, 2001; Jiménez, 2014) have established production rates for fuel models in Mediterranean ecosystems, we try to cover gaps in relation to new psychological and working variables. Firefighter production rate estimated in different wildfire scenarios would constitute a useful and necessary tool for decision-making at two planning level. Before the wildfire, knowing terrestrial firefighting efficiency afford land managers optimize firefighting resources and design crews with an efficient number of firefighters. During a wildfire, it provides a scientific basis on which making technical decisions for the efficient suppression planning and

resources assignment to contain a wildfire. Comparison of production rates based on the use of different suppression resources is a very useful tool for fire managers (Plucinski, 2019b).

2. Material and methods

2.1. Study area

The study area is limited to three spanish regions in southern Iberian Peninsula (Andalucia, Castilla La Mancha and Valencia), which cover a total of 190.000 km^2. Official statistics indicate an annual average of 1,993 fires and an annual burned area of 21,983 ha for them during 2008-2018. The climate of these regions are typically Mediterranean, with dry and hot summers making them fireprone areas.

2.2. Database creation

This study database was generated from direct observation during the firefighting crew work of three Spanish region wildfire agencies during the period 2013-2018. Fire technician or foreman filled in a report for each fire operation. A total of 229 reports were collected, 204 of which were used for this study. Fireline production rate was calculated by the ratio between fireline length and working time per number of firefighters. Fireline effectiveness is defined as the successful containment of the fire in the hand line build during firefighting. In addition to administrative information of each wildfire, the data gathered was (Table 1):

Table 1. Range of the variables gathered.

Variable	Range
Fireline production rate	0.1 - 2.85 m/min*firefighter
Fuel model (Anderson, 1982)	1-10
Fire size	0.5 - 3,400 ha
Working time	10 - 445 min
Temperature	21 - 41.5 ºC
Relative humidity	8 - 52%
Wind speed	2.5 - 60 km/h
Slope	0- 15% (value 1) - > 45% (value 4)
Stoniness	Low (value 1) - Very high (value 4)
Number of firefighters	5-27 firefighters
Type of attack	Direct (value 0) and Indirect (value 1)
Air resources support	No (value 0) and Yes (value 1)
Time interval between releases	3-15 min
Fireline effectiveness	No (value 0) and Yes (value 1)

2.3. Statistical analysis

Statistical analyses were performed by SPSS© software. Kolmogorov-Smirnov test was used to check the normal distribution. Krustal-Wallis and Mann-Whitney tests were used to identify significant differences ($p < 0.05$).

3. Results

In direct attack (Table 2), the highest production rate of firefighting crews was observed working in timber-litter fuel models, however, the lowest rate was found in chaparral fuel models. Fireline production rate in indirect attack (Table 2) was significantly increased in grassland and brushland fuel models in relation to timber fuel models.

Table 2. Fireline production rate for each fuel model group based on type of attack.

Fuel model type	Fireline production rate (m/min*firefighter) Direct attack	Fireline production rate (m/min*firefighter) Indirect attack
Grassland	$0.87(\pm0.45)^a$	$0.40(\pm0.16)^a$
Chaparral	$0.33(\pm0.19)^b$	$0.31(\pm0.12)^a$
Brushland	$0.67(\pm0.34)^c$	
Timber-understory	$0.44(\pm0.17)^b$	$0.16(\pm0.04)^b$
Timber-litter	$1.06(\pm0.1)^d$	

Mean values in a column followed by the same letter are not significantly different ($p < 0.05$).

Aerial resources support increased fireline production rate between the 8.14% (grassland fuel models) and the 20.63% (brushland fuel models) (Table 3).

Table 3. Fireline production rate based on air resources support.

Fuel model type	Fireline production rate (m/min*firefighter) with support of aerial resources	Fireline production rate (m/min*firefighter) without support of aerial resources
Grassland	0.87(±0.30)[a]	0.79(±0.45)[a]
Brushland	0.63(±0.39)[a]	0.51(±0.20)[b]

Mean values in a raw followed by the same letter are not significantly different ($p < 0.05$).

Statistical analysis of production rate did not provide significant differences ($p < 0.05$) according to meteorological conditions and environmental characteristics. However, fireline production rate decreased with increasing wildfire size (Table 4).

Table 4. Fireline production rate based on fire size.

Fire size (ha)	Fireline production rate (m/min*firefighter)
< 1	0.67(±0.55)[a]
1-50	0.55(±0.43)[a]
> 50	0.41(±0.25)[b]

Mean values in a column followed by the same letter are not significantly different ($p < 0.05$).

In addition, in brushland fuel models, fireline production rate was decreased by 41.79% after three hours of work (Table 5).

Table 5. Fireline production rate based on working time.

Working time (min)	Fireline production rate (m/min*firefighter)
< 60	0.67(±0.54)[a]
60-180	0.52(±0.28)[a]
> 180	0.39(±0.27)[b]

Mean values in a column followed by the same letter are not significantly different ($p < 0.05$).

The successful containment increased fireline production rate in both grassland and brushland fuel models (Table 6). The production rate was increased by 84.84% due to a successful containment of the fire perimeter.

Table 6. Fireline production rate based on fire successful containment.

Fuel model type	Unsuccessful fire containment	Successful fire containment
Grassland fuel models	1.09(±0.15)[a]	1.16(±0.42)[a]
Brushland fuel models	0.33(±0.09)[a]	0.61(±0.29)[b]

Mean values in a raw followed by the same letter are not significantly different ($p < 0.05$).

No significant differences in grassland fuel models were observed according to the number of firefighters (Table 7). In the case of brushland fuel models, significant differences were observed from 9 firefighters.

Table 7. Fireline production rate based on crew size.

Fire crew (firefighters)	Fireline production rate in grasslands (m/min*firefighter)	Fireline production rate in brushlands (m/min*firefighter)
< 7	1.02(±0.65)[a]	0.68(±0.47)[a]
7-9	0.77(±0.57)[a]	0.55(±0.35)[a]
> 9	0.90(±0.42)[a]	0.33(±0.26)[b]

Mean values in a column followed by the same letter are not significantly different ($p < 0.05$).

4. Discussion

Fuel models with the highest fireline production rate are those corresponding to grassland. Fireline production rate in indirect attack is lower than in direct attack regardless of fuel model. The fireline production rate estimated in this study is lower than those obtained in other Iberian studies (Chico, 2001; Chico and Poza, 2009; Jiménez, 2014). They overestimated fireline production rate values from simulated conditions or trainings while

we consider direct observations on active fires. In active fires, the working demands, thermal stress conditions and smoke inhalation are different (Rodríguez-Marroyo et al., 2011, 2012). The main differences between our findings and other studies (Chico, 2001; Chico and Poza, 2009; Jiménez, 2014) are found in chaparral and timber-litter fuel models. With regards to chaparral fuel models, the rate is almost half in our study, due to longer periods of work. The timber-litter fuel models have a higher rate due to the absence of tree cutting. Besides, as a finding of this study, it is worth highlighting the production rate increases with the support of aerial resources according to other authors (Holmes and Calkin, 2013; Florec et al., 2019).

Although some studies (Jiménez, 2014) have pointed out that slope and stoniness are important variables in fireline production rates, they have not been identified as representative variables in our research. Similarly, differences in meteorological conditions did not provide significant changes, except for wind speed above 50-60 km/h that reduces production rates. Further studies have highlighted the decline in fireline production rates under extreme fire conditions (Holmes and Calkin, 2013). Moreover, production rate decreased by 45.9% on unsuccessful containment operations. This fact seems to support the idea that productivity models must incorporate psychological variables.

The availability of a reliable dataset for estimating the productivity of fire crews expands wildfire suppression knowledge (Katuwal et al., 2016; Thompson et al., 2018). This study affords to reduce uncertainty about the productivity of suppression resources based on working conditions. As a result, efficiency in the suppression operations will improve (Thompson and Calkin, 2011; Rodríguez y Silva and González-Cabán, 2016).

Further studies should analyse and modelling the effects of aerial resources and the working time in fireline production rate. In this sense, time intervals between releases below 5 minutes greatly increase the productivity of fire crews.

5. Conclusions

Despite the difficulties in generating a fireline production rate dataset, supporting statistical analysis provides us accurate data under Mediterranean Basin conditions. Our findings show that firefighter productivity is lower under active fires than under simulated conditions or trainings. The methodological framework is very flexibility enabling an extrapolation to other territories and fire crew structures. However, more precise information of some variables, such as fuel models, slope and stoniness, is needed.

Several factors were identified as statistically significant to determinate fireline production rates. We emphasize in the idea that productivity models must incorporate working and psychological variables, such as working time, fire size and successful containment. Fire crew productivity increases with the support of aerial resources according to the time interval between releases. Direct attack increases the operational effectiveness of suppression resources. Fireline production rates provide a useful tool for fire managers to assign the right type and number of fire resources, mainly in simultaneous large fires occurrence. Fire managers could quickly predict and evaluate spatial and temporal allocation resources.

6. Acknowledgments

This research was supported by the European Union projects FirEUrisk (H2020-LC-CLA-2020-101003890), CILIFO (POCTEP-0753_CILIFO_5_E) and FIREPOCTEP (POCTEP-0756_FIREPOCTEP_6_E) and the projects VIS4FIRE (RTA2017-00042-C05-01) and ENFIRES (PID2020-116494RR-C44) of the Spanish Ministry of Science, Innovation and Universities. The authors of this study would like to express their gratitude to the engineers and firefighting crews that have contributed to provide the data used.

Keywords

Fire weather, risk assessment, support tool, vegetation fire, warnings

Abstract

Vegetation fires are among the most dangerous natural hazards. In Croatia, they are most common on the Adriatic coast and in the areas near the Adriatic, especially in summer when the peak of the fire season occurs. Meteorological risk of vegetation fires in Croatia is primarily assessed with the Canadian Forest Fire Weather Index and derived fire danger. However, due to the rare spatial and temporal availability of these data as well as the effects of climate change resulting in frequent enhanced fire danger during the summer, the need for additional risk assessment tool has emerged. In that sense, the fire weather warnings were introduced ten years ago and since then have been constantly improved and adapted to the needs of the firefighting community. The aim is to warn of weather conditions that can lead to the rapid spread and unpredictable behavior of the vegetation fires. As a basic condition, fire weather warnings are issued when the fire danger classes from the Canadian Forest Fire Weather Index are high and very high. Except the meteorological parameters of the Fire Weather Index, the most important of which is wind, the behavior and spread of vegetation fires can be further influenced by atmospheric turbulence and instability in the dry air near the ground and in the lower atmosphere. These parameters also depend on the orography of the terrain and are not included in the Fire Weather Index. Two years ago, three levels of warnings were defined, the thresholds of which depend on the values and duration of wind, turbulence and instability. In addition to the detailed explanation of the method for issuing fire weather warnings, the paper presents textual and graphical warning examples, describes five critical fire weather patterns when conditions for issuing warning are the most common, and in the end gives a brief overview of warnings statistics and the most recent evaluation. According to the feedback from the firefighting community, the warnings proved to be important in the organization of supervisory and preventive activities, as well as fire suppression activities in case of vegetation fire ignition. The evaluation also shows that most of the significant vegetation fires burned in the days and at the locations for which warnings were issued.

1. Introduction

Vegetation fires belong to the most dangerous natural hazards and are closely related to weather and climate. As official institution in Croatia that deals with dangerous weather and weather-related hazards, Croatian Meteorological and Hydrological Service (DHMZ) is responsible for issuing forecasts and warnings on such phenomena. DHMZ cooperates with the Civil Protection Directorate, the Ministry of Defence and the Croatian Firefighting Association - organisations participating in the protection and rescue of people and property.

In Croatia vegetation fires are most common in the warm part of the year on the Adriatic coast and in the areas near the coast with the peak of fire season in the summer months. Therefore, fire protection and related activities are conducted mostly from spring to autumn, usually from May to October. In the fire protection system DHMZ is acting as advisory body, providing specialized meteorological information to the stakeholders of the system, primarily Croatian Firefighting Association (Kozarić et al., 2015).

The assessment of meteorological risk of vegetation fires is primarily based on the Canadian Forest Fire Weather Index (FWI) system, described in Van Wagner C.E. (1987), and on the fire danger classes calculated from the FWI. The analysis and forecasts of these data are unfortunately rarely available, only once a day at 24 meteorological stations. Climatological analysis shows that since 1990s the mean temperature in Croatia has been increasing with prominent positive trend as well as the extreme meteorological events, such as long dry spells and heat waves, particularly in the Adriatic area (Gajić-Čapka et al., 2010). This climate change consequently affects Fire Weather Index which shows positive trend as well, while at the same time, the fire

danger clasess tend to exibit prolonged periods of the highest values during the peak of fire season in summer. On the other hand, FWI does not include information on wind shear or change in direction. For this reasons a need for additional risk assessment tool has emerged and led to the development of the fire weather warnings. They were introduced ten years ago and since then have been constantly improved and adapted to the needs of the firefighting community. Basically, its purpose is to warn of weather conditions that can lead to the rapid spread and unpredictable behavior of the vegetation fires.

2. Method

As a basic condition, the fire weather warnings use the fire danger classes calculated from the Forest Fire Weather Index. A definition of classes is described in Dimitrov (1987) and shown in Table 1. Fire danger classes account for the total amount of fuel available for combustion, represented as the Buildup Index (BUI), and the relevant meteorological parameters included in FWI, the most important of which is wind speed. In terms of fire danger, classes have been assigned the following values: 1-very low, 2-low, 3-moderate, 4-high, and 5-very high. FWI represents the expected intensity of the spreading fire.

Table 1 - Fire danger classes calculated by combining FWI and BUI. Color is assigned to each class.

		Fire Weather Index (FWI)				
		0-4	5-8	9-16	17-32	33+
Buildup Index (BUI)	0-48	1	2	2	3	3
	49-85	2	2	3	3	4
	86-118	2	3	3	4	4
	119-158	2	3	4	4	5
	159+	3	3	4	5	5

The spread rate and the erratic, unpredictable behavior of wildland fires can be strongly increased by the atmospheric turbulence (Heilman and Bian, 2010) and the instability in a dry air (Haines, 1988), both near the ground or in the atmospheric boundary layer. Atmospheric turbulence is most often represented by turbulent kinetic energy (TKE) and instability in dry air by the Haines Index (HI). TKE takes into account an increased influence of orography on the wind, particularly causing gustiness and shear which are not included in the FWI. The highest values of HI are generally coincident with the large burned area and increased number of forest fires which is also the case in the Adriatic region of Croatia (Kozarić and Mokorić, 2014).

Two years ago, three levels of warnings were defined, i.e., yellow, orange, and red, allowing more precise distinction between dangerous weather conditions. The thresholds for levels depend on the values and duration of the three important meteorological parameters – wind speed, TKE and HI. Typically, red warning alerts of the most dangerous fire weather conditions. The latest improvements and adaptation of the fire weather warnings done in 2021 will be explained.

The criteria for fire weather warnings are given in Table 2. Meteorological parameters and fire danger classes are placed in rows of the table. Threshold values for these are in the cells of table columns.

Table 2 - The criteria for fire weather warnings. First condition is monitored in the first row, second condition in the rows 2 to 4.

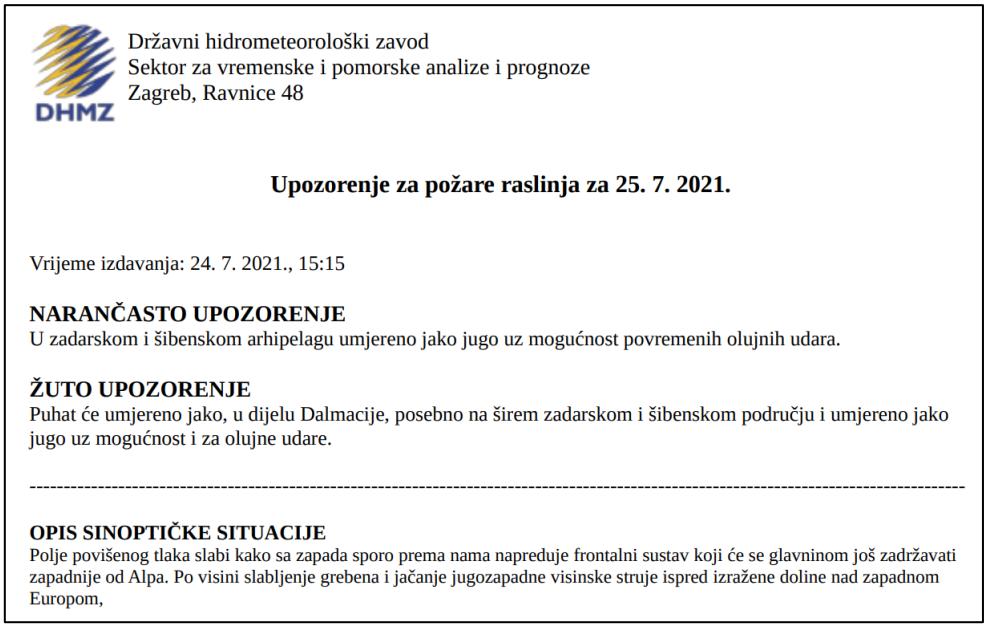
	Warning level			
	Yellow		Orange	Red
Fire danger class	Moderate	High and/or very high	High and/or very high	High and/or very high
Wind speed (ms^{-1})	>9 (5 hrs or more)	6 to 9 (5 hrs or more)	>9 (2-3 hrs or more)	>9 (18 hrs or more)
TKE (m^2s^{-2})		3 to 5 (5 hrs or more)	>5 (2-3 hrs or more)	>5 (18 hrs or more)
HI		6 (5 hrs or more)		

First condition to be monitored by the DHMZ's forecasters is the fire danger class which should be high and/or very high indicating increased dryness of the fuels. These values tend to be present in most days during peak of the fire season in the Adriatic, particularly in the south. As already mentioned, fire danger classes data are calculated at 24 locations at 12 UTC every day, either as analysis or forecast for next day. It is supposed that classes at 12 UTC represent fire danger for the whole day. Moderate fire danger class is also relevant but only in cases of particularly strong wind lasting for prolonged time.

Second condition to be monitored are the values of parameters of wind speed, TKE and HI, and a duration when exceeding the threshold values in the certain area. These data are available as model fields from numerical weather prediction (NWP) models, e.g., mostly used is in-house mesoscale model ALADIN (Tudor et al., 2016).

If values of at least one meteorological parameter, i.e., wind speed, TKE or HI, or any of their combinations meet the second condition and overlap with the first condition, the warning level is defined. For example, condition for yellow warning will be met if the fire danger class is very high and TKE in the area is from 3 to 5 m^2s^{-2} for 5 or more hours. Special maps in our workstation system have been developed to help forecasters in making these decisions. Note, Haines Index of the highest value 6, can only contribute to yellow warning. According to Croatian firefighters' feedback wind-driven fires cause major problems and the influence of instability (HI) was agreed to be reduced in the alerting process.

In accordance with the criteria, fire weather warnings are produced daily from the beginning of May to the end of October and issued to firefighting community as textual (Figure 1) and graphical product (Figure 2). Warnings are produced separately for the current day, using the analysis of fire danger classes, and for the next day using the forecasted fire danger classes as a first condition. In addition to the warning levels descriptions, a large-scale weather pattern description is included in the textual product.



Državni hidrometeorološki zavod
Sektor za vremenske i pomorske analize i prognoze
Zagreb, Ravnice 48

Upozorenje za požare raslinja za 25. 7. 2021.

Vrijeme izdavanja: 24. 7. 2021., 15:15

NARANČASTO UPOZORENJE
U zadarskom i šibenskom arhipelagu umjereno jako jugo uz mogućnost povremenih olujnih udara.

ŽUTO UPOZORENJE
Puhat će umjereno jako, u dijelu Dalmacije, posebno na širem zadarskom i šibenskom području i umjereno jako jugo uz mogućnost i za olujne udare.

OPIS SINOPTIČKE SITUACIJE
Polje povišenog tlaka slabi kako sa zapada sporo prema nama napreduje frontalni sustav koji će se glavninom još zadržavati zapadnije od Alpa. Po visini slabljenje grebena i jačanje jugozapadne visinske struje ispred izražene doline nad zapadnom Europom,

Figure 1 - An example of the textual fire weather warning product (in Croatian). List of warnings sorted by the level is followed by the large-scale weather pattern description.

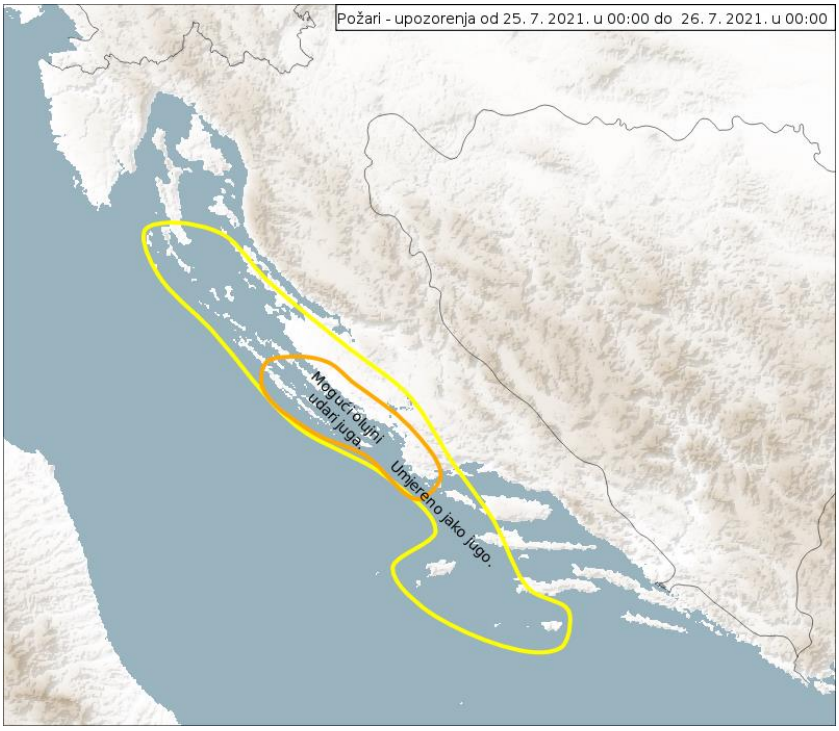


Figure 2 - An example of the graphical fire weather warning corresponding to the textual one (also in Croatian).

3. Critical fire weather patterns

This section describes five critical fire weather patterns when conditions for issuing warnings were most common. These large-scale patterns have been determined by the analysis of synoptic weather situation over Europe, both at surface and aloft, in the days when fire weather warnings were issued due to increased values of meteorological parameters (Mokorić and Hojsak, 2018).

- Pattern 1. Cold front passage followed by high pressure ridge strengthening from the North-west. Usually lasts a few days accompanied by enhanced northeasterly gusty downslope wind, called "Bura", turning to moderate to strong northwesterly wind.
- Pattern 2. Cold front passage with little or no rain ("dry" cold front) and gusty variable winds.
- Pattern 3. Situation of medium or slightly higher air pressure filed, usually non-gradient, accompanied by the instability in dry air (high values of the HI). Usually lasts for several days.
- Pattern 4. Enhanced southeasterly wind (called "Jugo") without rain, prior to approaching cold front.
- Pattern 5. The anticyclonic ridge that extends from northern Europe towards the Adriatic. Often lasts for a few days accompanied by enhanced "Bura".

There are some indications that the annual frequency of these patterns has been increasing in the last ten years, however this has to be explored more thoroughly.

4. Statistics and evaluation of fire weather warnings

Fire weather warnings in Croatia were first introduced in 2012 and since then have undergone changes in terms of improvements and adaptations. In Figure 3 an overview of warnings statistics is presented. It can be seen that in the last ten years the number of days with warnings was gradually increasing. The positive trend in the number of warning days seems to coincide with the positive trend in the fire danger, what can be addressed to the climate change. A notable jump in the last two years in the number of warning days is partly a result of the use of three-level warning method.

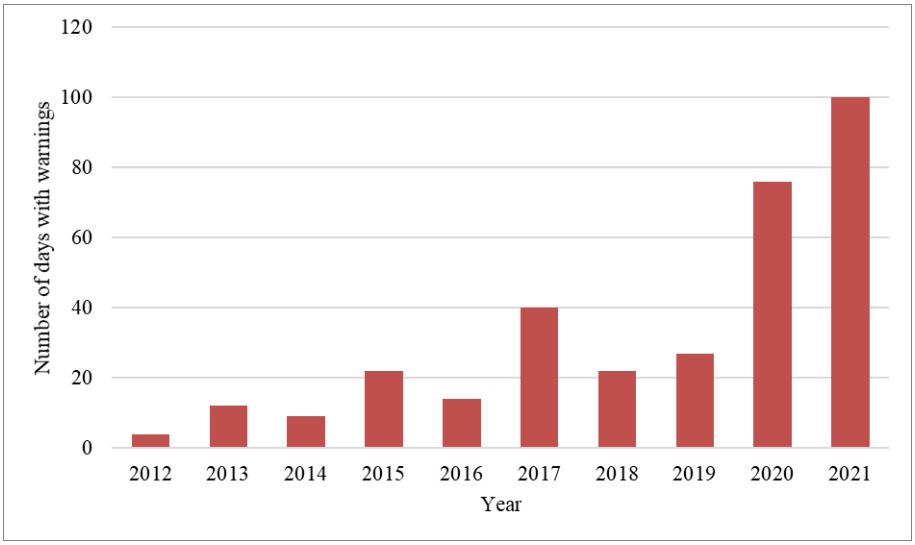

Figure 3 - The number of warning days per fire season in the period from 2012 to 2021.

In order to investigate a possible benefit of fire weather warnings, a simple evaluation was performed with the most recent data from 2021. Forty five days with the significant vegetation fires, i.e., which were hard to suppress or had large burnt area according to reports, were compared with 100 days with issued warnings during fire season. It has to be noted that every warning day is included, no matter how small the warning area was or how short it lasted. With the more strict filtering in terms of coverage and duration of fires, the number of warning days could be reduced significantly, however this was not intention. Furthermore, for the purpose of evaluation only days with the fire occurrence were considered since warnings have not been designed as an indicator of the fire ignition, rather as the indicator of possibility for rapid fire spread and unpredictable behavior. With those restrictions, for 31 out of 45 of the fire days warnings were correctly issued (Figure 4). In case of bigger fires, e.g., 100 ha or more, 7 fire days were covered by the warning and 3 were missed.

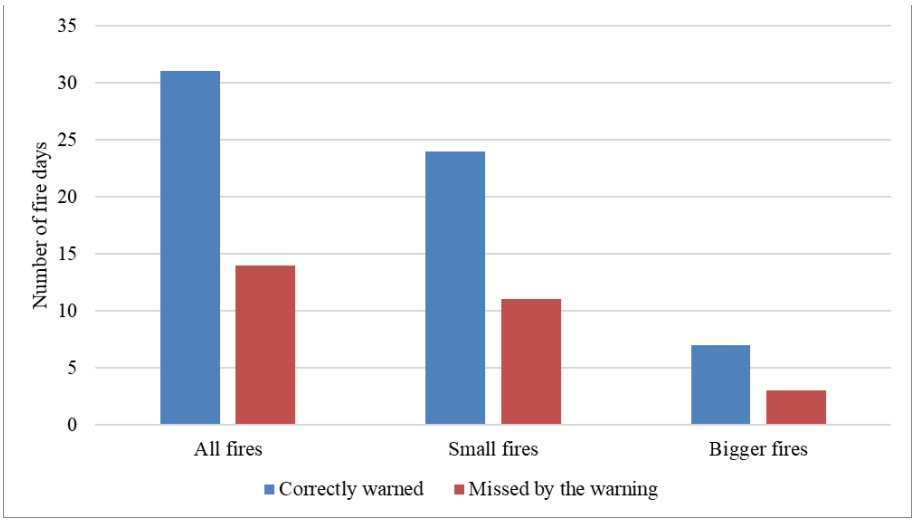

Figure 4 - A simple evaluation of fire weather warnings in the fire season 2021 in case of occurrence of vegetation fires, small and bigger ones. Correctly warned fire days are in blue, missed by the warning are in red.

5. Conclusion

Fire weather warnings in Croatia have been designed to reduce limitations of the assessment of meteorological risk of vegetation fires using only Canadian Fire Weather Index. The limitations are caused by the climate change, poor data availability and the lack of specific meteorological parameters in the FWI, i.e., turbulence and instability.

The main purpose of warnings is to alert to the weather conditions that can lead to rapid spread and unpredictable fire behavior. They are not necessarily an indicator of the fire ignition. The method for issuing is relatively simple, based on predefined criteria, improved over time, and tailored primarily to the needs of firefighting community.

Five critical fire weather patterns have been determined to cause weather conditions favorable for issuing fire weather warnings in Croatia. Most of them are related to strong and gusty wind.

The evaluation showed that most of the significant vegetation fires burned in the days and at the locations for which fire weather warnings were issued. More importantly, according to the feedback from the firefighting community, the warnings have proved to be very useful in the organization of supervisory, preventive and suppression activities.

Fire danger, wildfire hazard, wildfire risk, forecasting, dynamic

Abstract

Wildfires are a common global disturbance. Many of these fires fill important ecosystem roles but others must be suppressed to prevent loss of life or property. Decision support tools can provide critical information to support effective wildfire management, but the many components of these tools lack a supporting framework to integrate risk components to produce effective and useful wildfire risk forecasts. Here we present a framework to support wildfire preparedness and response decision making that incorporates both static and dynamic components of wildfire hazard to produce risk forecasting. Static model components provide a time-invariant ignition probability for both human and natural caused ignitions and are developed using topographic and fuel quantity metrics. Dynamic model components are evaluated using a combination of fire danger rating indices from the new US National Fire Danger Rating System Version 4.0 released in 2016 and the newly derived Severe Fire Danger Index. Fire danger forecasts can be normalized to percentiles using an appropriate climatology and then used to assess the dynamic, temporally varying wildfire hazard. We show that a simple model using Energy Release Component and Burning Index from the USNFDRS captures the majority of the temporally variability in wildfire occurrence (AUC = 0.823). When combined, we demonstrate the effectiveness of this model forecast system to predict the spatial and temporal locations of new wildfire ignitions across large areas using a blend of high, moderate and low-resolution spatial terrain, fuels and weather forecast data. We demonstrate various components of this framework across the United States and Northern South America specifically across Colombia, Ecuador, and Peru. This work will improve our ability to leverage modern fire danger rating systems with over conventional wildfire risk assessments to provide better decision support products throughout the world and these products have the potential to reduce wildfire impacts to firefighters and communities.

1. Introduction

Wildfires are a common global disturbance. Many of these fires fill important ecosystem roles but others must be suppressed to prevent loss of life or property. Many traditional and / or emerging tools are available to provide effective decision support for wildfire preparedness and response, but these tools are often developed in isolation without an effective framework for integrating the various components of wildfire hazard and risk together to produce meaningful and useful metrics of wildfire potential over the next several days or weeks. Such information is critical to informing resource needs or effectively pre-positioning limited fire response resources in areas of highest potential.

2. A Dynamic Wildfire Risk Forecasting Framework

Wildfire risk has been defined as the product of hazard and vulnerability. However, different types of wildfire risk assessments have never been considered in the context of a larger framework. For example, most spatial wildfire risk assessments only use static factors or scenarios to assess spatial risk and those risks can be assumed static for most purposes. However, when considering the spatial and temporal likelihoods of new wildfire ignition, some of the important factors may be static, such as accessibility from roads or navigable rivers, fuel availability, slope, aspect, elevation and other variables. Dynamic factors generally track seasonal weather severity and are best assessed using fire danger indices from systems such as the Canadian Forest Fire Danger Rating System (Stocks et al., 1989), the US National Fire Danger Rating System (Figure 1) (Jolly et al., 2019)

or other global fire danger metrics. When static and dynamic factors are combined, one can produce spatio-temporal maps of wildfire hazard.

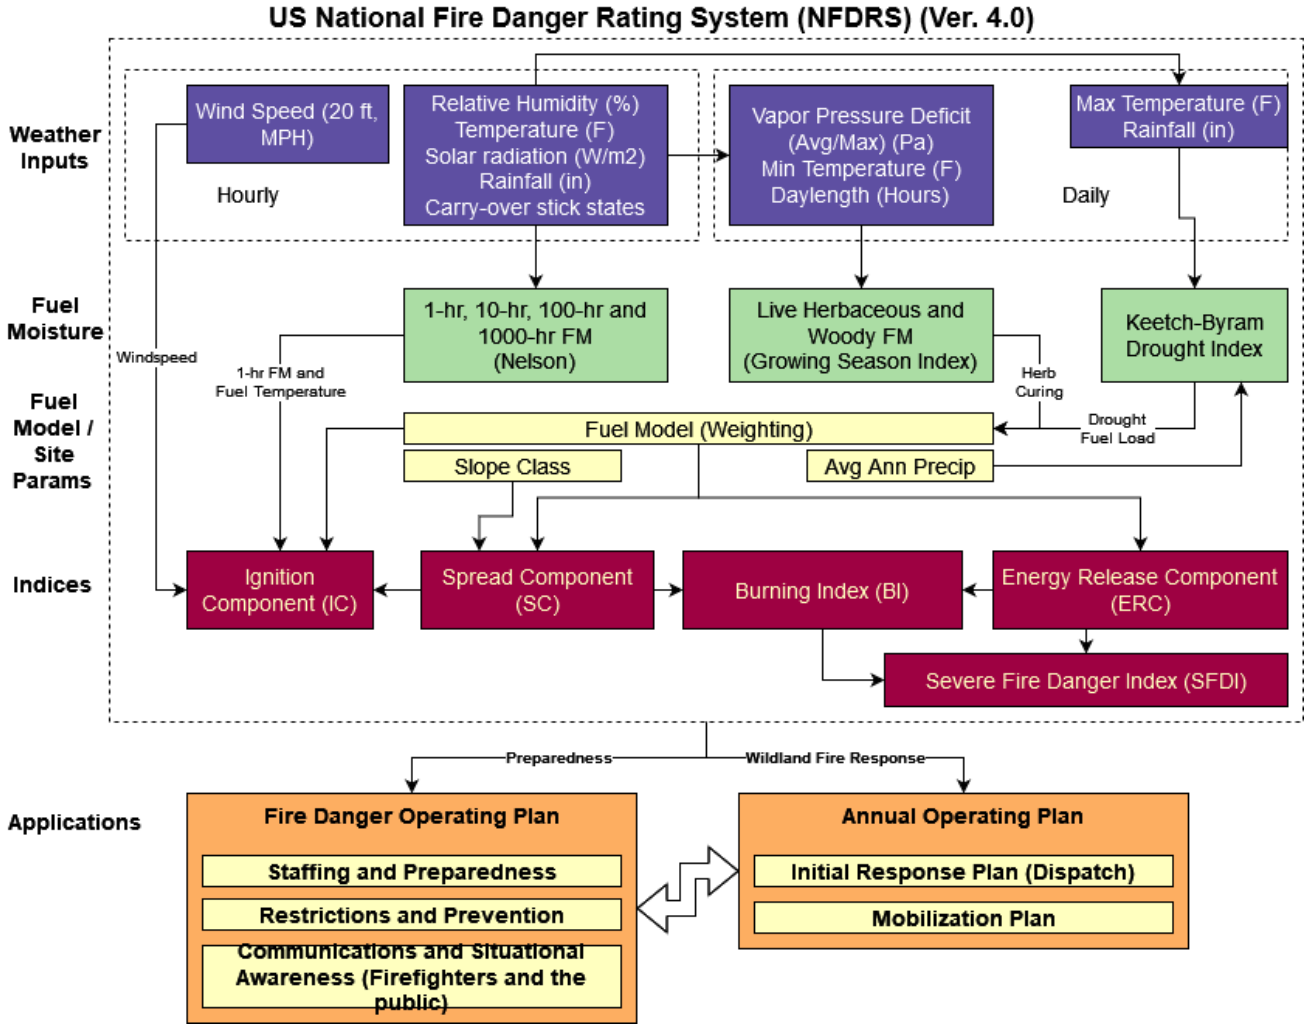

Figure 1 - The new US National Fire Danger Rating System Version 4.0 is one option for modelling and forecasting the dynamic components of wildfire risk. These forecasts can be produced for up to two weeks out.

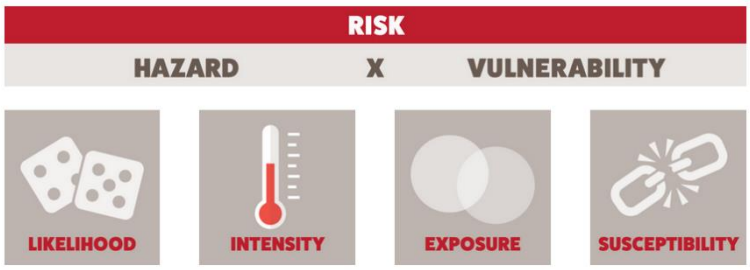

Figure 2 – Definition of Wildfire Risk from the Wildfire Risk to Communities (US Forest Service)

Vulnerability is more difficult to assess but it is generally considered the product of susceptibility and exposure but even these two components have both static and dynamic. Susceptibility is the propensity of a home or community to be damaged if a wildfire occurs and exposure is the spatial coincidence of wildfire likelihood and

intensity with communities (Wildfire Risks to Communities[4]) (Figure 2). Static vulnerability is an instantaneous measure, while dynamic vulnerability recognizes that both exposure and susceptibility can be modified over time to reduce overall risk.

To clarify linkages between static wildfire risk assessment products and dynamic components of risk that vary from day to day or week to week, we need a clearly defined conceptual model of how each piece fits together in the wildfire risk assessment spectrum. Essentially, fire danger rating is a major component of a dynamic wildfire hazard forecast but it can build on some static assessment of ignition risk. For example, terrain variables such as elevation and slope don't vary much over time except when large, geologic events occur and can thus be assumed static. Further, road networks are known to influence the spatial locations of new wildfire ignitions (Monjarás et al., 2020) but road density doesn't vary drastically from year to year except in places with extensive land-use changes.

Two separate models of wildfire hazard were developed. The first was a 'static' ignition hazard model that produces a spatial ignition probability and the second was a 'dynamic' model that include temporally variants factors from NFDRS. The static ignition model was developed separately for human and natural ignitions using slope, distance from roads, maximum NDVI and spatial locations. Fuel availability has been shown to affect fire probabilities in other studies (Briones et al., 2019). The dynamic model used Energy Release Component and Burning Index percentiles. Both models had very high AUC > 0.82. An example ROC for the dynamic model is shown in Figure 5.

The final framework is shown in Figure 6 and an example spatial assessment of dynamic wildfire hazard is shown in Figure 7. This conceptual framework can be used to better characterize the types of wildfire risk products produced for various applications. For example, typical wildfire risk mapping products are static and used for spatial planning. In contrast, fire danger assessment either in real-time or forecast are best used for characterizing dynamic wildfire hazard because they vary over time. When combined, these static and dynamic components of wildfire hazard and vulnerability form a framework that can guide how to leverage the combined components to produce effective wildfire risk forecasts that can support decision making at fine spatial and temporal scales or that can be scaled to larger areas over summarised over time to support longer-term decisions. Finally, we present an example spatial, normalized forecast for three countries in South America (Figure 8).

This framework demonstrates that a unified description of wildfire risk can be obtained when we consider the dynamic and static components of both the hazard and vulnerability. Future work will expand these assessments to the entire Continental United States, will leverage vulnerability assessments from the Wildfire Risk to Communities project across the United States and build on the forecasting system for Latin America to produce similar products and forecasts for Peru, Ecuador and Colombia.

Dead Fine Fuel Moisture Content, Wildfire Spread Simulation, AdriaFirePropagator

Abstract

Fuel moisture content (FMC) is the mass of water contained within vegetation in relation to the dry mass. It is one of the most important variables in all wildfire prediction and spread simulation models. FMC has great influence on wildfire ignition and combustion. For accurate wildfire spread simulations and wildfire risk index estimations, fuel moisture is a very important input variable. Since 2016, Croatian firefighters in everyday practice use Web based System for wildfire behaviour modelling and wildfire spread simulation named AdriaFirePropagator. The simulator is based on semi-empirical Rothermel's surface fire spread model for wildfire behaviour modelling and cellular automata for wildfire spread simulation. Fuel moisture, both live and dead is a very sensitive parameter in wildfire behaviour modelling. Live fuel moisture defines the moisture content of live fuels and dead fuel moisture is defined as moisture of dead fuels with time-lag of 1 hour, 10 hour and 100 hours. In Croatia there is no organised service for daily measurement of fuel moisture content, so values of these variables has to be estimated from meteorological parameters. This paper compares three approaches to fine dead fuel estimation, all implemented in AdriaFirePropagator. The first one, used in most wildfire simulation software, was based on standard mathematical models that relate air temperature, air humidity, 24-hours rainfall and wind speed with fine dead fuel moisture (FFMC). The second one was based on standard Fire Behavior Analysis Tables (FBA Tables) and the third one was based on intensive experimental research of dead fine fuel moisture content of Aleppo pine (*Pinus halepenses* Mill.). After intensive experimental research new Croatian fine dead fuel model PhFFMC was developed, tested in selected pine species stand and applied in AdriaFirePropagator for fuel regions where this pine species dominate. Croatian model is much better correlated with experimental data, therefore for more accurate wildfire simulations, similar models have to be developed also for other typical vegetation fuel types.

1. Fuel Moisture and wildfire spread simulation

Fuel moisture, both live and dead, is a very sensitive parameter in wildfire spread simulation. Live fuel moisture defines the moisture content of live fuels (Moist_live), and dead fuel moisture is usually defined as moisture of dead fuels with time-lag of 1 hour (Mois_dead_1h), 10 hour (Mois_dead_10h) and 100 hour (Mois_dead_100h). To illustrate how important fuel moisture is for wildfire simulations, in Figure 1 we show wildfire spread simulation results where all parameters are the same except live and dead fuel moisture content. The moisture content of **dead fuels** (DFMC) is controlled by fuel properties and external weather conditions: relative humidity, precipitation, temperature, and solar radiation, and the moisture content of **live fuels** (LFMC) is controlled largely by internal physiological mechanisms, so it is difficult to predict them only from meteorological parameters.

2. Determination of Fuel Moisture Content without direct measurement for AdriaFirePropagator simulations

AdriaFirePropagator is a Web base simulation tool for wildfire behaviour modelling and wildfire spread simulation. Since 2016. it is in everyday practice used by Croatian firefighters as one of modules of advanced wildfire surveillance and monitoring system named OiV Fire Detect AI (OiV (2022)).

AdriaFirePropagator is based on semi-empirical Rothermel's surface fire spread model for wildfire behaviour modelling and cellular automata for wildfire spread simulation.

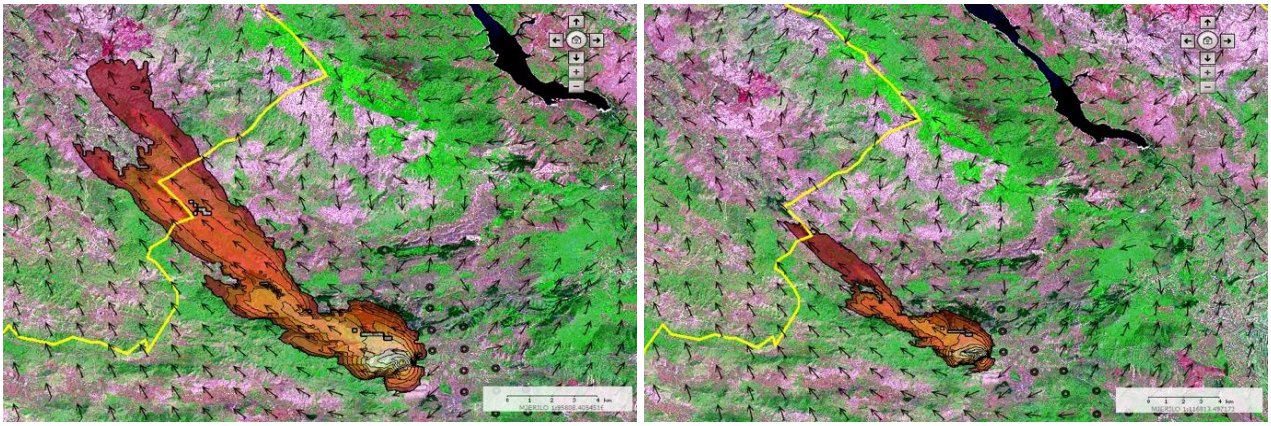

Figure 1 - Wildfire spread simulation using AdriaFirePropagator with the same input parameters except live and deal fuel moisture. In the left simulation the moisture content was 50% of the moisture content used for the right simulation).

In AdriaFirePropagator estimation of the moisture content of dead fuels is estimated by two models. The first one is based on Canadian FWI and its Fine Fuel Moisture Content (FFMC) calculation using air temperature, relative humidity, wind speed and 24-h rainfall. Van Wagner (1987) has proposed the scale equation that connect fine dead fuels moisture content m in % and FFMC:

$$m\ (\%) = 147.2\ (101 - FFMC)/(59.5+FFMC) \quad (1)$$

Formula is valid for the whole FFMC range $FFMC \in [\ 0, 100\ ]$.

Viegas also has shown in Viegas (2005) the correspondence between FFMC and fine dead fuel moisture:

$$m\ (\%) = (9*10^{9})/(FFMC^{4.54}) \quad (2)$$

but this formula is valid only for $FFMC \in [\ 65, 95\ ]$.

In AdriaFirePropagator moisture content m (%) is related to Mois_dead_1h.

Van Wagner (1987) has also proposed scales between Duff Moisture Code (DMC) and real moisture content in %, but AdriaFirePropagator moisture simulation is based on time-lag fuel moisture models corresponding to fuel particle size and not on fuel position used in Canadian FWI moisture codes, therefore here only correlation between FFMC and 1h fuel moisture was used. Other coarser dead fuel particles moisture content (Mois_dead_10h, Mois_dead_100h) is calculated by correlation models based on Scott and Burgan (2005) dead fuel moisture scenarios (very low, low, moderate and high) using simple equations:

$$Mois\_dead\_10h\ (\%) = Mois\_dead\_1 + 1 \quad (3)$$

$$Mois\_dead\_100h\ (\%) = Mois\_dead\_1 + 2 \quad (4)$$

Additionally, according to report published in Scott (2012) we have implemented weighting factors used to combine 1-, 10-, and 100-hr timelag class moisture contents into a single characteristic dead fuel moisture content for standard Scott–Burgan fuel model classes.

The second model for fine dead fuel moisture content estimation was based on standard Fire Behavior Analysis Tables (FBA Tables), published in Rothermel's (1983) guide on fire behavior prediction and implemented in BehavePluse utility named *Fine Dead Fuel Moisture Tool*. In these tables dead fuel moisture content is estimated using as input variables air temperature and relative air humidity. Tables are different for daytime and nighttime with additional corrections for season, time of day, elevation of the projection point relative to the weather observation, slope steepness class, aspect, and whether the fuelbed is shaded as reported in Scott (2012).

Meteorological data for both models are automatically collected from Croatian Meteorological and Hydrological Service server two times a day together with weather predictions calculated by ALADIN forecast model for the next 12 hours in the time resolution of 2 hours.

Moisture content of live fuels unfortunately could not be estimated from meteorological parameters. It is entirely based on field observations using approach published by Scott (2005, 2012) based on estimated by the percentage of cured leaves and introduced in simulator manually.

3. New Croatian model for dead Fine Fuel Moisture Content of two pine species typical for Croatian Adriatic vegetation

In order to improve the models for fine dead fuel moisture estimation, intensive experimental research was initiated at the Faculty of Forestry and Wood Technology, University of Zagreb (Bakšić 2017, Bakšić et al. 2017). As a case study, a typical Adriatic pine species, Aleppo pine (*Pinus halepensis* Mill.) was selected. Equilibrium moisture content (EMC) and response time of dead Aleppo pine needles were determined in the laboratory. These species-specific values were used to modify the Canadian hourly FFMC model. Thus, the basic modifications were changes in the EMC equations and changes in the response time equations of the hourly FFMC model. The input variables were hourly weather data: temperature, relative humidity, and wind speed. At this stage of model development, precipitation phase was not considered, so in case of precipitation the original equation from hourly FFMC should be used. A detailed explanation of the materials and methods as well as the final equations of the new model named PhFFMC (*Pinus halepensis* FFMC) can be found in Bakšić et al. (2017).

For model validation, intensive destructive sampling for moisture content determination was conducted in a mature Aleppo pine forest on Lastovo Island in July 2013. During sampling, a portable weather station was installed in the study site. Figure 2 shows the model validation results: the estimated moisture content for both the hourly FFMC model and the Croatian PhFFMC model compared to the actual observed moisture content.

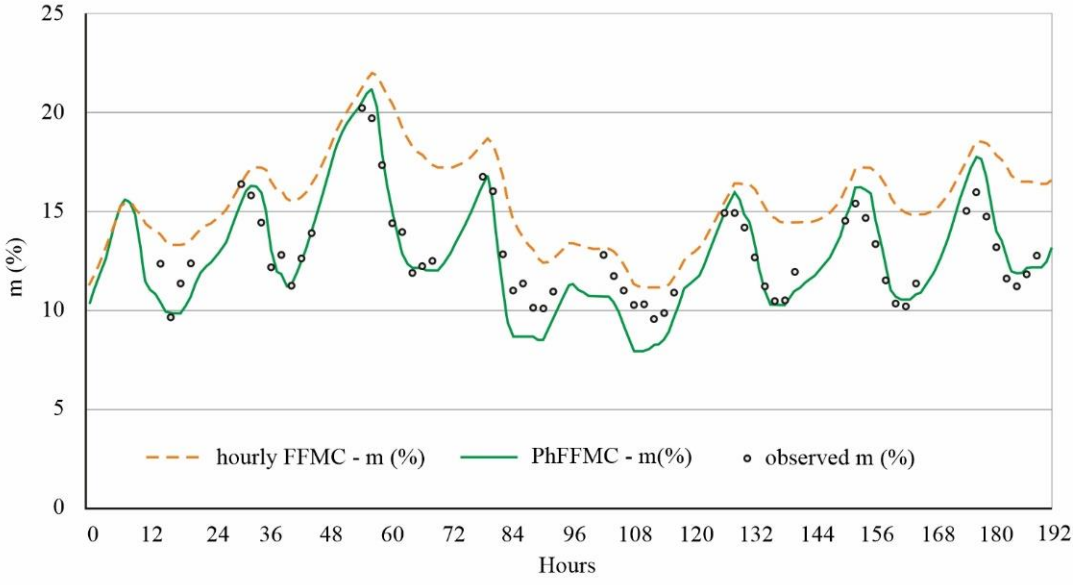

Figure 2 - Estimated moisture content (m) from hourly FFMC and Croatian PhFFMC models compared to actual moisture content (m) (Bakšić 2017).

Model validation results showed that the hourly FFMC model continuously overestimated the moisture content of Aleppo pine needles. Aleppo pine needles lose and gain moisture faster than the hourly FFMC model suggests. This is particularly evident when the actual moisture content reaches a minimum value, as this is when the largest average deviation from the hourly FFMC model occurs. On the other hand, the PhFFMC model follows the moisture content of Aleppo pine needles more closely throughout the period and reduces the mean absolute error in predicting moisture content to only 1%.

4. Comparation of various dead fuel models in AdriaFirePropagator simulator

Croatian model for dead fine fuel moisture content was implemented in AdriaFirePropagator and compared with other standard fuel moisture models based on Van Wagner equation and FBA tables. For testing purposes, we have used the large fire that occurred on the island Lastovo at 0:30 on Sept 4, 2003 and lasted almost 8 days. This fire was very well documented, so we were able to reconstruct its development. Figure 3 shows one of fire images taken by firefighters and ignition point location.

Figure 3 – Lastovo wildfire that has started on Sept 4, 2003 and lasted almost 8 days (left). Ignition point (right).

The weather conditions at the time of fire ignition were: Temperature T = 19.4 ^{0}C (66.92 ^{0}F), Atmospheric pressure at sea level SLP = 1024.7 hPa, Relative Humidity H = 29 %, Total Rainfall PP = 0 mm, Wind Speed W = 27 km/h, Wind Direction WD = 75^0 ('bura' wind). In simulations we have used Albini-Anderson vegetation categories. In its initial stage, fire propagated through vegetation class *"Long Needles and Hardwood Litter"*. Simulation was satisfactory regarding shape, but unfortunately not regarding time as Figure 4 shows. The fire front reaches real fire front in 360 min instead of 150 min. Therefore, we have changed fuel parameters to better fit the real fire spread. The difference was in fuel load and fuel bed depth, that has to be increased.

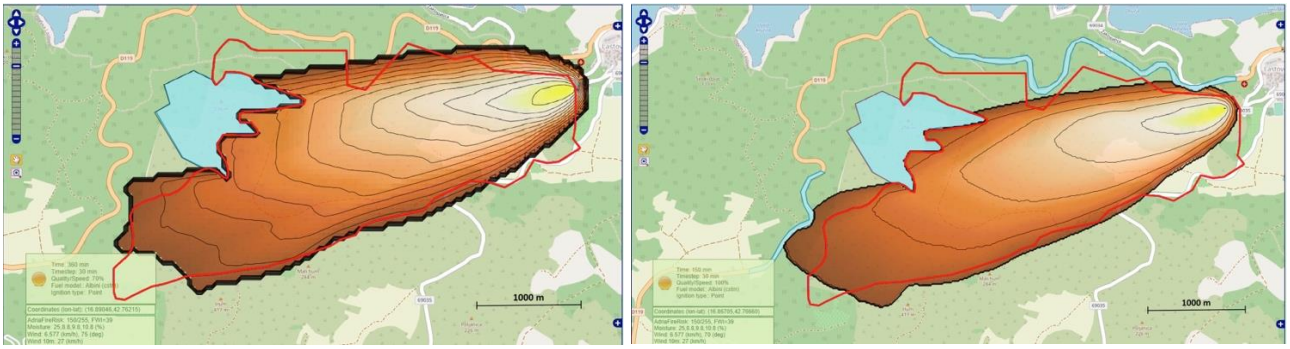

Figure 4 – With original Albini-Anderson fuel model parameters the fire front reaches real fire front (red line) in 360 min (left) instead of real 150 min. After fuel parameters adaptation satisfactory simulation was obtained (right).

Our next step was comparison of various dead fine fuel moisture content models. Live fuel moisture in all simulations was estimated to 80%. Three model for fine dead fuel moisture were compared:

a) Moisture model based on Canadian Fine Fuel Moisture Content (FFMC) calculation: Moisture 1h: 9.6; Moisture 10h: 10.6; Moisture 100h: 11.6 (same for the whole simulation)
b) Croatian model based on PhFFMC (Dominant vegetation on Lastovo island is Aleppo pine): Moisture 1h: 8.8; Moisture 10h: 9.8, Moisture 100h: 10.8 (same for the whole simulation)
c) Moisture model based on standard Fire Behavior Analysis Tables (FBA Tables): Moisture 1h: 6; Moisture 10h: 7; Moisture 100h: 8 (same for the whole simulation)

Figure 6 shows AdriaFirePropagator simulations for various moisture content models in comparison with real fire front recorded by firefighter commander Miloslavić (2003).The red line represents the real fire front.

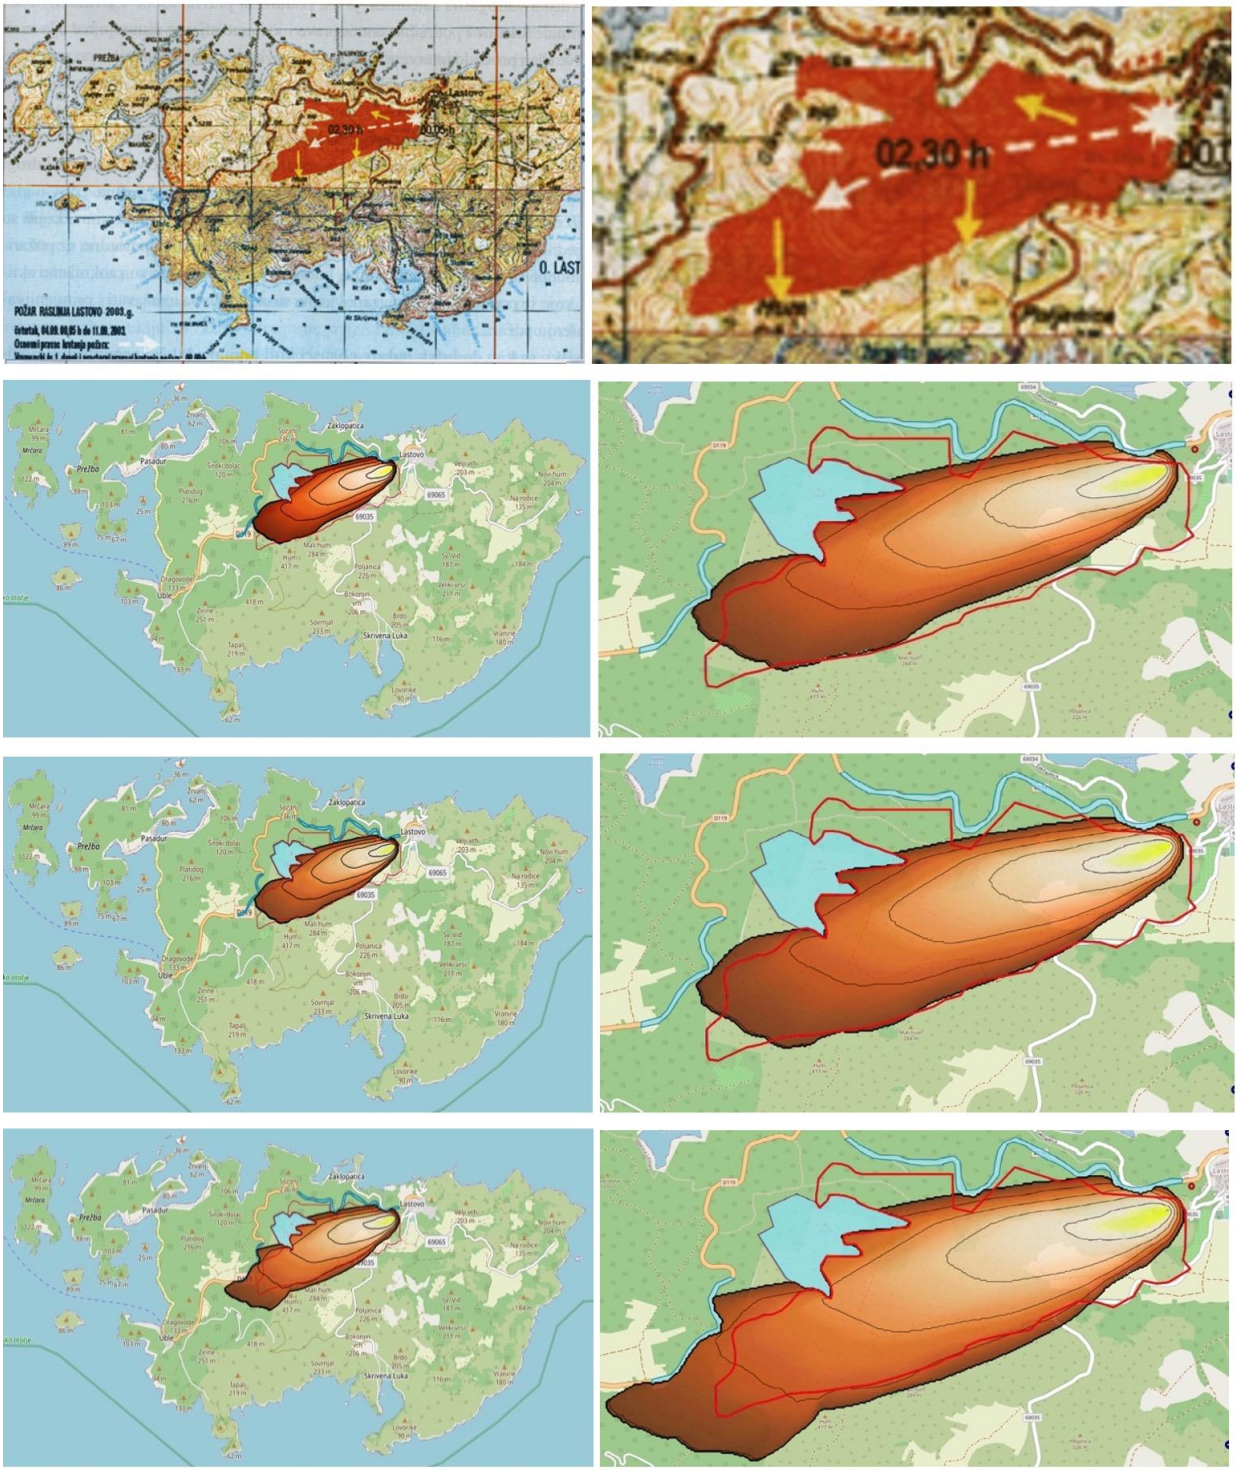

Figure 6 – Comparison of real fire front (1st row and red line on simulations) and AdriaFirePropagator simulations for various moisture models: 2nd raw – Canadian FFMC, 3rd raw– Croatian PhFFMC model, 4th raw – FBA Tables.

Table 1 summarise obtained results and shows precision, recall, F1 score and Intersection over Union (IoU).

Table 1 – Statistical comparison of simulation results from Figure 6 for various moisture models

	Precision	Recall	F1 score	IoU
Canadian FFMC	**0,93811805**	0,79243403	0,854375306	0,753069534
Croatian	0,929727814	0,827800566	**0,880604881**	**0,779056441**
FBA tables	0,742912923	**0,878384288**	0,804988789	0,673624466

Simulation based on Croatian PhFFMC model gave the best result in cumulative measures, because simulated fire front for this model was the closest to the actual fire front. FFMC based model gives the biggest moisture content, therefore the simulated fire front is smaller than the actual fire front. The situation is opposite for FBA tables model: the moisture content is the smallest and the simulated fire front is bigger than the actual one.

5. Conclusion

AdriaFirePropagator is a wildfire simulation software used in everyday practice by Croatian firefighters as a part of the advanced wildfire surveillance and monitoring system named OiV Fire Detect AI. Fuel moisture, both live and dead is a very sensitive parameter in wildfire spread simulations. Paper compares three different models for dead fuel moisture estimation: model based on Canadian FFMC, model based on Fire Behavior Analysis Tables (FBA Tables) and a new Croatian model based on intensive experimental and field research for fine dead fuel model for Aleppo pine PhFFMC. A well-documented 2003 Lastovo fire was used as a case study. From aforementioned models, the Croatian PhFFMC model has shown the best fit with real fire front, therefore our suggestion is that similar models should be made for all other vegetation categories characteristic for Adriatic region. The authors of PhFFMC model also have developed the similar model for Dalmatian black pine (*Pinus nigra* (Arnold) subsp. *dalmatica* (Vis.) Franco)) named PnFFMC (Bakšić 2017, Bakšić & Bakšić 2022). We hope that similar models will be develop for all other typical Adriatic vegetations. Also, we have shown that the original parameters of Albini-Anderson vegetation models do not give good results, especially in relation to the time component of fire spread, therefore we had to adjust them to match the actual fire spread. We hope that new vegetation models proposed through FirEUrisk project will resolve this problem.

Wildfire modelling, Fuelbreak, Fire Safety Engineering

Abstract

Dimensioning a fuelbreak remains always a challenging problem. For a long time, this problem was tackled using an empirical approach from the experience of operational users such as the fire fighters and the foresters. During the last decades, new approaches coming from fire safety engineering have completed the set of tools adapted to study this problem. These tools are all based on physical considerations, more or- less sophisticated. The simplest ones, consist in assimilating the flame as a radiant panel, calculating the distribution of radiant heat flux as a function of the distance separating the flame to a potential target and defining at what distance this heat flux reached a critical threshold level susceptible to produce damages on this target (pain for people or ignition for materials). The most complex ones, consist in solving the conservation equations (mass, momentum, energy ...) governing the behaviour of complex coupled problem formed by the vegetation, the flame front and the surrounding atmosphere. This new generation of engineering tool, based on CFD approach allows to directly predict the behaviour of a fire front propagating toward a fuelbreak, in order to evaluate its efficiency as a function of the amount of surface fuel (grass, shrubs) removed to reduce locally the fuel load and therefore the intensity of an incoming fire. These two approaches are fully complementary, only the first one has the potentiality to be spread operationally on the field, whereas the second one can contribute to improve the first one and to study with more detail some very sensitive situations such as those encountered in the wildland urban interface (WUI). The main part of this study concerns numerical simulations of the propagation of a fire front through a homogeneous vegetation layer (a grassland) in the vicinity of a fuelbreak represented by a band more or less wide inside which all the fuel was removed. The simulations were performed using a fully physical wildfire model (FIRESTAR3D), three variable parameters were considered in this study: the 1m open wind speed (U1 ranged between 3 and 10 m/s), the fuel height (HFuel ranged between 0.25 and 1m) and the fuelbreak width (LFB). With these conditions, the simulations covered a large range of values of the Byram's convective number NC ($0.3 < NC < 60$) in order to explore wind as well driven fires ($NC < 2$) and plume dominated fires ($NC > 10$). The 72 simulations carried out in this study have been classified in three categories: 1/ Propagation (if the fire has crossed the fuelbreak with a propagation after); 2/ Overshooting or Marginal (if the fire has crossed the fuelbreak without a propagation after); 3/ No-propagation (if the fuelbreak has stopped the fire). The main objective of this study was to determine the optimal fuelbreak width LFBx separating between the Propagation and the No-propagation regimes, in order to generalize the conclusion, the results have been presented in dimensionless form (similitude theory) in representing as an example the ratio LFBx/HFuel versus the Byram's convective number NC.

1. Introduction and numerical configuration

Most of criteria used to design the optimal width of a fuelbreak are based on the assumption that the ignition of the fuel located beyond the fuel break will be due to radiation heat transfer. One of the first formula proposed by Emmons (1964) assumed that the ignition of the solid fuel located ahead of the fire front was initiated from the foot of the fire (1D vision), conducting to an expression including the extinction length scale characterizing the solid fuel layer and the depth of the fire front. Whereas other ones included the role played by the flame inside and above the vegetation layer (2D vision), proposed criteria based on the geometry (length or height) of

the flame (Rossi & al, 2011; Butler & Cohen, 1998). We propose with this work to explore this problem with more details and without a priori ideas, using numerical simulations based on a fully physical approach, with the objective to study both the influence of heat transfers coming from radiation and convection upon the effectiveness of a fuelbreak built in an homogeneous grassland. The spotting phenomena, which can play also a great role for this problem, was not taken into account in this study.

A set of 72 numerical simulations of the propagation of a quasi-infinite fire front has been carried out in a grassland inside which a x-meter width (L_{FB}) fuelbreak has been positioned. Outside the fuelbreak the vegetation layer was constituted as follows: a dry grass (FMC = 5%) with a fuel load ranged between 0.25 and 1 kg/m^2. In order to reproduce a quasi-infinite fire front (to avoid some effects, such as the curvature of the fire front resulting from finite ignition line), periodic boundary conditions have been imposed on the lateral sides of the domain (see Figure 1) (Frangieh & al, 2021). As indicating in the abstract, a quite large set of conditions (wind, fuel height) has been tested to cover the two regimes of propagation identified in the literature, namely the wind-driven fires and the plume-dominated fires. As suggested in many previous studies, the transition between these two regimes of propagation can be defined from the Byram's convective number N_C representing the power ratio between the buoyancy (plume) and the inertia (wind) forces (see Eq.1): $N_C < 2$ for wind-driven fires and $N_C > 10$ for plume-dominated fires (Morvan, 2014).

$$N_C = \frac{2\ g\ I}{\rho\ C_P T_0 (U_{10} - ROS)^3} \quad (Eq.1)$$

Where g and I represent respectively the acceleration of gravitation and the fireline intensity, ρ, C_P and T_0 the density, the specific heat and the temperature of the ambient air, U_{10} and ROS the 10m open wind velocity and the fire rate of spread.

The numerical simulations have been performed using a multiphase formulation, consisting in solving the balance equations (mass, momentum, energy …) governing the evolution of the coupled system formed by the vegetation and the surrounding atmospheric layer. The main advantage of this approach is its ability in reproducing main physical phenomena, such as the thermal decomposition of the vegetation, the mass and heat transfer between the vegetation and the atmosphere, the combustion process both in the gas phase (the flame) and in the solid phase (embers), the radiation heat transfer, the atmospheric turbulence, and the interactions (drag effect) with the vegetation and so on … To achieve these objectives a relative fine grid must be used for the representation of the computational domain. As shown in previous studies, the size of the grid must respect some criteria in order to represent correctly the radiative heat transfer between the flame and the vegetation (at least the grid size must be smaller than the extinction length scale characterizing the vegetation layer). But this level of details needs also to pay a high price in terms of computational resources and to collect numerous data on the field to describe the structure and the state of the fuel. For these reasons, this kind of formulation is presently limited to describe a fire front at a relatively small scale (< 1 km), however sufficient in many fire safety engineering problems, such as the present one, the evaluation of the effectiveness of fire breaks (Frangieh & al, 2021; Morvan, 2015), or others more fundamental problems associated to wildfires physics (Morvan, 2014, 2013; Frangieh & al, 2020).

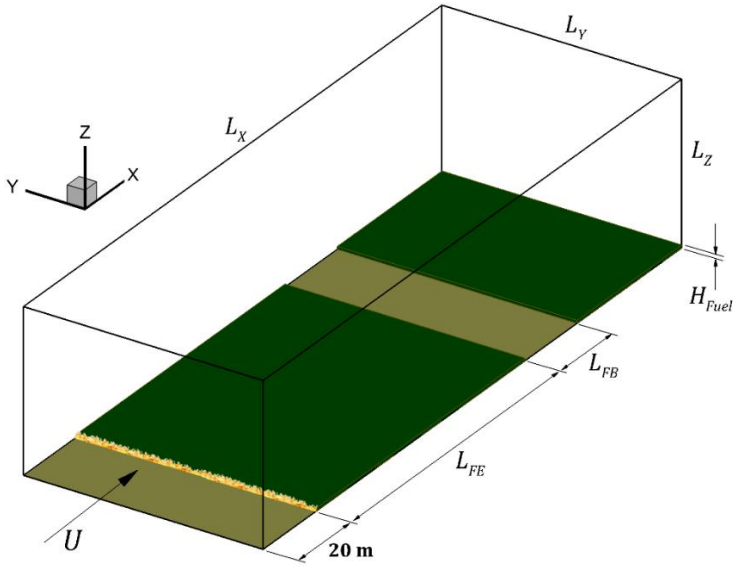

Figure 1- Numerical configuration: L_{FB} fuelbreak width .

2. Some numerical results

After analysis, the set of numerical results was classified in three categories: 1/ Propagation; 2/ Overshooting or Marginal; 3/ No-propagation. The first and the last ones are easily understanding, they correspond respectively to the cases for which the fire front was able to propagate (1) or was stopped (3) beyond the fuelbreak. The middle case (2) includes two sub-cases: Overshooting (2.a) for which some pocket ignition was observed beyond the fuelbreak followed by a propagation along a short distance and an extinction; Marginal (2.b) very similar to Overshooting, the fire behaviour switch to No-propagation if the fuelbreak width increased by 1 m. A 3D view of a fire front crossing a 6.5 m wide fuelbreak is shown in Fig.2. This representation illustrates how a fire front was able to cross such fire prevention device. As the fire front reached the border of the fuelbreak, the fuel located on the opposite side is ignited punctually (see Fig.2), forming a set of burning pockets. Then these punctual fires merged in forming a continuous fire front which can then propagate again through the solid fuel layer. In comparison the Overshooting situation was observed when the ignition points were too distant to be able to merge and to sustain a continuous propagation of the fire (Frangieh & al, 2021).

The yellow surface represents the isovalue surface (T = 1000 K in the gas phase), therefore this zone includes both the flaming zone and the smoldering zone. It is for this reason that it seems so wide.

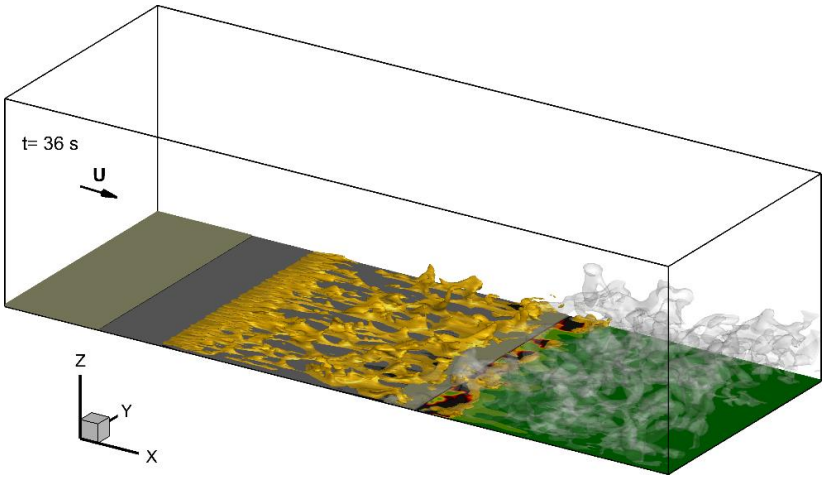

Figure 2- 3D visualization of grassland fire obtained for U_1 =8 m s^{-1} and W = 0.35 kg m^{-2} (Nc = 1.95) as it crosses a 6.5-m wide fuelbreak. The yellow surface is the isovalue surface T = 1000 K of the gas temperature and the semi-transparent grey surface is the isovalue surface $Y_{H2O} = 10^{-3}$ of the mass fraction of water vapor.

The ratio between the critical fuel break width with the fuel height (L_{FBx}/H_{Fuel}) versus the Byram's convective number N_C is reported in Fig.3. This curve shows clearly the role played by the regime of propagation. The range of variation of the ratio L_{FBx}/H_{Fuel} seemed to be particularly important for wind-driven fires ($N_C < 2$), between 30 and 80 (for the present cases), whereas the same parameter varied between 25 and 10 for plume-dominated fires ($N_C > 10$). This effect can be attributed to the mechanisms of heat transfer between the flame and the fuel located beyond the fuel break: for plume-dominated fires the fuel is exclusively heated by radiation whereas for wind-driven fires heat transfer by convection and sometimes by flame contact (the flame can be significantly tilted by the wind flow) plays an increasing role (Emmons, 1964; Butler & Cohen, 1998). These results highlight that the optimal design of a fuel break cannot be only reduced to a constant ratio between the fuel break width and the upwind fuel depth (and therefore the fuel load), this ratio must necessarily depend on the wind flow conditions and also of the slope (not study in this work). However, in looking the worst case (wind driven fire with $N_C << 1$), a ratio LFBx / HFuel nearly equal to 100 (see Fig.3) seems to be quite secure to avoid a crossing of an incident fire front.

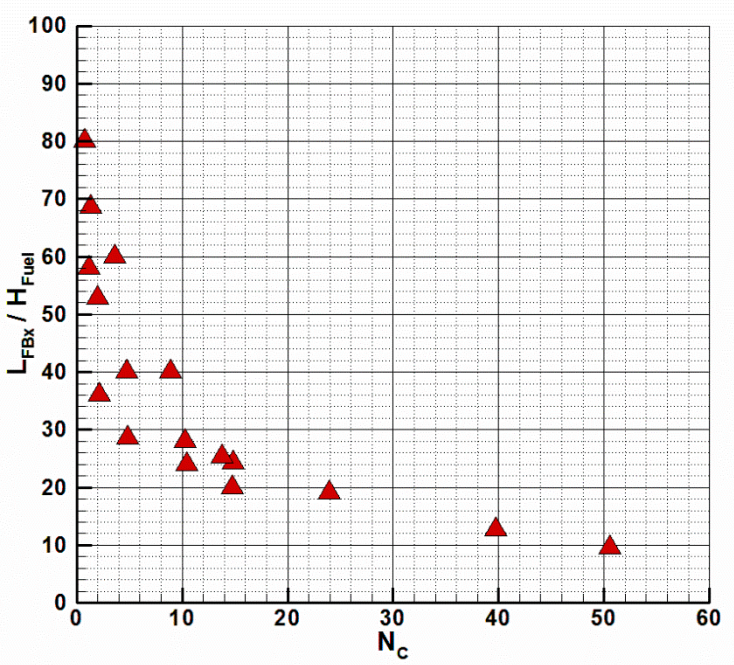

Figure 3- Optimal fuelbreak width L_{FBx} (lower limit of extinction) scaled by the fuel height H_{Fuel} versus Byram's convective number N_C (Frangieh & al, 2021).

The results obtained at various fireline intensity in the present study, have been also confronted to those predicted with a more operational tool (DIMZAL), based on a simplified physical analysis (mainly the radiant panel theory) (Rossi & al, 2011; Bisganbiglia & al, 2017). This comparison has allowed to highlight some agreements but also some differences between the two set of data, allowing to foresee some progress in a new version of this operational tool. Better agreement between these two approaches can be noticed in Fig.4 for relatively less critical configurations, obtained here for weak wind conditions, i.e. plume dominated fires mainly piloted by radiation heat transfer. This result is not surprising in considering the scientific base retained in DIMZAL tool. As suggest in (Frangieh & al, 2021), a adaptative evolution of the critical heat flux implemented in DIMZAL to evaluate the optimal fuel break width could be an interesting way to cover a larger spectra of fire behaviour, from plume dominated fire to wind driven fire. This work is already in progress and could be presented in a future publication.

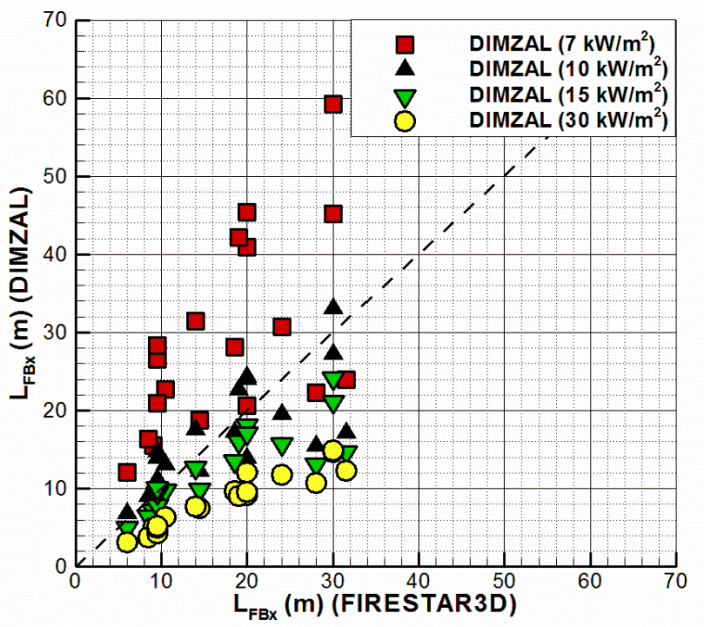

Figure 4- Optimal fuelbreak width obtained by numerical simulations (FIRESTAR3D) and from DIMZAL operational tool for critical heat flux values (Rossi & al, 2011; Frangieh & al, 2021).

Keywords

Burning rate, wood cribs, design fire

Abstract

A new wildfire spread model is being developed to alleviate many of the limitations of current operational models. This new model consists of sub-models for ignition, burning and heat release rate, and heat transfer. Unfortunately, the factors that control the burning rate of wildland fuels are not well understood. In this work, we use an extensive database of experimental data with wood cribs to examine curve forms that can be used to describe the time-dependent nature of the burning rate of porous fuel beds. Fifty crib designs and 148 individual mass data curves of cribs burned with unrestricted airflow were available for analysis. Both a power law and a Weibull-distribution-like curve are shown to capture the main shape of the experimental data. Further work will incorporate data with restricted airflow, wind, and moisture content.

1. Introduction

Operational fire behaviour models are either empirically (such as the Canadian and Australian systems (Fire Danger Group 1992, Cruz et al. 2015)) or semi-empirically derived (Rothermel model in the US system (Rothermel 1972). Because of their origin, there are inherent limitations to their use. For example, these three systems consist of fire spread models, designed to output a spread rate for a given set of conditions. There is no built-in ability to determine if a fire will even spread, a question that is relevant to planning prescribed fires and determining the burning period for long duration modelling. In order to alleviate such limitations, a new fire behaviour model is being developed by the Missoula Fire Sciences Lab that treats fire spread as a series of ignitions (Finney et al. 2021). Once an initial ignition is realized, the fuel begins to burn releasing heat at a given rate, and some of that heat is transferred to the unburnt fuel ahead. The new fire behaviour model thus consists of several sub-models: ignition, burning and heat release rate, and heat transfer. This paper focuses on work towards the burning and heat release rate sub-model.

Unfortunately, the burning rates of wildland fuels beds are not well understood. Though it is not actually used in spread prediction, the related residence time of a wildland fire is predicted in BehavePlus as simply 8 times the fuel diameter in inches, which does not take into consideration the variety of other parameters that are likely at play, such as packing, moisture content, and wind (Albini 1976, Anderson 1969). Studying the burning rate in natural fuels beds during a spreading fire is very challenging and it is difficult to accurately manipulate the relevant variables to understand the underlying governing physical processes. For this reason, a simplified fuel bed is often used called a wood crib. Wood cribs have been used to study wildland fire for decades (Fons 1963, Byram 1964, Rothermel 1971, Thomas 1973, Anderson 1990). Wood cribs are frequently used in fire protection engineering as ignition sources and there are several correlations to predict their burning rates (Gross 1962, Block 1971, Heskestad 1973, Thomas 1973). Previous work (McAllister and Finney 2016a) has shown that a slightly modified version (from McAllister and Finney 2016a) of the correlation from Thomas (1973) works best to predict the burning rate for a wide variety of crib designs and stick thicknesses:

$$\frac{100\dot{m}}{A_s\rho_o(gh)^{0.5}} = \frac{0.85}{(0.26h/s)} \qquad \text{(Eq. 1)}$$

where $\dot{m}$ is the burning rate (g/s), A_s is the exposed surface area (cm^2), ρ_o is the air density (g/cm^3), h is the crib height (cm), and s is the spacing between sticks (cm). The new fire behaviour model under development currently uses a simple empirical relation based on a somewhat limited set of laboratory experiments as a place

holder for a more complete sub-model. This place holder consists of a burning rate that is constant in time, which is a gross simplification for the time-dependent burning rate so often seen in actual scenarios where the fire builds in intensity, reaches a peak, and then decays to extinction. The goal of this paper is to develop a more physically-based time-dependent relation for the burning rate based on experiments using wood cribs. Such a "design fire" is common in the fire protection literature (for example see Bwalya 2008, Quintiere 2017).

2. Methods

McAllister et al. have conducted a wide range of experiments using wood cribs and have generated an extensive database of experimental data that will be exploited for this work (see McAllister and Finney 2016a, McAllister and Finney 2016b, McAllister 2019, McAllister 2021, McAllister 2022). For a detailed description of the experimental procedures, please see the original papers. The same general procedure was followed. The cribs were conditioned in a conditioning chamber at 35°C and 3% RH for at least three days so that the moisture content was about 1%. The cribs were place on 7.62 cm tall rectangular steel tubes to create a sufficient space between the crib and the weighing platform (see McAllister and Finney 2016a). The cribs were ignited by briefly dunking them in 99% isopropyl alcohol and allowing them to drain. The mass was measured with three 6-kg load cells recording at 10 Hz for the majority of tests. The reported burning rates were found by determining the maximum slope of a linear fit to the data. In all, the database consists of 50 crib designs with a wide variety of stick thickness (0.16-1.27 cm), stick lengths (6.4-60.96 cm), crib heights (1.27-31.75 cm), and porosities (0.00196-0.211 as evaluated by the Heskestad (1973) formulation). See Appendix A for a full list of crib designs. Most cribs were tested three times so a total of 148 mass loss curves were available for analysis.

To prepare the data for analysis, the data was trimmed to only include the time when the crib was actively burning. The ignition point was manually determined, but the burnout time was chosen to be the time when the burning rate, found from a spline fit with ten degrees of freedom, dropped to 5% of the peak value. The consumed mass (initial mass – mass(t)) was then scaled by the initial mass minus the residual mass, and the time scaled by the burnout time so that both mass and time ranged between 0 and 1. The scaled burning rate was found by a spline fit of the scaled mass and scaled time. The scaling can be done for both the consumed mass and burning rate with the measured values ("observed scaling") as well as predicted values ("predicted scaling") based on the number of sticks, wood density, and peak burning rate estimated from the Thomas correlation (Equation 1). Because the peak burning rate only occurs in most cases for a short period of time, an average burning rate would be more appropriate to estimate the burnout time. To estimate this average burning rate as a proportion of the peak, a subset of the data was examined, and it was found that the average burning rate was approximately 60% of the peak value. Thus, an average scaled burning rate of 0.60*(peak burning rate) was used to estimate the predicted burnout time for scaling the data (predicted burnout time = predicted initial mass / average predicted burning rate). Two curve forms were then fit to this collection of scaled data, first with the scaled consumed mass then the scaled burning rate. The first curve form, a power-law relation, was used based on experience:

$$m^*_{consumed} = \left(\frac{2t^*}{1+t^{*\alpha}}\right)^{\beta} \qquad \text{(Eq. 2)}$$

The second was found from a literature survey to be quite useful for fitting heat release rate curves from cone calorimeter tests to passenger vehicles (Numajiri and Furukawa 1998, Ingason 2005, Tohir et al. 2021):

$$m^*_{consumed} = \left[1 - e^{-\gamma t^*}\right]^{\delta} \qquad \text{(Eq. 3)}$$

where $m^*_{consumed}$ is the scaled consumed mass (dimensionless), t* is the scaled time (dimensionless), and α, β, γ, and δ are fitting constants. Note that Equation 3 is similar to the Weibull distribution but will be referred to here as the "N&F" fit in reference to the work by Numajiri and Furukawa (1998). The derivatives of Eqs. 2 and 3 were used to fit the scaled burning rate:

$$\dot{m}^* = 2\beta\left(\frac{2t^*}{1+t^{*\alpha}}\right)^{\beta-1}\frac{1+(1-\alpha)t^{*\alpha}}{(1+t^{*\alpha})^2} \qquad \text{(Eq. 4)}$$

$$\dot{m}^* = \gamma\delta e^{-\gamma t^*}\left[1 - e^{-\gamma t^*}\right]^{\delta-1} \qquad \text{(Eq. 5)}$$

where $\dot{m}^*$ is the scaled burning rate (dimensionless).

3. Results and Discussion

Table 1 shows the fitting constants in Equations 2 and 3 that best fit the experimental scaled consumed mass ("mass curve fits") and the fitting constants in Equations 4 and 5 for the scaled burning rate ("rate curve fits"). Also included in Table 1 are measures of fit including the coefficient of determination (r^2), root-mean-square error/deviation (RMSE), and the median absolute error/deviation (MDAE).

Table 1 – Curve fit constants and measures of fit for "observed scaling."

	Power law mass curve fit (Eq. 2)	N&F mass curve fit (Eq. 3)	Power law rate curve fit (Eq. 4)	N&F rate curve fit (Eq. 5)
Fitting constant 1 [ ]	$\alpha = 1.450$	$\gamma = 3.784$	$\alpha = 1.687$	$\gamma = 3.212$
Fitting constant 2 [ ]	$\beta = 1.845$	$\delta = 3.265$	$\beta = 2.160$	$\delta = 3.250$
r^2 to mass [ ]	0.9593	0.9535	0.9620	0.9614
RMSE to mass [ ]	0.0659	0.0713	0.0688	0.1044
MDAE to mass [ ]	0.0407	0.0519	0.0448	0.0846
r^2 to rate [ ]	0.5206	0.4879	0.6006	0.5470
RMSE to rate [ ]	0.3281	0.3735	0.3093	0.3203
MDAE to rate [ ]	0.2652	0.2690	0.2329	0.2418

Figure 1 compares the "mass curve fits" to the experimental mass consumed data using both the "observed scaling" on the left and the "predicted scaling" on the right. Immediately, it is observed that there is considerably more spread in the data when the "predicted scaling" is used. This is due to the accumulation of errors in estimating the initial mass (7.7% average difference from observed), the residual mass (29-31% for 1.27 and 0.64 cm sticks; 110-117% for 0.32 and 0.16 cm sticks), and the burning time (30% average difference from observed). A noticeable portion of the spread is from a handful of crib designs whose burning rate (and thus burning time) was not well predicted by the Thomas correlation (Eq. 1). In general, however, both curve fits are centred in the data cloud, with the power law (red) curve appearing to increase at a slightly earlier time than the N&F (blue) curve and pass through the point (1, 1).

Figure 2 compares the "mass curve fits" to the scaled burning rates using both the "observed scaling" on the left and the "predicted scaling" on the right. Here again, as expected, when the "predicted scaling" is used there is more spread in the data for the same reasons as above. What is more problematic is that the time when the peak burning rate occurs does not seem to be well predicted when the consumed mass is used for fitting. Key metrics for the burning rate are compared in Table 2. The "experimental" values are averages from each individual data file. By considering the first three columns in Table 2, it appears that power law fit to the consumed mass data might be slightly better at matching the time to the peak scaled burning rate, but the N&F curve fit to the consumed mass data is better for capturing the mean and peak scaled burning rates.

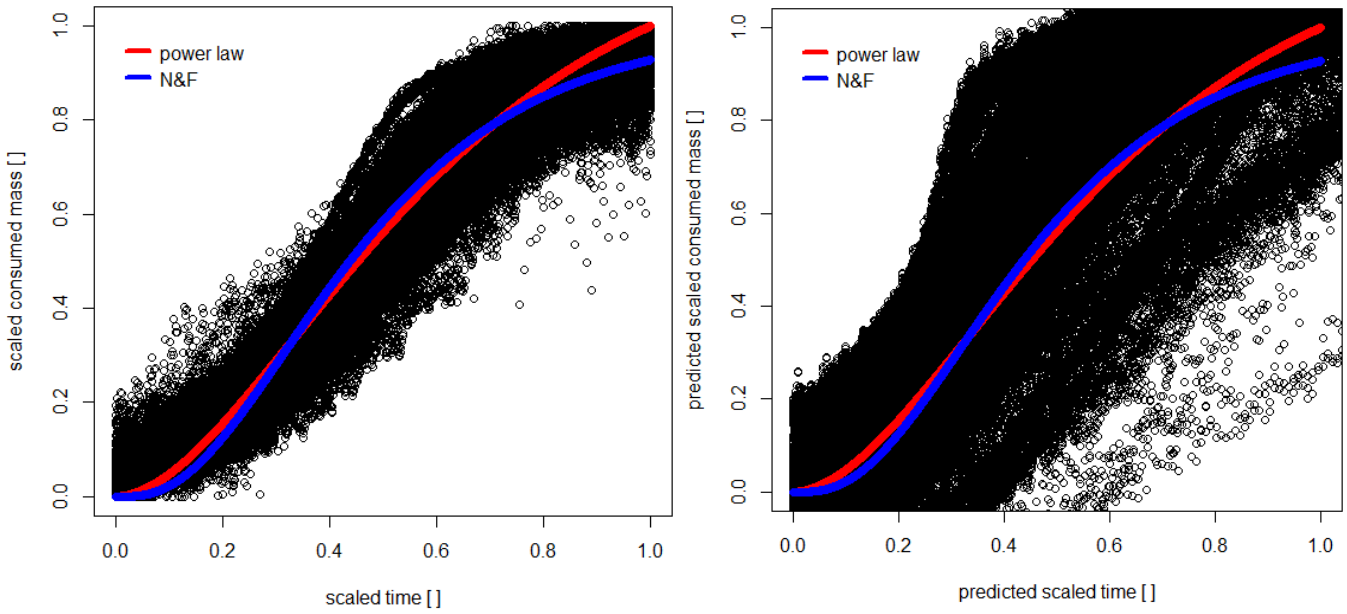

Figure 1 – "Mass curve fits" for consumed mass versus time using observed scaling (left) and predicted scaling (right).

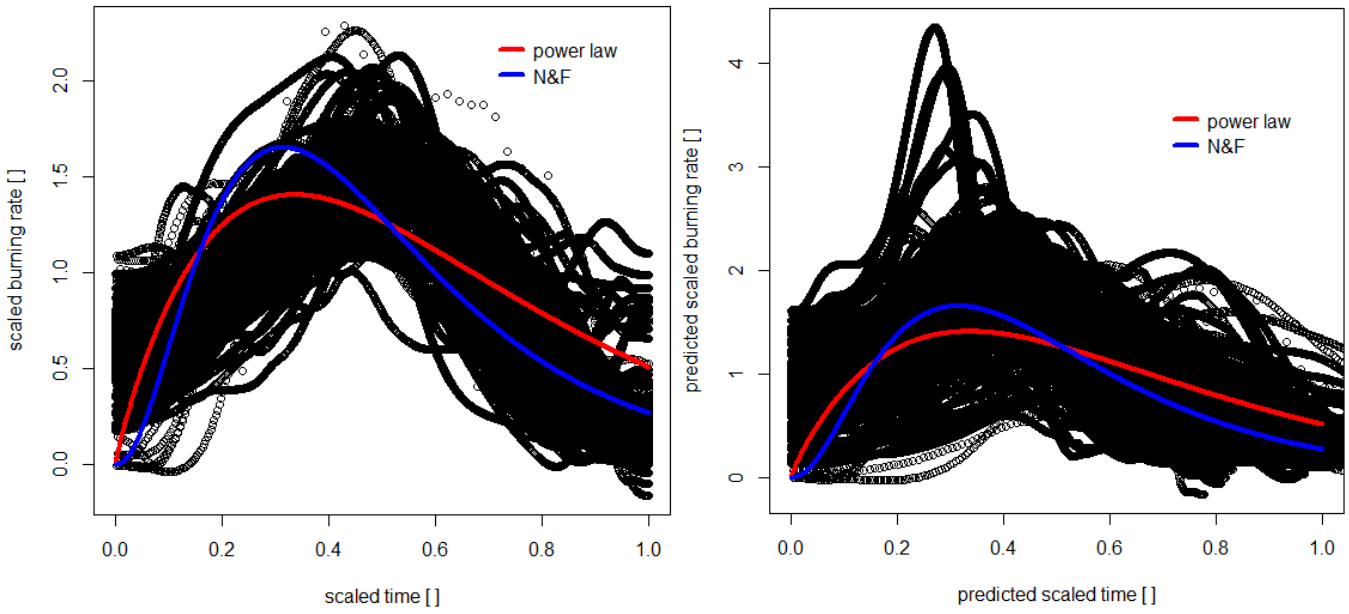

Figure 2 – "Mass curve fits" applied to scaled burning rate using observed scaling (left) and predicted scaling (right).

Table 2 – Key burning rate parameters as measured in the database and calculated from curve fits.

Burning rate parameter	Experimental average	Power law to mass data (Eq. 2)	N&F to mass data (Eq. 3)	Power law to rate data (Eq. 4)	N&F to rate data (Eq. 5)
Mean scaled burning rate [ ]	0.9286	1.000	0.9276	0.9992	0.8742
Peak scaled burning rate [ ]	1.5940	1.4057	1.6527	1.5477	1.4041
Time to peak scaled rate [ ]	0.4949	0.333	0.312	0.386	0.367

Figure 3 shows the results if the curves in Eqs. 4 and 5 are fit to the scaled burning rate (using the "observed scaling"). As shown in Table 1, the curve fitting constants and goodness of fits are slightly different. As expected, the measures of fit to the rate data have improved, while the fitness has decreased slightly for the consumed mass. Though the differences between the two curve fits are still slight, Table 2 shows that when the burning rate is fit, the time to peak is shifted somewhat to match the experimental average more closely but is

still skewed slightly early. The power law fit now slightly better predicts the peak burning rate, while the N&F still better matches the average.

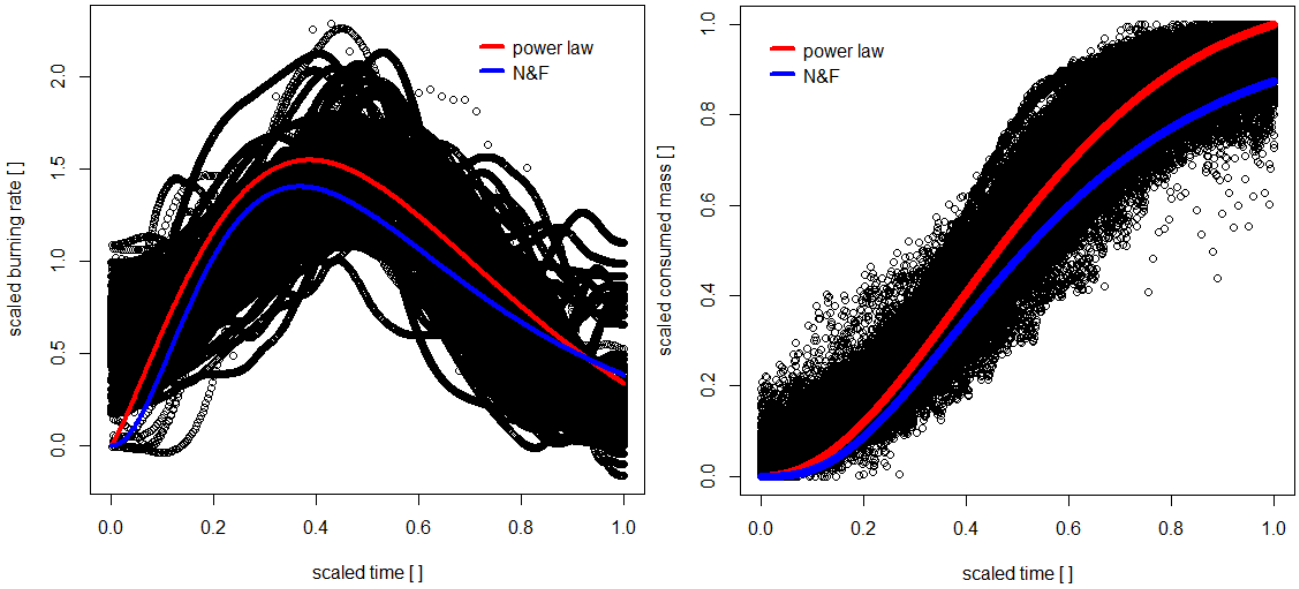

Figure 3 – "Rate curve fits" plotted with scaled burning rate data (left) and scaled consumed mass (right).

4. Summary and Future Work

Two curve forms were fit to an experimental database of crib burns. Both curve forms show promise and captures features of the data slightly differently. Determination of which curve form is most appropriate will likely depend on which feature is more important to the application. Further data also needs to be incorporated that includes the effect of restricted air flow, wind, and moisture content.

5. Acknowledgements

This work was funded by the National Fire Decision Support Centre. The authors want to thank James McGuire, Jennifer Kennedy, Sophia Vernholm, and Chelsea Phillips for building the many cribs and help performing the experiments; Randy Pryhorocki and Josh Deering for building the apparatuses used for the experiments; and Cyle Wold for setting up the data acquisition system.

Decision support tools, past fires database, behavior and impact Simulator, hot spot geolocation, guide to prescribed fires

Abstract

The GOLIAT project is a consortium of academics and firefighting operators and land-use planning professionals of Corsica. One goal of GOLIAT project is to provide four operational decision support tools. To reach this goal, a survey of past fires occurred in Corsica since the twentieth century beginning is made. This inventory contributes to build up a database with a web display interface easy to use as fire patterns history. A fire behavior and impact simulator prototype for vegetation fires, a geolocation tool for hot spots using UAV images, and a guide of good practices of prescribed fires in the undergrowth are building. At the same time, experimental fires are carried out to improve knowledge about high intensity fire and the experimental results were compared to the predictions provided by a complete physical 3D model, namely FireStar3D.

1. Introduction

The GOLIAT project brings together academics from the University of Corsica, Aix-Marseille University, University of Toulon and Lebanese University with Corsican fire-fighting operators and land-use planning professionals and a company carrying out computer developments. The partners are : the National Forestry Office, Fire and rescue Service of Southern Corsica, Fire and Rescue Service of Northern Corsica, Regional Nature Park of Corsica and Arobase company. The aim of the program is to develop tools, studies, guides, and awareness-raising activities to provide a response to wildfire issues. This program is co-financed by the Corsican Collectivity and the French State. It started in January 2020 and will last for three and a half years.

The GOLIAT project is divided into three main objectives. The first objective is to deepen the phenomenological and historical knowledge of vegetation fires in Corsica. Research is carried out to increase knowledge of the behavior of vegetation fires, the fires that have occurred in Corsica, and the methods used to control fire in traditional Corsican society. The second objective is to build decision-making tools prototypes that meet the needs of firefighting and land-use planning operators. Four prototype tools are under development: 1) A database associated with an information display tool dedicated to fires that have taken place in Corsica 2) A behavior and impact simulator for vegetation fires 3) A geolocation tool for hot spots using UAV images 4) A guide to prescribed burning in the undergrowth. The third objective is to carry out many awareness-raising and prevention actions on the vegetation fire problem in Corsica, aimed at schools, public and local authorities.

In the context of global warming that we are experiencing, intense fires affect several countries growing and over larger periods. Prescribed burnings are used by operators for land-management thanks to its low cost and high efficiency in hard-to-reach areas. In the context of this program, high intensity fires across Corsican *Genista salzmannii* vegetation and prescribed burnings on a Mediterranean pine forest are instrumented and studied mixing numerical and experimental approaches and disciplines such as physics, chemistry, ecology, and UAV vision.

2. Decision support tools

From the needs expressed by the firefighting and land-use managers, the GOLIAT project has been elaborated to provide decision support tools usable by them when fire occurs.

Three tools are created to give to firefighters in a web display information about the past and the future of Corsican fires.

When a fire will occur, using the GPS position of the ignition point, operators will have web server services to see (1) the past fires information correlated with meteorological data, (2) the prediction of the future fire front positions and heat fluxes and (3) the geolocation tool for hot spots obtained from UAV IR images.

One tool is created specifically for land managers, it concerns a guide to prescribed burning in the undergrowth in *Pinus laricio* forest.

2.1. Fire database associated with an information display tool

A survey of past fires occurred in Corsica since the twentieth century beginning is made. This inventory contributes to build up a database. This last contains information about fires, which size is greater than 10 ha, occurring in Corsica since 1904. It also contains meteorological data (Fig. 1) and noteworthy events in relation with the firefighting. 2 048 fire contours and 1 593 ignition points are included, a work is in progress to show this information in a web server in a format display adapted for firefighters easy to use as a fire patterns history.

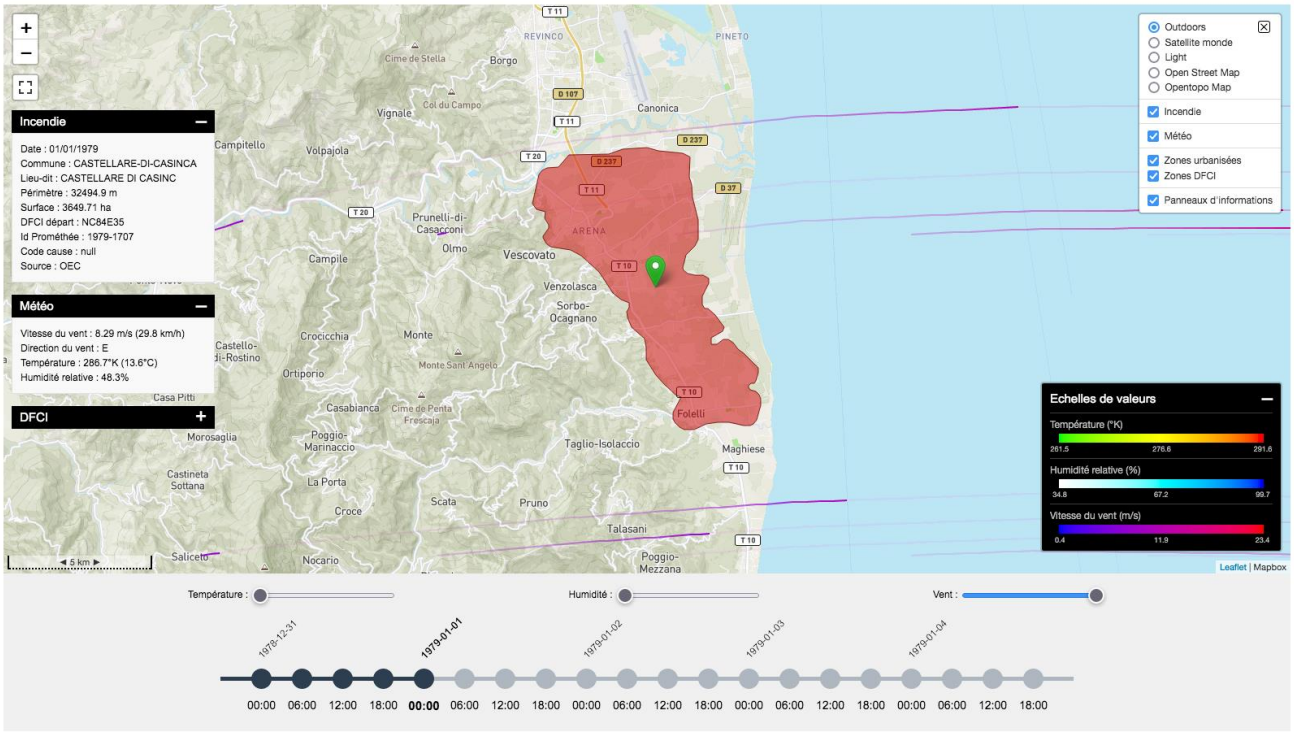

Figure 1- Screenshot of the web interface presenting data associated to a past fire

The meteorological data which allowed this representation come from the Copernicus project (https://cds.climate.copernicus.eu/cdsapp#!/dataset/reanalysis-uerra-europe-complete?tab=overview) (Fig. 2). A script has been created that collects the dates of all fires and collects weather data from T-24h to T+96h with a 6h time step.

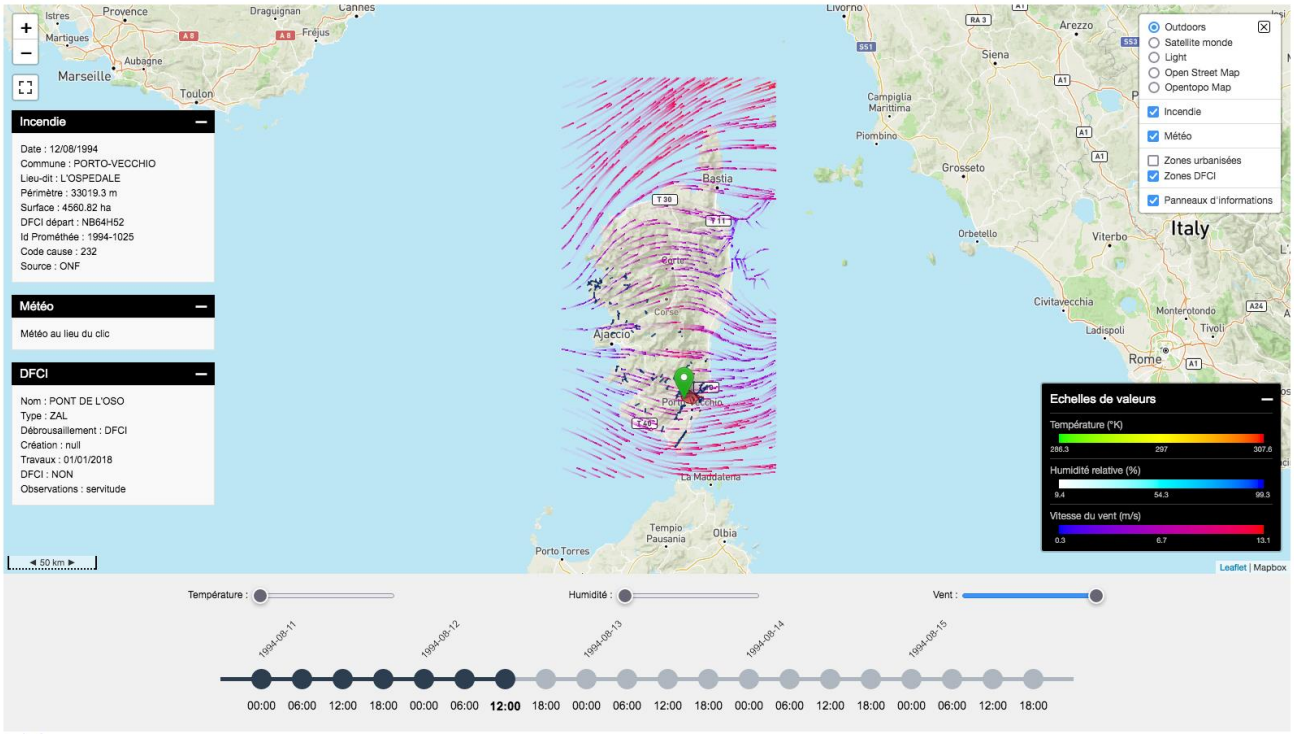

Figure 2- Wind flow all over Corsica screenshot

2.2. A behavior and impact simulator for vegetation fires

The behavior and impact fire simulator is developed on the requirements drawn up between researchers and operators. Physics used to predict fire behavior is the last version of the Balbi model (Balbi *et al*. 2020) developed at the University of Corsica. This simulator will predict from an ignition point or a contour (Fig. 3) the fire front evolution (Fig. 4) and an acceptable safety distance (Rossi *et al*. 2011). Indeed, the knowledge of the impact zone in front of flames is a relevant information for firefighters to stay in safety conditions when they fight fire.

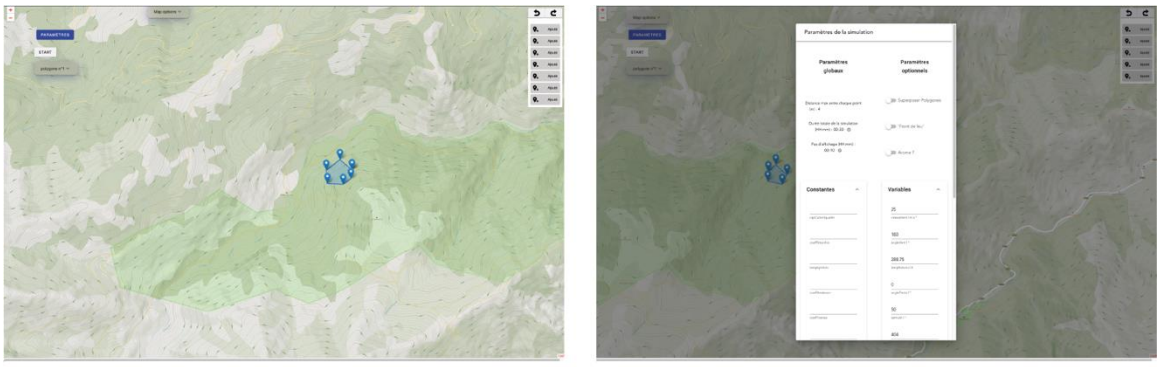

Figure 3- (a) Start contour screenshot (b) Simulation parameters configuration panel

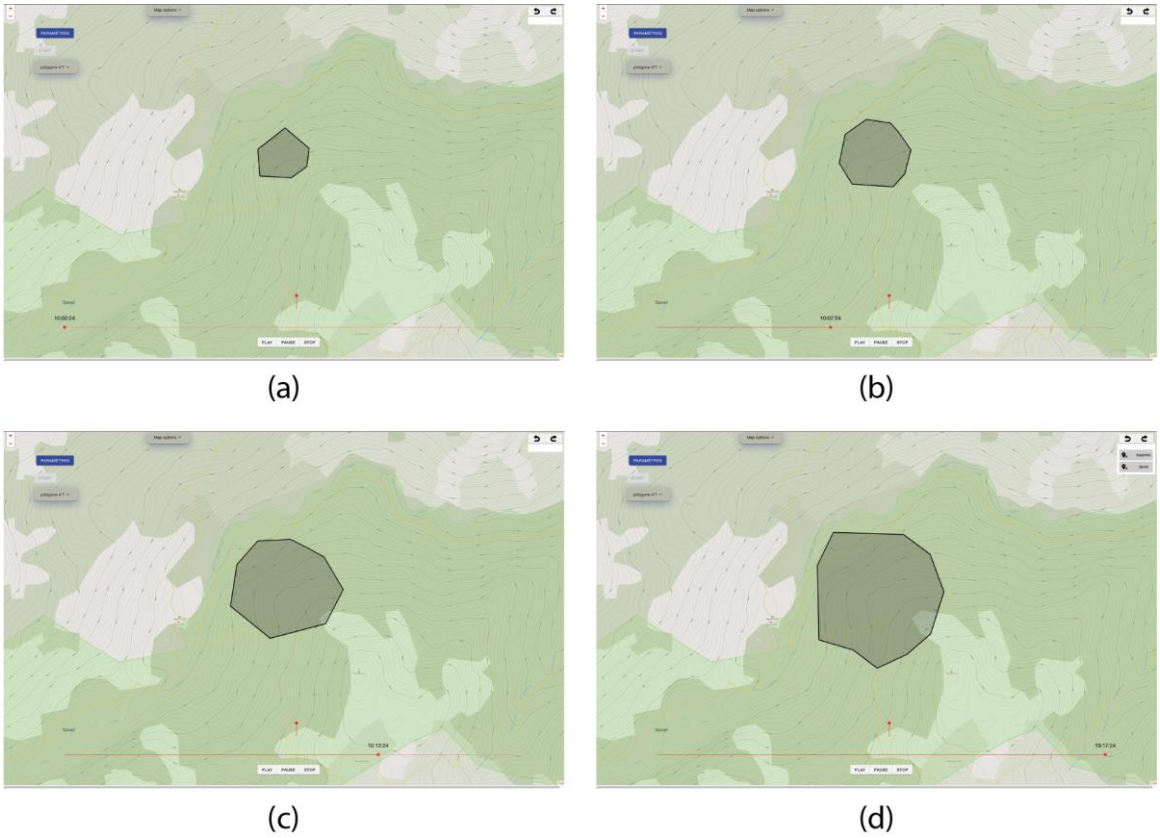

Figure 4- Fire front evolution simulation (a) t = …

Experimental fires were conducted with the main objective of providing data to test the predictions of the theoretical physical fire models, in the case of a high-intensity fire spreading upslope at field scale (Fig. 5). To understand and investigate the different phenomena encountered in this type of fires, the experimental results were compared to the predictions provided by the multiphase code FireStar3D (Fig. 6) (Frangieh *et al*. 2020). These predictions were used to examine the fire front dynamics, to evaluate the fire intensity that was difficult to accurately assess during the experiment (Fayad *et al*. 2022).

Figure 5- Experimental fire at Speluncatu (Corsica)

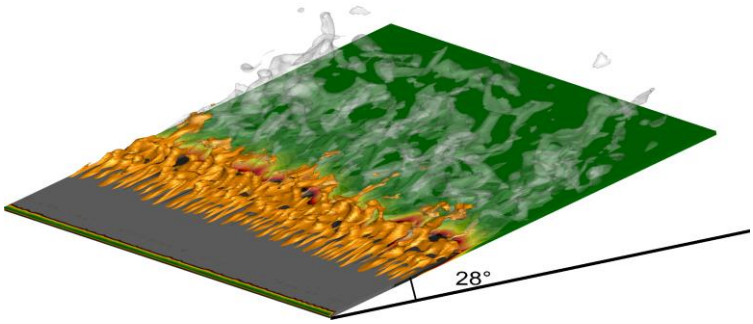

Figure 6- FireStar3D simulation on the Speluncatu experiment

2.3. A geolocation tool for hot spots using UAV images

The geolocation tool answers the needs expressed by the Fire and Safety Services of Corsica. When the fire is stopped, it is necessary to keep an eye on for several days and they need to cover burnt aeras for extinguishing hot spots whom are potential resumption of fire.

Thank to DJI SDK, programs have been developed to automate the pattern of the drone with cameras on board working simultaneously on the UAV and far IR, to detect and to geolocate the hot spots (Fig. 7).

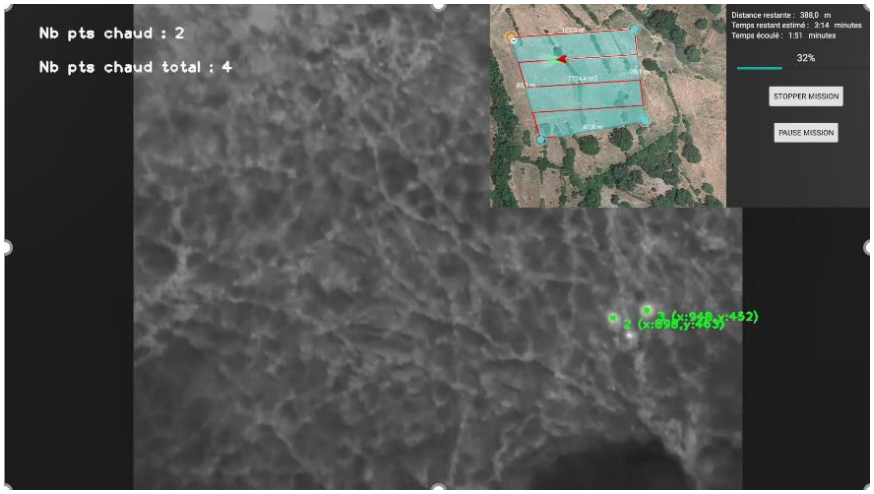

Figure 7- Hot spot software screenshot

2.4. A guide to prescribed burning in the undergrowth

Research works are conducted to improve the knowledge on fire resistance of *Pinus laricio* forests. Undergrowth prescribed fires are carried out (Fig. 8). Samples of vegetation, soil, insects, and pine needles are taking on witness parcels. Sensors for tree growth, sap fluxes, temperatures are located on these parcels.

The analysis of the collected data will allow to give recommendations on undergrowth prescribed fires to minimize impact on *Pinus laricio* forests.

Figure 8- Prescribed fire on a* Pinus laricio *forest in Corsica

3. Conclusion

The GOLIAT project is based on the research developed at the University of Corsica and develops new work to meet the needs for tools, studies and knowledge expressed by firefighting and land-use operators. It allows synergy between academics and fire professionals, technology transfer to build decision support tools: a database of fires occurred in Corsica with a display tool, a behavior and impact simulator for vegetation fires, a geolocation tool for hot spots using UAV images and a guide of good practices to prescribed fires in the undergrowth of *Pinus laricio* forest.

The improvement of knowledge on the phenomenology of vegetation fires will make it possible to increase the effectiveness of the prediction of fire behavior and, thanks to the strong interaction with the operational staff, to develop tools that meet their needs.

Wildland fire-spread, Rate-of-spread parameterization, Perturbed physics ensemble, Parameter uncertainty, Sensitivity analysis

Abstract

Coupled atmosphere/fire models are recognized as an efficient and representative way to simulate wildland fire behavior at geographical-to-meteorological scales by representing the two-way interactions between the fire front propagation and the surrounding atmosphere. These coupled models rely on a rate-of-spread (ROS) parameterization to represent the fire front propagation speed as a parametric function of environmental factors characterizing biomass fuel properties and moisture content, near-surface wind conditions and terrain slope. In actual wildland fires, these input parameters are only partially known and induce significant uncertainties in the coupled model predictions. To estimate the envelope of plausible wildland fire behavior, we aim at designing a perturbed-physics ensemble prediction capability based on a coupled atmosphere/fire model. To make the approach feasible, it is essential to identify the relevant subset of parameters to perturb to generate an ensemble of fire front positions and shapes. In the present study, we carry out a global sensitivity analysis based on Sobol' indices to rank the environmental factors by order of influence on the Balbi's ROS parameterization applied to typical conditions for grass fire experiments. Results show, for the given experimental conditions, the predominance of the near-surface wind speed on the ROS variability, followed by the leaf area index LAI, the ignition temperature T_i, the dead fuel moisture content M_d, the dead fuel particle mass density ρ_d, and the fuel layer height e. Results also show that the sensitivity of each fuel parameter to the ROS is not constant with respect to the near-surface wind speed, and that the most influential input parameters differ between the head and the back of a fire. This indicates the importance of exploring the spatial and temporal dependencies of coupled model sensitivities in future work. The subset of input parameters already identified as influential allows to reduce the dimension of the uncertain space over which to analyze the coupled model response, and thereby the perturbed-physics ensemble size. This is a key aspect to extend the global sensitivity analysis to the coupled model framework. While the present sensitivity analysis is limited to experimental grass fire conditions, this approach could be easily extended to more wildland fire configurations - to analyze to what extend the sensitivity analysis results obtained here are applicable to different biomass fuels.

1. Introduction

Coupled atmosphere/fire models (Kochanski *et al.* 2013; Filippi *et al.* 2018; Costes *et al.* 2021) provide an efficient but representative way to simulate wildland fire behavior at landscape-to-meteorological scales. They predict the propagation of the fire front at the land surface, the dynamics of the fire plume, and their mutual interactions. These two-way interactions can modify the near-surface wind and enhance the fire front propagation during a wildland fire. The fire model requires from the atmospheric model the near-surface wind at a given height to evaluate the rate of spread (ROS) and propagate the fire front. It also provides the surface heat fluxes as surface boundary conditions to the atmospheric model. Both ROS (Rothermel 1972; Balbi *et al.* 2009) and surface heat fluxes are evaluated through parameterizations, which require as inputs a large number of environmental factors related to biomass fuel, near-surface wind and terrain slope. These input parameters are partially known (Jimenez *et al.* 2008) and thereby introduce uncertainties in the coupled simulations. They also have their own intrinsic variability. For these reasons, it is necessary to adopt a stochastic viewpoint, i.e., to

run ensembles of the coupled atmosphere/fire model to represent the range of possible wildland fire behavior over a given time window (Costes *et al.* 2021).

To limit the computational cost of ensemble simulations while obtaining a physically and spatially-consistent ensemble, an appropriate experimental design is essential. The main issue addressed in this work is to identify a subset of input parameters that contributes most to the ROS variability along the fire front, and thus on the fire front propagation through variance-based global sensitivity analysis (Wilks 2011). The influential input parameters will be good candidates to perturb to build a perturbed-physics ensemble that is representative of fire front uncertainties in coupled atmosphere/fire modeling.

2. Global Sensitivity Analysis Method

2.1. Principles

The objective of sensitivity analysis is to quantify how uncertainties in each input parameter influence the output variability in a given model. This is useful to spot the most influential parameters on a given model response (factor prioritization), and to constrain irrelevant parameters to an arbitrary value (factor fixing) (Wilks 2011). There are two main types of sensitivity analysis methods. On the one hand, local methods are centered around one point in the parameter space, and, for each parameter, the impact of small parameter perturbations on the model output is calculated. They have some limitations if the model response is subject to nonlinearity since the local output variability may not be representative of the model response for all possible values of the input parameters. On the other hand, in the global methods, the entire parameter space is considered and the model response is analyzed in a multi-query framework, meaning that multiple model evaluations of simultaneously-modified input parameters are performed and that the induced model variability provides a measure of the parameter influence on the model output. Global methods are known to be very efficient, even for a nonlinear and non-monotonic model, where interactions between input parameters can occur. Still, their results largely depend on the parameter space boundaries and sampling.

2.2. Sobol' Sensitivity Indices

In the present study, we consider a global sensitivity analysis method based on variance decomposition (the model output variance is used as the measure of the input parameter influence on the overall model output variability) to estimate Sobol' sensitivity indices (Sobol 1990; Saltelli *et al.* 2008).

The model output Y is a function of d independent and uncertain input parameters, i.e., $Y = \mathcal{M}(X_1, \dots, X_d)$, where X_i is the ith parameter that is considered as a random variable, $\boldsymbol{X} = (X_1, \dots, X_d)$ is a random vector of dimension d, and $\mathcal{M}$ is the model operator. By using Hoeffding's decomposition theorem, the output variance $V = V(Y)$ can be written as

$$\mathrm{V} = \sum_{i=1}^{d} V_i + \sum_{1 \le i < j \le d} V_{ij} + \cdots + \mathrm{V}_{1\dots\mathrm{d}},$$

where V_i is the output variance only due to parameter i, V_{ij} is the output variance due to the pair of parameters i and j, and $V_{1\dots d}$ is the output variance due to the d parameters. Using these notations, Sobol' first-order index for the ith parameter X_i (Sobol 1990) is defined as

$$S_i = \frac{V_i}{V}.$$

S_i varies between 0 and 1, and represents the proportion of the model output variance due to the ith parameter (if S_i = 1, this means that 100% of the model output variance is explained by the ith parameter alone). By analogy, higher-order indices represent the proportion of the model output variance due to a set of parameters. The full contribution of the ith parameter (including interaction effects with other parameters) can be estimated using total-order indices S_i^T (Saltelli *et al.* 2008):

$$S_i^T = S_i + \sum_{j>i}^{d} S_{ij} + \cdots + S_{1,\dots,d}.$$

The first-order index S_i represents the main effect of the *i*th parameter X_i that is used in factor privatization, and the total-order index S_i^T represents the total effect of the parameter that is used in factor fixing. The difference between the two indices represents to which extent the parameter effects on the model response comes from an interaction with the other parameters (if the total-order index for a given parameter is equal to its first-order index, this implies that there are no interaction effects for this parameter).

3. Sensitivity Analysis Application to Rate-Of-Spread (ROS) Parameterization

The model due to Rothermel (1972) is the most well-known ROS parameterization. Its formulation relies on the energy conservation principle and provides a ROS value only at the head of the fire front (i.e., in the upwind direction). In practice, Rothermel's formulation is combined with geometrical relationships to evaluate the ROS all along the fire front. This is the main difference with Balbi's parameterization (Balbi *et al.* 2009) that directly provides a ROS value that varies all along the fire front, even if the fuel is homogeneous. Balbi's formulation is based on mass, momentum and energy conservation, but still provides an analytical formulation for the ROS through flame geometry simplifications.

In this study, we consider Balbi's ROS parameterization adapted for landscape-scale wildland fires (Santoni *et al.* 2011) and already implemented in the Meso-NH/BLAZE coupled model. It was, for instance, used for the coupled model evaluation against the FireFlux I grass experimental data (Costes *et al.* 2021). The change made by Santoni *et al.* (2011) compared to Balbi *et al.* (2009) is the consideration of the different properties of live and dead fuels, and their impacts on the ROS. Following previous work by Costes *et al.* (2021), we consider here the conditions of a grass fire experiment, without slope, to carry out the sensitivity analysis. The slope parameter is therefore not among the perturbed input parameters.

3.1. Sobol'-Saltelli Estimation Approach and Experimental Design

We adopt the well-known Saltelli's approach (Saltelli *et al.* 2008) to estimate first- and total-order Sobol' indices (altogether $2 \times d$ indices, where d is the number of uncertain input parameters). This approach corresponds to a Monte Carlo estimation of the Sobol' indices at a total cost of $N \times (d + 2)$ ROS evaluations (where N is the ensemble size), and thereby provides a confidence interval for the resulting Sobol' indices estimates.

In this study, the uncertain space is made by all the input parameters of Balbi's ROS parameterization (fifteen parameters including the near-surface wind speed U_0, Table 1). This space is sampled by N points using Sobol' low-discrepancy sequence. This is a quasi-random Monte Carlo method, where the generated sequence has many interesting properties: *i)* the sequence has a low discrepancy (i.e., there is a more homogeneous coverage of the parameter space than in a classical Monte Carlo method for a limited number of samples N), and *ii)* the sequence is coherent (the N first points of a sequence with $(N + 1)$ points are the same as for a sequence with N points, implying that, if more samples must be generated, it is not necessary to recompute the previous points and that a large model dataset can be generated in an incremental way). It is worth noting that we consider here a large number of samples N to guarantee convergence of the Sobol' indices (N = 20,000). This is feasible here since the ROS parameterization can be evaluated at a low cost (the sampling strategy will have to be adapted when switching to a coupled atmosphere/fire model, which is very demanding in terms of computing resources). Table 1 provides a detailed description of the fifteen input parameters. Without further information, they are perturbed according to a uniform statistical distribution, which is characterized by a variation interval. The center of this interval corresponds to a so-called standard value, which corresponds to a tall grass fuel typical of the FireFlux I experiment that was simulated in Costes *et al.* (2021) using the Meso-NH/BLAZE coupled model configured with the Balbi's ROS parameterization. We consider here a large variation interval to study how the ROS changes for a wide set of environmental conditions, and to identify which are the most influential input parameters that could then be used to generate ensemble coupled model simulations and study the coupled model response in a variety of situations.

3.2. Results

3.2.1. Predominant wind factor

Figure 1 shows the first- and total-order sensitivity indices for all parameters presented in Table 1 (d = 15). For example, the first-order index for the dead fuel particle density ρ_d is equal to 0.05 (circle symbol), and the

associated total-order index is equal to 0.06 (square gray symbol). This means that ρ_d is responsible for 6% of the ROS variability within the ensemble (5% without accounting for the interaction with the other parameters).

Table 1- Input parameters (Balbi's ROS parameterization) perturbed in the sensitivity analysis

Name	Symbol	Unit	Standard value	Lower bound	Upper bound	Coefficient of variation
Fuel calorific capacity	c_p	J kg^{-1} K^{-1}	1,912	1,720.8	2,103.2	6%
Fuel layer height	e	m	1.5	1.0	2.0	19%
Leaf area index	LAI	—	4	2	6	29%
Dead fuel moisture content	M_d	%	10	5	15	29%
Living fuel moisture content	M_l	%	80	60	100	14%
Dead fuel particle surface-to-volume ratio	s_d	m^{-1}	5,000	4,250	5,750	9%
Living fuel particle surface-to-volume ratio	s_l	m^{-1}	5,000	4,250	5,750	9%
Ignition temperature	T_i	K	590	490	690	10%
Near-surface wind speed	U_0	m s^{-1}	4	0	8	58%
Combustion enthalpy	ΔH	MJ kg^{-1}	15.43	14.66	16.20	3%
Air density	ρ_a	kg m^{-3}	1.2	1.0	1.4	10%
Dead fuel particle mass density	ρ_d	kg m^{-3}	400	300	500	14%
Living fuel particle mass density	ρ_l	kg m^{-3}	400	300	500	14%
Dead fuel surface loading	σ_d	kg m^{-2}	1	0.8	1.2	12%
Living fuel surface loading	σ_l	kg m^{-2}	0.1	0.05	0.15	29%

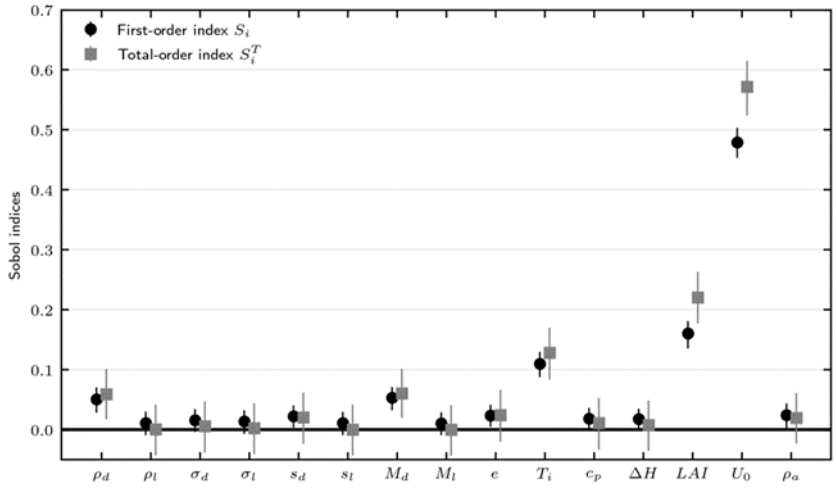

Figure 1- Sobol' indices quantifying the sensitivity between the 15 perturbed parameters and the ROS as evaluated by Balbi's parameterization at the fire front head. Circles represent first-order indices. Squares represent total-order indices. Vertical bars represent estimation uncertainties.

From Figure 1, the most influential parameters on the Balbi's ROS parameterization can be identified. The near-surface wind speed U_0 is the predominant factor by explaining by itself 48% of the ROS variability (57% in total). The difference between the first- and total-order indices is important for U_0, implying that there are important interaction effects between the wind factor and the other parameters. Other influential parameters are by order of importance the leaf area index LAI, the ignition temperature T_i, the dead fuel moisture content M_d, and the dead fuel particle mass density ρ_d for which the first-order Sobol' index is equal to 16%, 11%, 5% and 5%, respectively.

3.2.2. Sensitivity analysis by near-surface wind speed level

Previous results correspond to the ROS at the head of the fire front. We now apply the same sensitivity analysis method when the near-surface wind speed U_0 is equal to 0 m s^{-1}, in order to represent the situation of a back fire (fourteen parameters are perturbed). The most influential parameters are by order of importance the fuel

layer height e, the ignition temperature T_i, the combustion enthalpy ΔH, the dead fuel moisture content M_d and the dead fuel surface loading σ_d for which the first-order Sobol' index is equal to 38%, 21%, 9%, 8% and 8%, respectively. This shows that T_i and M_d are influential parameters at the head and at the back of a fire.

This results also indicates that the sensitivity of the ROS to the different fuel parameters is variable according to the value of the near-surface wind speed U_0. This is consistent with the difference previously-observed between the first- and total-order Sobol' indices for the near-surface wind speed U_0 indicating significant interaction effects. Since the wind velocity seen by the fire front changes all along the fire front (the wind speed used in the ROS parameterization corresponds to the normal component of the wind velocity to the fire front), the order of importance of the input parameters may change along the fire front. To further analyze this dependency, the near-surface wind speed U_0 is removed from the perturbed parameters and Sobol' indices are estimated for different wind levels varying between 0 and 20 m s^{-1} (the mean ROS within the ensemble changes from 0.39 to 3.82 m s^{-1}). We focus the sensitivity analysis on the eight most influential parameters identified in the previous steps (the near-surface wind speed U_0 is no longer included in the perturbed parameters to generate the N samples). Figure 2 presents Sobol' first-order indices obtained for the different wind levels. Results confirm that the order of importance of the input parameters largely depends on the wind level. Without wind, more than 60% of the ROS variability is explained by two parameters, the fuel layer height e and the ignition temperature T_i. When the wind speed increases, for instance for U_0 = 5 m s^{-1}, the fuel layer height e is far less important (4%), and the leaf area index LAI becomes very influential (41%). This is consistent with Balbi's ROS parameterization. First, the parameter e is only involved in the radiation submodel to estimate the radiant panel size, and radiation is assumed to be independent of the wind speed. Second, as part of the definition of the upward velocity of the combustion gases, the parameter LAI is involved in the tilt angle estimation that depends on the wind speed. This study indicates that the most influential parameters that are relevant to perturb to generate an ensemble depend on the portion of the fire front that is considered (head, flanks or back).

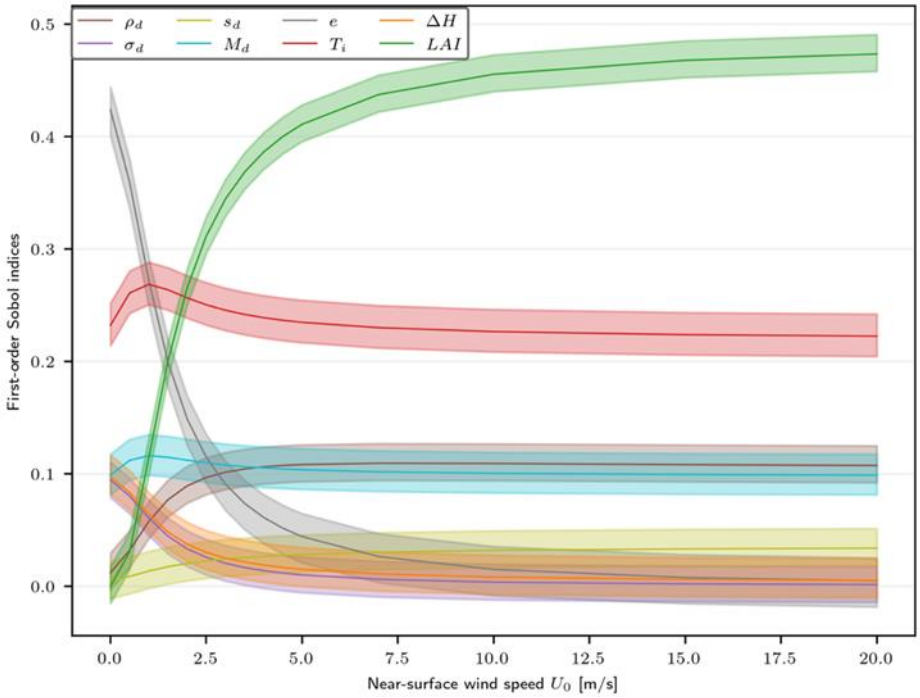

Figure 2- First-order Sobol' indices relating the ROS and 8 perturbed inputs, which are obtained for different levels of the near-surface wind speed U_0. One input parameter corresponds to one color. Shaded intervals represent estimation uncertainties.

4. Conclusions

This study identifies the most influential parameters involved in Balbi's ROS parameterization through Sobol'-Saltelli sensitivity analysis approach to estimate the first- and total-order Sobol' indices. The most influential

parameter is the near-surface wind speed U_0. The influence of the other parameters depends on the value of the near-surface wind speed U_0, but overall, the five most influential fuel parameters are the leaf area index LAI, the ignition temperature T_i, the fuel layer height e, the dead fuel particle mass density ρ_d, and the dead fuel moisture content M_d. The next step is to extend this sensitivity analysis approach to a coupled atmosphere/fire model to represent the spatio-temporal impact of input parameters on the wildland fire behavior. This will provide access to the fire-induced wind and to the temporal and spatial variability of the near-surface wind speed, which in turn has an influence on the spatial and temporal variability of the fire front. This will also be helpful to define a protocol for generating a perturbed-physics ensemble and estimating the range of plausible wildland fire behavior for a given event. For this purpose, the sensitivity analysis approach will include different ROS parameterizations and different environmental conditions to go beyond the conditions of a flat grass fire experiment, and thus have sensitivity analysis results that cover a wider range of wildland fire conditions.

Abstract

Canadian fire management agencies track drought conditions using the Drought Code (DC). The DC is one of three fuel moisture codes in the Fire Weather Index System, which is part of the Canadian Forest Fire Danger Rating System. The DC represents the moisture of deep organic layers (15-18 cm nominal depth) and is used operationally to assess potential lightning ignition holdover, persistent deep smoldering, and mop-up problems. As the climate changes and drought conditions arise more frequently, our understanding of drought and how to measure it become more important. Determining what the DC means in areas without deep organic soils is a question commonly proposed by fire operations personnel. Recent studies have indicated that some more complex models (e.g. the Canadian Land Data Assimilation System – CaLDAS) may provide added intelligence about the fire environment and drought conditions, something that has not been explored in Canada. To shed light on these questions we carried out field studies in the provinces of Alberta and Ontario. Four field sites were included in our study, two in Alberta near Edson and Red Earth Creek, and two in Ontario near Dryden and Chapleau. At each of the seven plots within these four sites, we installed 8-12 water content reflectometry (WCR) probes at two different depths. The probes were installed from the surface through the organic layers, and in some cases, into the mineral soil. Overall, our results indicated that the simple DC model predicted the moisture content of the deeper organic layers (10-18 cm depths) well, even compared to the more complex CaLDAS model. The WCR probes at these depths, exhibited good agreement with how the DC model estimated moisture changes. The DC may therefore be representative of changes in moisture content in a wide range of depths and soil horizons. Issues with model inputs, particularly missed precipitation events and incorrect DC spring starting values, had a greater influence on DC model fit than other factors. Calibration and validation of the CaLDAS model to mineral soils may be the cause of its consistent under prediction of organic layer moisture.

1. Introduction

Throughout most typical fire seasons the principal day-to-day short-term indicators of fire danger, ignition potential and rate of spread, are of primary concern to fire managers. The moisture content of the litter layer and underlying fine to medium organic fuels heavily influence fire behaviour through their interaction with local weather and topography. Hot, dry and windy conditions can quickly dry out these layers, which can lead to more fire activity and more intense fires. Longer-term drought and continuous drying into deeper, denser organic fuels can make a challenging fire season quickly turn to something much worse.

Drought in the Canadian Forest Fire Danger Rating System (CFFDRS) is measured by the Drought Code (DC), one of three moisture codes in the Fire Weather Index (FWI) System. Similar drought indices used for fire danger rating exist in other jurisdictions, such as the Keetch-Byram Drought Index (Keetch and Byram, 1968) and the Palmer Drought Index (Palmer, 1965). One significant, but subtle difference is that the DC is designed to directly estimate the lack of moisture in denser organic layers rather than using hydrologic drought in the mineral soil as a proxy for fuel moisture deficiencies. The layer of the forest floor tracked nominally by the DC has depth of 15-18 cm and nominal fuel load of 25 kg/m^2, in keeping with the standard pine fuel on which the FWI System is based (Van Wagner, 1987).

Since the development of the DC, most efforts to account for carrying-over drought from fall into spring and its impact on fire activity in Canada has focused on how to establish the starting spring values and field validation of the DC using destructive sampling methods (Otway et al., 2007, Stocks, 1979, Alexander, 1982, Lawson and Dalrymple, 1996). Most of Canada is snow covered, or receives significant precipitation during the winter months. More recent studies have developed correlations with organic soil moisture using electronic moisture probes (Terrier et al., 2014, Elmes et al., 2018, Keith et al., 2010). Such methods are less time consuming and allow greater temporal and spatial variability in measurements. Those instruments rely on soil dielectric properties, which can vary with soil composition, clay content and organic content (Bourgeau-Chavez et al., 2010, Kellner and Lundin, 2001). Despite good correlations with the measurements produced with these probes, questions remain operationally around probe installation and use and what layers best correlate with the DC.

The DC has also been shown to have strong correlation to C-band (~6 cm wavelength) Synthetic Aperture Radar (SAR) backscatter in low-biomass areas (Bourgeau-Chavez et al., 1999, Bourgeau-Chavez et al., 2007). An algorithm developed by Bourgeau-Chavez was shown to be useful to initialize DC start-up values in Alaska. Further work by Bourgeau-Chavez using polarimetric C-band SAR (Radarsat2) was successful at improving the soil moisture estimation in higher biomass areas (Bourgeau-Chavez et al., 2013). Although such research demonstrates the potential use of earth observation to map organic soil moisture, there remain limitations to remote sensing of soil moisture in forested regions (Jin et al., 2017, Magagi et al., 2013, Pan et al., 2016).

More sophisticated land surface models may alleviate some of the remote sensing issues; studies in other regions have shown improved drought estimation by incorporating land surface modelling outputs (Vinodkumar and Dharssi, 2019, Cooke et al., 2012, Yang et al., 2015) into fire danger methods to represent soil moisture changes. This approach has not been explored for the dense boreal forests in Canada. Inclusion of earth observations from an existing product, like the ECCC's (Environment and Climate Change Canada) Canadian Land Data Assimilation System (CaLDAS) (Carrera et al., 2019, Carrera et al., 2015) is an emerging area for fire science in Canada. CaLDAS integrates information from L-band satellite SMOS (Soil Moisture Ocean Salinity) as well as the geostationary satellite GOES (Geostationary Operational Environmental Satellite) with high-resolution land surface modelling and ground level observations to produce estimates of soil moisture across Canada every three hours. To further explore what organic depths the DC is tracking and determine the potential added intelligence electronic soil moisture content probes and land surface modelling data could provide, a field-based study was conducted in the provinces of Alberta and Ontario. This study had the following three objectives:

1. Determine how well the DC correlates to organic soil moisture and at which depths, using WRC (water content reflectometry) probes.
2. Explore the use of land surface models (CaLDAS) to represent moisture changes in these deep organic layers.
3. Determine if CALDAS estimates of soil moisture can be used to estimate/correct the DC.

2. Methods

We installed 8-12 WCR probes at depths of 10 and 18 cm in seven forest plots (Figure 1), from the surface through the organic layers, and in some cases, into the mineral soil. We compared these observed moisture contents with the DC model estimates of moisture and CaLDAS estimated Volumetric Moisture Content (VMC). DC values were estimated from nearby fire weather stations. The version of CaLDAS used included short-range forecasts calculated from ECCC's High Resolution Deterministic Prediction System every three hours. Precipitation within the model was assimilated from the Canadian Precipitation Analysis (CaPA)

(Mahfouf et al., 2007), in addition to other atmospheric variables, using an Ensemble Kalman Filter methodology. The land surface model was built around the SVS (Soil, Vegetation and Snow) scheme also developed by ECCC (Alavi et al., 2016, Husain et al., 2016). Daily soil moisture outputs from CaLDAS were obtained from ECCC for our analysis.

The field measurements of moisture content observed at depths of 10 cm and 18 cm were compared to the following: 1) daily DC values, converted to VMC, 2) CaLDAS VMC estimates at all three depths (0-5 cm, 5-10 cm and 10–20 cm) and 3) daily DC values (expressed as VMC) to CaLDAS VMC at three depths. All analysis were first conducted on daily time series of VMC during the fire season from late spring (May) until early fall (September) for 2019-2021 where available. The hydroGOF R package was used to calculate goodness of fit statistics for these time series comparisons including: R^2 (Coefficient of Determination), RMSE (Root Mean Square Error), Pbias (Percent Bias), and NSE (Nash Sutcliffe Efficiency; Nash and Sutcliffe, 1970). Goodness of fit statistics were first calculated for the entire 2019-2021 time series (May through September), then again for each individual year separately to show annual variations.

3. Results

Overall results indicated that the simple DC model did a good job of predicting the moisture content of the deeper organic layers (i.e. 10-18 cm) depths (Table 1), even compared to the more complex land surface model CaLDAS (Table 2). The WCR probes installed through the litter, fermentation and humus layers, and in some cases into the mineral soil, had good agreement with the DC model estimated VMC (Figure 2). Therefore, the DC may be representative of moisture changes in a wider range of depths, soil horizons and forest types. There was greater variability between different forest plots than between years and probe depths (Table 1). Model inputs, particularly precipitation and DC starting values had a large influence on DC model fit.

Differences in statistics and time series plots showed a clear trend that the DC had the best fit with the observed VMC in the wetter and deeper mixedwood Chapleau plot (Figure 2). In contrast, much poorer goodness of fit statistics were observed at the shallower and drier aspen plot also at the Chapleau site (Figure 2). Beyond those bookends there was no obvious indication of what is influencing overall organic moisture changes and the ability of the DC to represent them (i.e. duff depth, moisture regime, forest type); more advanced analyses may be required to investigate this further.

Results showed that better representation of precipitation is a simple way to improve DC tracking of forest floor moisture. This is not surprising as other studies have shown that FWI System codes and indices overall were improved compared to basic interpolation of stations with better precipitation inputs (i.e., gridded precipitation especially with radar) estimates (Hanes et al., 2017, Cai et al., 2019). Although the CaLDAS model includes high-resolution gridded precipitation products (Carrera et al., 2015) its outputs still consistently underestimated observed moisture contents (Table 2, Figure 3). It also had little skill in predicting DC values directly and consistently underestimated DC moisture content (Table 3, Figure 4). This strong bias is most likely due to the validation and calibration of CaLDAS to focus primarily on agricultural areas and mineral soil moisture (Carrera et al., 2019). This is similar to other remote sensing soil moisture calibrations/validations (Magagi et al., 2013, Pan et al., 2016). Although land surface models have been proposed as an alternative to drought modelling for fire danger in some areas (Vinodkumar and Dharssi, 2019, Cooke et al., 2012, Vinodkumar et al., 2017) the majority of studies assume mineral soil moisture as proxy measure of fuel moisture content. It is clear that overall, drier conditions are more conducive to fire, but it is the day-to-day changes in fine fuel moisture that are of primary importance, influencing daily variability in fire behaviour (Van Wagner, 1985). Many remote sensing and fire danger studies to date largely ignore the organic layer and focus only on “surface soils”, which can include litter but are essentially mineral soil. Organic material contains more pore space and are therefore generally wetter than mineral soils (Otway et al., 2007). Therefore, to better model organic moisture directly, remote sensing retrieval algorithms and land surface models need to refine the soil dielectric models based on soil organic carbon properties (e.g., higher porosity and typically lower bulk density) (Jin et al., 2017). Organic soils typically have a lower dielectric content than mineral soil with same VMC (Jin et al., 2017, Bourgeau-Chavez et al., 2010). Integration of national maps of organic layer thickness (e.g., Hanes et al. 2022) into CaLDAS in combination with organic layer specific algorithms are needed to improve model skill for estimating drought indices for fire. Doing so would allow greater use of land surface models directly as additional sources

of fire intelligence, especially for regions without good weather station coverage; this would also allow fire managers to take advantage of the forecast capabilities of these complex models.

4. Conclusions

Our results indicate that the relatively simple DC model does a reasonable job of representing observed moisture changes in deeper organic layers over a wide range of forest types for depths of 10 to 18 cm. Electronic probes that use the dielectric content of soil moisture, installed at these depths, can be used to supplement or correct DC estimates. Physically based hydrologic models have been proposed because we have the capacity to use them (i.e., Johnson et al., 2013, Keith et al., 2010). Yet the simplicity of the DC model and ease of application without the necessity to parameterize to a specific region still outweigh any validation improvements in moving to a more complex model. Although land surface models like CaLDAS hold much promise to integrate earth observation and high-resolution numerical weather prediction outputs into wildfire danger prediction, their bias to mineral soils limit their use at this time. We anticipate better performance in the future once organic soils are integrated into CaLDAS and the SVS land surface scheme. This is not to say the DC model is perfect. Much clarity could come from expanding the definition of what the DC model represents (i.e. beyond the elusive standard 15-18 cm depth in a standard pine forest). This may require a shift in the definition from an exact moisture value for a specific soil horizon towards a definition that includes a wider range of slower drying organic layers/fuels as data permits.

Abstract

Electricity transmission power lines are critical infrastructures in a country's electrical system, and wildfires represent extreme events that jeopardize their function. In addition, in the absence of proper vegetation management, these infrastructures can be the cause of ignition. The management of vegetation, or fuel, near these structures has specific rules, at least in Portugal, with the objective of protecting the infrastructure itself and minimizing the risk of ignition due to an electrical discharge or the physical contact of the vegetation with the conductors. The extent of the transmission power line network may hinder the application of extensive fuel management actions, and in many cases the trees that falls outside the fuel management that goes with it may also pose a danger.

This work explores the possibility of combining LiDAR with ancillary data and specific algorithms to identify those trees that may put the power line in danger in case they fall due to any external or internal circumstances. As a result of the application of the proposed methodology, it was possible to classify individual trees according to a risk class, as well as critical areas of intervention. With this information the Portuguese company REN, responsible for the transmission power line network, was able to plan and calendarize critical fuel management interventions in trees that fell outside the fuel breaks that they manage, but that posed imminent risk to the infrastructure.

1. Introduction

Urban infrastructures, such as power lines, are sometimes the cause of ignition (Miller et al., 2017; Viegas et al., 2017, 2019), and in case of a wildfire, their extension and diffusion in the landscape exposes them to a high probability of damage (Viegas et al., 2011). Some infrastructures have characteristics that, when hit by a fire, can lead to episodes of great danger. Besides being critical, many of these infrastructures are also strategic, since their affectation can compromise the response to the fire. The power (electric) network, water supply and natural gas infrastructures are good examples of this reality (Ribeiro et al., 2021).

In Portugal, as in many other countries, fuel breaks are maintained in the areas where the power lines are installed. This fuel (vegetation) management strategy aims fundamentally at 1) minimizing the probability of electrical cables producing ignitions, either by contact with vegetation or by discharges to the ground and 2) minimizing the probability of the fire affecting the structure itself, causing interruptions in the power supply. Although the importance of these strips may be higher in medium and low tension lines, because they are usually placed closer to the ground, the high and very high tension (VHT) lines have the same problems (Viegas et al., 2020). The width of these linear strips of fuel management depends on the voltage of the lines, and for the VHT that value is of 10 m for each side, counting from the most external line (Figure 1).

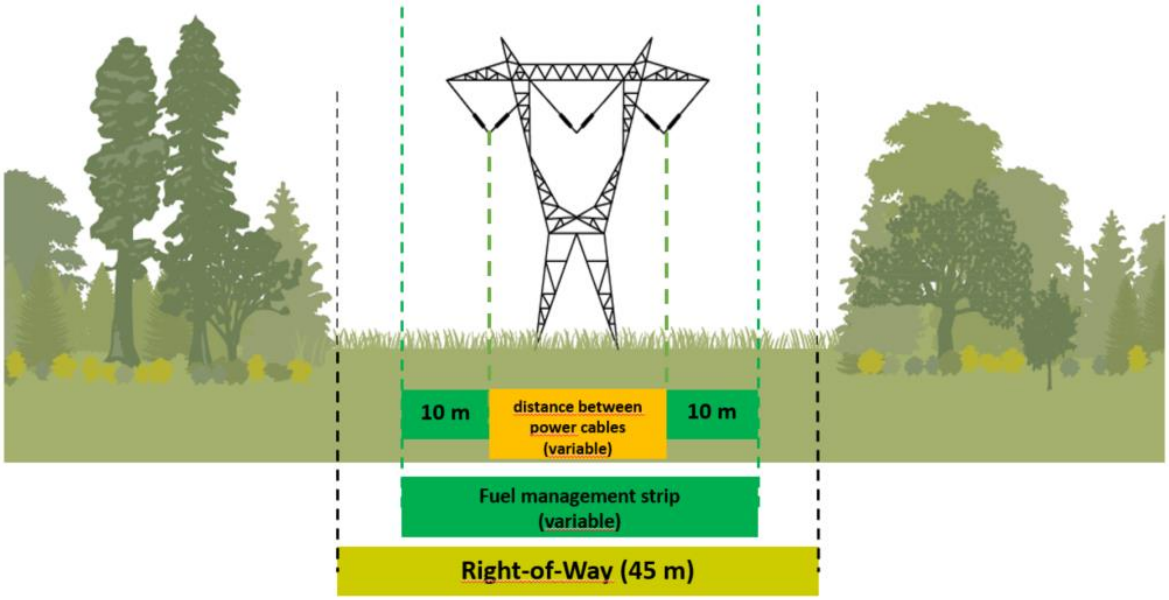

Figure 1. Power lines Fuel management strip vs. power lines right-of-way (RoW).

REN (*Rede Elétrica Nacional, SA*) is the Portuguese Transport System Operator (TSO) and is responsible for the operation and maintenance of the electric transport infrastructures. In their planning they have extended the fuel break width to at least 45 m, more than the legally mandatory distances, in what is called a "right-of-way" (RoW) strip, in a demonstration that their concern with all externalities that may pose danger to the infrastructure is very real. Nevertheless, often they identified several cases with the presence of trees that fall outside these linear fuel breaks that in case of falling, could potentially impact the cables. Trying to identify where and when this could happen was the genesis of this work, proposed to us by REN.

2. Objectives and methodology

The main goal of the work was to identify both individual trees that could impact on the electric power cables and critical areas of intervention where one or more trees could also pose danger to the infrastructure. The reason for having both outputs was to have a redundant mechanism, as the identification of individual trees may be subject to errors. Having in mind that the current fuel management is implemented in the RoW strip of at least 22.5m for each side of the line axis, it was a requisite that the analysis should be performed in an extension of that strip until 40 meters were reached (also counting from the axis of the line). The methodology consists in a series of algorithms implemented a sequence of models in ArcGIS Pro, allowing for a semi-automatization of the process of identification. It is based on the analysis of LiDAR and other ancillary data, mostly the possibility of identification of each pixel's height to the ground. Generically, for each point on the terrain of the analysis area, a critical tree height was calculated, from which, in case of a fall, trees may eventually contact the power line. The critical tree height is nothing more than the height relative to the ground of each pixel of the vegetation height layer created during the processing phase ($H_{critical\_pixel}$ in Figure 2). For this purpose, the height of the vegetation in the analysis area, the height of the lower power line and its maximum deflection (corresponding to the maximum arrow), i.e. the maximum deviation that the line can assume in relation to an imaginary line horizontally joining the two supports where it is inserted (Figure 3), were taken into account.

Figure 2 schematically presents the reasoning behind the process described and Figure 3 illustrates the concept of "maximum arrow".

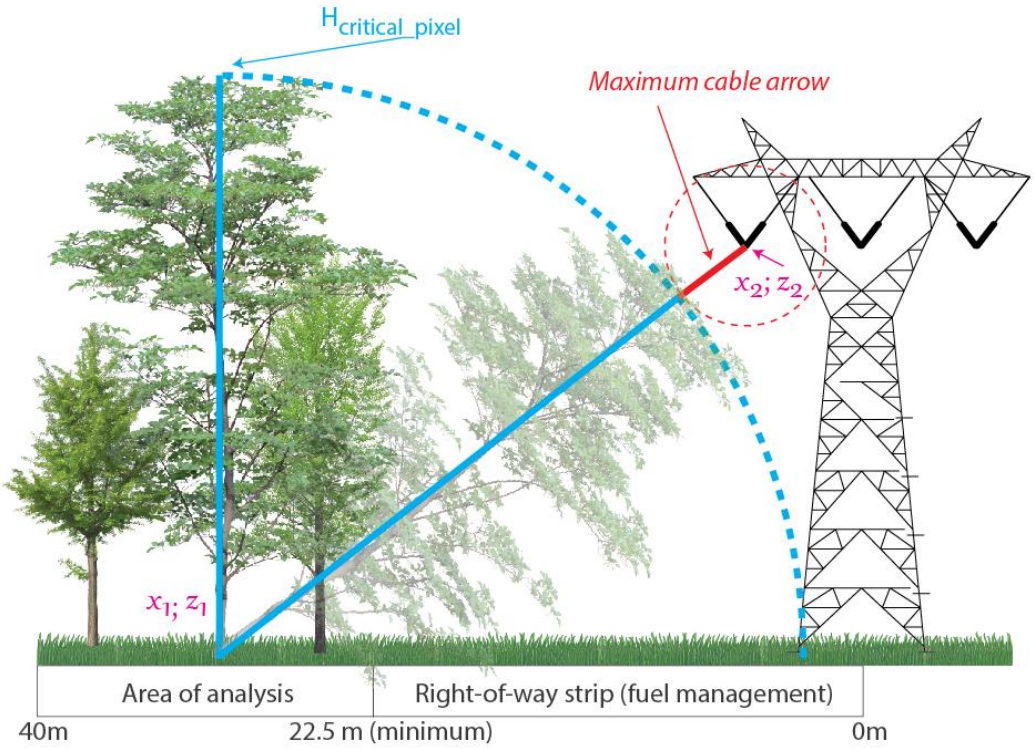

Figure 2. Simplified scheme of the relationship between critical vegetation height and maximum arrow (deflection).

The critical height was considered to be the height at which, if the tree falls, the curve it describes will cause it to touch the line, considering its arrow in the position closest to that curve. We also assumed the worst case scenario, i.e., that the tree falls with its axis of rotation at the point of contact with the ground, towards the line, while the cable wobbles with maximum deflection in its relative position on the line, towards the tree. Note that no whiplash effect was considered, although it can happen. Also, to simplify the algorithms, all power lines were considered to be of the same type (*Zambeze*) and the power line deflection to be in straight lines, forming 2 triangles between the imaginary straight line connecting the poles (black line connecting them in Figure 3) and the point of maximum deflection where the cable arrow is maximum (dashed blue line in Figure 3). The possible errors incurred by these assumptions are not significant in the overall analysis and having straight lines allows for the establishment of trigonometric relationships in the process.

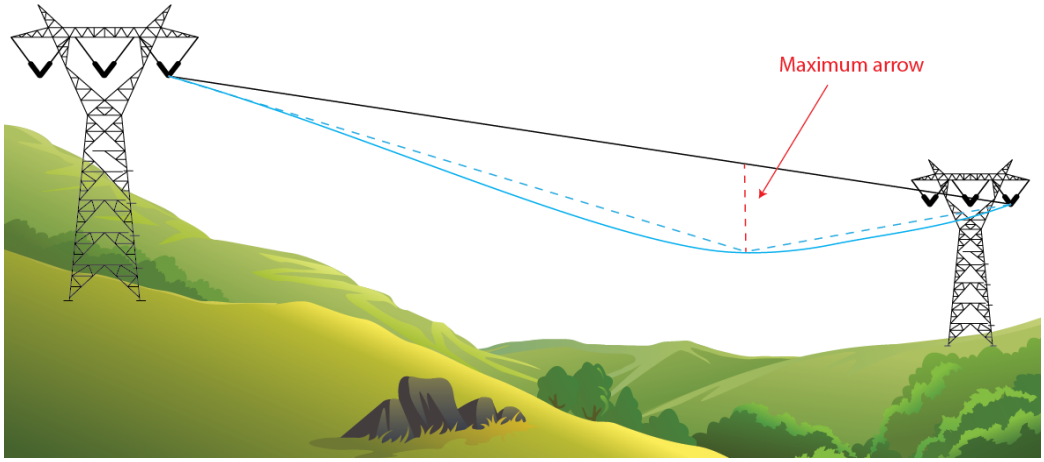

Figure 3. Concept of maximum arrow of deflection.

The calculation of this critical tree height, or pixel height, was performed using Equation 1.

$$\boldsymbol{H_{critic\_pixel}} = \sqrt{(x_1 - x_2)^2 + (z_1 - z_2)^2} - maximum\ arrow \qquad \textbf{Equation 1}$$

Where

$\boldsymbol{x_1}$ – Horizontal coordinate of each pixel to be analyzed, perpendicular to the line at point $\boldsymbol{x_2}$.
$\boldsymbol{x_2}$ – Horizontal coordinate of the line at each point, at the intersection location of a perpendicular of the line with the pixel being analyzed ($\boldsymbol{x_1}$).
$\boldsymbol{z_1}$ – Altitude of each pixel (= real height above ground).
$\boldsymbol{z_2}$ – The actual altitude that the line assumes at the intersection location of a perpendicular of the line with the pixel under analysis.
$\boldsymbol{maximum\ arrow}$ – Maximum distance of the horizontal line joining the two fixation points at the tangent to the maximum arc it actually makes.

Data preparation involved several consecutive operations, modelled in ArcGIS, and a brief resume is shown here.

2.1. Preparing and homogenizing data

The collected data from all lines was analysed for inconsistencies and stored with a common reference system in specific Geodatabases. The main datasets used were vectorial data from electric towers and power lines, alphanumeric data for tower characteristics (total height, height of cable insertion, dimension of cable connectors and width of cables insertion in relation to the axis) and LiDAR data.

2.2. LiDAR analysis and processing

The LiDAR data processing was divided in three steps. First the production of the raster layers for elevation (DEM), surface (DSM) and object height (or canopy height in the literature, CHM), based on the methodology described in ESRI (2020). This step included the metadata analysis, the quality assessment and the masking of the analysis area. The second step related to the individual trees identification, and was based on processes described in the existing literature, e.g. Popescu & Wynne 2004, Khosravipour et al., 2014 and Millikan et al., 2019. Finally, a visual inspection on LiDAR analysis, eliminating false positives, such as roofs, communication or electric towers, or other artificial or natural structures that were not trees. Figure 4 shows, from left to right, a) the insertion of one tower (yellow and black dot), the power line (orange line), the analysis area (red lines), b) the object height layer (CHM) and c) the individual trees identification prior to the visual inspection, showing the misidentification on roofs.

Figure 4. Example of the CHM and individual tree identification.

2.3. Powerlines and towers data processing

The maximum arrow for each line segment between poles was calculated following Sequeira (2009) and REN (2016). To achieve the best resolution possible in the final analysis, the power lines were then split into 1 m segments (to match the resolution of the DEM) and each segment was parametrized with all the needed variables for the models' calculation. Also, the towers were characterized with the needed parameters. Using trigonometric relations, the following variables were calculated: altitude of each 1-meter segment ($\boldsymbol{z_2}$), distance of each 1 meter segment to the axis of the line ($\boldsymbol{x_2}$) and the maximum arrow in each 1 meter segment (taking into account the real altitude of insertion of each tower).

2.4. Buffering variables to the analysis area

For the analysis of the possible intersection of the cables with the trees a raster processing methodology was adopted. The analysis area was populated with the variables needed at 1 meter resolution, with a process of buffering all the 1-meter segments of the power lines. The process was repeated for all the needed variables, creating as many raster files.

3. Results

The critical height of each pixel was calculated according to Equation 1 for each 1-meter cell of the analysis area. This height refers to the height a pixel should have (in this case the tree that stands on it) to impact on the power line in case it falls and in the worst possible conditions. The resulting raster layer with the critical height was then compared to the actual height of each pixel to assess if the trees were in fact posing a threat to the line, i.e., if the pixel was critical or not. The value of this critical pixel is the difference, in meters, between the height a tree should have to impact the line (if falling) and its real height. A risk scale was created assigning to each class a priority of intervention, as depicted in Table 1, allowing for the classification into critical areas of intervention.

The results of the analysis were obtained in the form of a raster layer for the critical areas of intervention and a vector layer for the individual critical trees. The critical height for each vector point was obtained from the respective raster layer.

Table 1. Risk levels, critical pixel value and priority of intervention.

Risk class	Risk	Critical pixel value (Pc)	Interpretation (in case a tree falls, for the worst scenario)	Priority of intervention
N/A	None	Pc < -7	No risk/no trees at risk of collision with the line	Ignored
I	Low	-7 ≤ Pc <-5	Tree has to grow at least 5-7 meters to reach the line	4
II	Medium	-5 ≤ Pc < -3	Tree has to grow at least 3-5 meters to reach the line	3
III	High	-3 ≤ Pc < 0	The tree is at the limit of being able to reach the line or not	2
IV	Very high	Pc ≥ 0	The tree has a height equal to or greater than the critical value from which it can hit the line	1

Figure 5 shows the result of the identification process, in the same area as the earlier example. From left to right we can see *a)* the raw critical pixel evaluation (the colours are merely indicative), *b)* the critical areas of intervention, as reclassified based on Table 1 (with the colours of the classes), and *c)* the respective critical trees.

Figure 5. Example of the processing results.

In total, 11 power lines were analysed, in a cumulative extension of more than 600 km and with an area subject to analysis of more than 2000 ha. Table 2 resumes the results for the priority of intervention 1 and 2.

Table 2. Resume of the results for priority levels 1 and 2.

Line	Entension (Km)	Analysis area (ha)	Area of intervention in priority 1 (ha)	Area of intervention in priority 2 (ha)	Number of trees in priority 1	Number of trees in priority 2

About 1.13 % of the total area was deemed as posing level 1 danger to the power line infrastructure, i.e., immediate risk of contact in case of falling. A total of 39205 trees were identified, being 12057 in class 1 and 9561 in class 2.

4. Validation and application

The validation of the methodology was performed by a series of field visits to the identified critical areas. In those areas, the critical trees were visually identified, and its height measured with a digital laser hypsometer. A total of 103 trees were visited and the relation between the observed and predicted height resulted in a R^2 of 0.98, which is representative of the good accuracy of the methodology. In terms of identification of trees, in some cases we identified points that were very close and referred to the same tree. This highlights the value of also producing the results as a raster of critical areas.

Since this work was developed, REN used the results to implement extraordinary fuel management actions in the areas identified, consisting of individual trees extraction (Figure 6), hence increasing the resilience of its infrastructure. Until now around 35500 trees were removed, but the work is still ongoing.

Figure 6. Example of an individual tree extraction, after being identified as critical.

Sea-breeze front, pyroCumulus, weather radar, Dual-polarization

Abstract

During the afternoon of 20 June 2017, two massive wildfires were ongoing more than 30 km to the east-southeast of the city of Coimbra, central Portugal. There were no clouds over the location and surrounding areas. As these fires were progressing, smoke plumes were observed with their tops at around 6-7 km a.m.s.l. However, as a sea-breeze front arrived at the buoyancy sources it was observed an outstanding vertical growth of the plumes. One of these developments was particularly analyzed and it was found that the plume topped at nearly double that altitude in less than 60 min. As a result of this interaction, an impressive pyroCumulus cloud formed. This process was analyzed using weather radar with Dual polarization capabilities.

1. Introduction

The fire complex of Pedrogão Grande, during 17-22 June 2017, was considered as the worst on record in Portugal due to the large burnt area and related fatalities, as described in Viegas et al. (2017). The influence of a mesoscale convective system over the fires was analyzed in Pinto et al. (2022) for an event of 17 June.

Further from convective flows induced by meteorological systems, the progression of sea-breeze fronts (SBF's) over fire areas has also been described as an important mechanism of interaction with smoke plumes, generating transient, though significant, increase in fire intensity, as discussed by Hanley et al (2013). A SBF is the outcome of a thermally-driven mesoscale circulation that results from the differential heating over land and oceanic bodies. During the day, warmer and less dense air over land generates lower air pressure than over the ocean where cooler, denser air, resides. As a result, the mesoscale front propagates inland as the cooler air flows towards land to replace warmer air. These phenomena are known to trigger convection inland, as increased low-level convergence lifts the air and facilitates moisture convergence, Pielke et al. (1991). As a SBF propagates over a location, air moisture usually increases, temperature drops, wind direction may suddenly shift, gusts may be produced and air quality may also change, as shown by Miller et al. (2003). Coupled atmosphere-fire models are required to understand, in detail, the interaction between SBF's and the fires, as pointed out by Hanley et al (2013). However, the monitoring of the interaction between the SBF and the pyroconvective plume may suggest important impacts on the fire. During the afternoon of 20 June, a SBF was observed to propagate across the area where two fires were progressing.

2. Sea-breeze front

2.1. Numerical Weather analysis and forecast

At 12:00 (all times are UTC) of 20 June 2017, the UK Met Office mean sea-level pressure analysis showed a low to the west of Portugal and an anticyclone over central Mediterranean that was promoting the advection of a hot and dry airmass over western Iberia (Figure 1a). Over central Portugal the low-level flow was weak from the east-southeast, inland, and also light, but from the west-northwest along the coast as shown by the 12:00

ECMWF forecast (Figure 1b). Above 500 hPa (5900 m a.m.s.l.), at 12:00, the flow was from the west according to the rawinsonde from Lisbon (Figure 2). The sounding also showed an inverted-V type profile with relatively moist air in the 700-600 hPa layer but a dry airmass below 700 hPa (Figure 2). This typical profile has been referred in pyrocloud case studies such as Fromm et al. (2012) and Peterson et al. (2017).

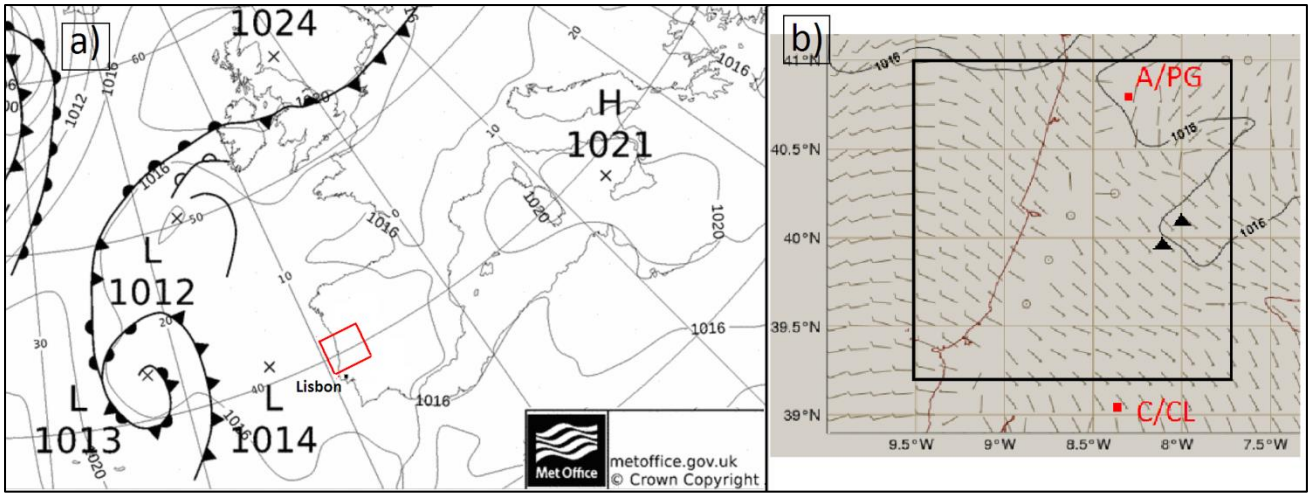

Figure 1- (a) Mean sea-level pressure analysis (solid contours, 4-hPa intervals) over the Northeast Atlantic (adapted from Uk Met Office), red square defines area in (b), Lisbon sounding station represented by a dot and (b) Zoomed-in area from (a) 10 m wind speed and direction (wind barbs notation) over mainland Portugal, ECMWF forecast H+12, black square defines central Portugal, A/PG and C/CL radars are represented by a red square symbol and fire locations are represented by black triangles, 12:00 UTC, 20 June 2017.

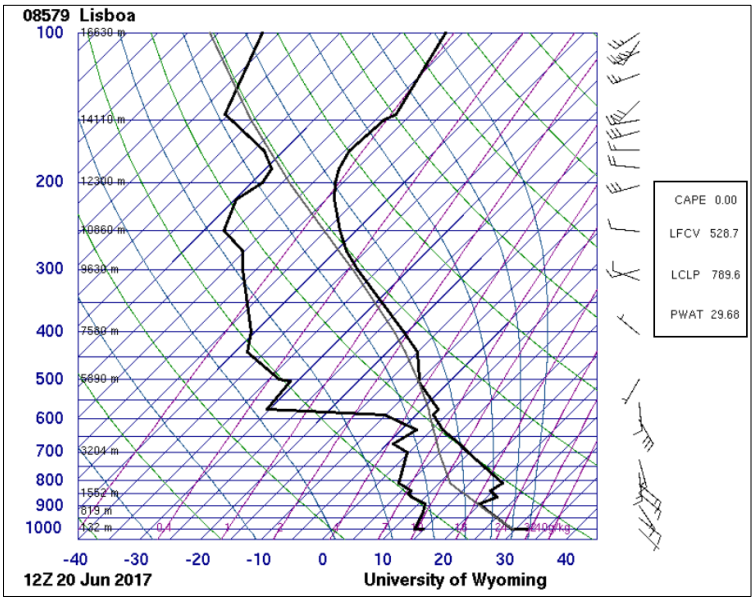

Figure2- Skew-T chart for rawinsonde profile for Lisboa station (08579) at 12:00 UTC, 20 June 2017 (location is indicated in Figure 1a). Dry bulb air temperature (black line, right), dew point temperature (black line, left), parcel trajectory (grey line, middle) and wind barbs at different levels are represented. Sounding indices: CAPE (J/Kg), LFCV (Level of free convection using virtual temperature, hPa), LCLP (Lifting condensation level, hPa) and Precipitable water for the entire sounding(8mm), adapted from University of Wyoming (http://weather.uwyo.edu/upperair/europe.html)

An area of low-level convergence (LLC) was identified to the west of the fires along a coastal strip in the 10 m wind forecast, at 12:00 (Figure 1b), coinciding with a large horizontal gradient in relative air humidity (Figure 3a). Dry air (<35%) was located to the east of the LLC whereas moister air was forecasted to the west of it (Figure 3a). Forecasts also showed that the LLC was separating warmer air to the east, from cooler air to the west, at 12:00 (not shown). Forecasts from 12:00, 15:00 and 18:00 anticipated that the LLC would propagate

eastwards, over the fires area (not shown) always separating cooler, moister air (Figure 3b,c) to its west, from warmer, drier air (Figure 3b,c) to its east. This was materializing the propagation of a SBF.

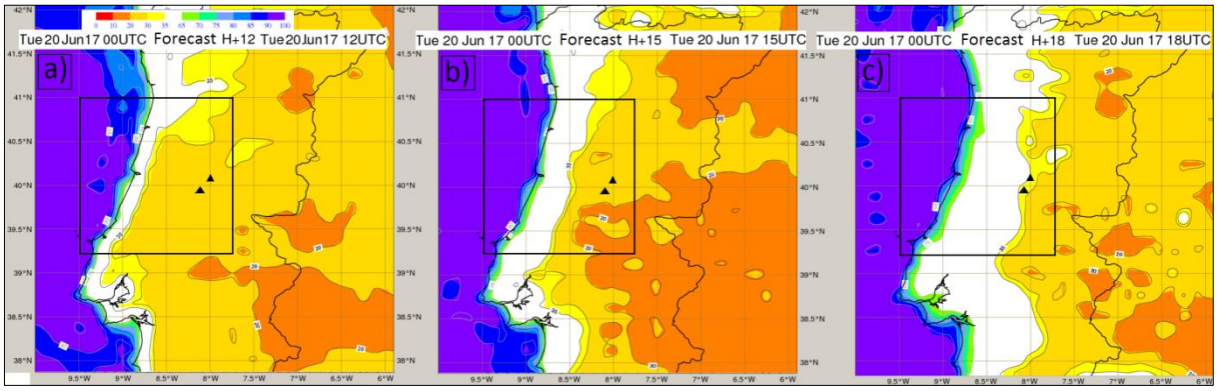

Figure 3- (a) 10 m Relative humidity (shaded, %) ECMWF forecast H+12, 12:00 UTC, (b) H+15, 15:00 UTC, and (c) H+18, 18:00 UTC, 20 June 2017. Fire locations are represented by black triangles.

2.2. Radar and surface observations

Two Doppler radars from the Instituto Português do Mar e da Atmosfera (IPMA) network were used. The Porto radar (A/PG), a dual polarization system (DP), it is located 100 km to the north of the fires (Figure 1b) and at 1100 m a.m.s.l.. The Lisbon radar (C/CL), a single polarization system (SP), it is located 100 km to the south of the fires (Figure 1b) and at 200 m a.m.s.l.. From each of the radar, reflectivity scan observations were extracted every 10 min. C/CL observations offered the best view of the low-level reflectivity due to the lower altitude of the beam, thus low elevation plane position indicators of reflectivity (PPZ) were extracted from this radar. The A/PG radar processed the correlation coefficient (ρhv) due to its DP technology.

Low-level reflectivity from C/CL radar was detected 400 m above two main active fires that were progressing in central Portugal (Figure 1b). The follow-up of reflectivity allowed the identification of the buoyancy sources (Figure 4). Visible channel satellite imagery (not shown) has confirmed that the sky was clear in the area, thus the fire plume was the only object detected on radar. Orientation of the plume and its evolution were derived from a reflectivity pattern extending downwind of the buoyancy sources (Figure 4b).

As a result of fires intensification, there is an increase in the combustion processes and in buoyancy that transport more and larger pyrometeors (McCarthy et al., 2019) upwards, according to McCarthy et al. (2019) and Jones et al. (2010). These effects will increase reflectivity (considering its dependency on the sixth power of the backscatterers diameter) and generate taller plumes. Thus, magnitude of low-level reflectivity close to the fire site and the vertical extent of the plume are good indicators of the general intensity of the strong convective processes caused by the fire (pyroconvection).

The parameter ρhv is a correlation, in a time series, between horizontally and vertically polarized echoes and is a fine particle type discriminator according to Balakrishnan et al. (1990). Lang et al. (2014), LaRoche et al. (2017) showed that fire particles exhibit ρhv values lower than those associated to hydrometeors. In accordance with Pinto et al. (2022), this study assumes that atmospheric volumes with $\rho hv \leq 0.7$ are mainly filled in by pyrometeors without significant condensation, whereas larger values correspond to atmospheric volumes with significant condensation/glaciation of pyrometeors.

Thin reflectivity lines that are traceable on radar may result from the local increase in reflectivity that is associated with the stacking of scatterers generated by low-level convergence. This can be associated with convective outflows, Srivastava et al. (1987), but also, as shown by Hanley et al (2013), with SBF's. A thin reflectivity line was identified on the lowest tilt from the C/CL scan during the afternoon of the 20 June (Figure 4).

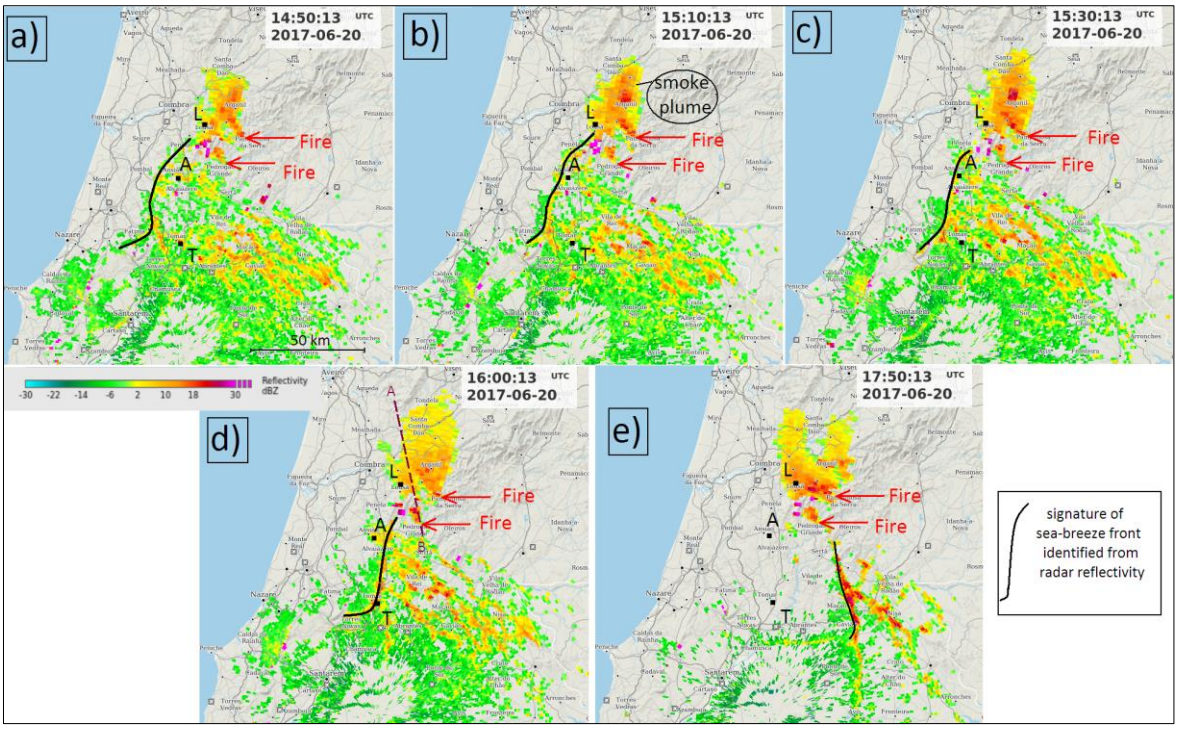

Figure 4- PPI of reflectivity, 0.1° tilt, 20 June 2017, C/CL radar. (a) 14:50 UTC, (b) 15:10 UTC, (c) 15:30 UTC, (d) 16:00 UTC, (e) 17:50 UTC. "L" Lousã, "A" Ansião, "T" Tomar AWS's. Buoyancy sources are represented by red arrows and "FIRE". "AB" dashed segment in (d) represents transect of the vertical section represented in Figure 7(a). "Smoke Plume" in a black circle in (b) highlights the pattern of a smoke plume.

The line started to be identified at 14:50, still to the west of three automatic weather stations (AWS) of IPMA (Figure 4a). Two-meter air temperature and relative humidity, 10m wind gusts and average wind speed and direction, were recorded every 10min. At this time AWS's ("L", Lousã; "A", Ansião; "T", Tomar) were influenced by a hot and dry airmass (40 °C, < 25%) and light winds from the south or southeast (Figure 5). The line was propagating eastwards and as it arrived at "L" by 15:10 the AWS started to record a decrease in air-temperature and an increase in relative humidity. However, the sudden shift to a westerly flow was the most noticeable change (Figure 5c). The other AWS's remained under the influence of a hot and dry airmass (Figure 5a,b). By 15:30, as the line arrived at "A" (Figure 4c) the AWS started to record a substantial decrease in air-temperature and increase in relative humidity (Figure 5b). It was also observed a shift to a westerly flow and average wind and gusts increment (Figure 5b). "T" AWS, still located to the east of the line (Figure 4c), remained under the influence of a dry and hot airmass in southeasterly winds (Figure 5a). At 16:00, as the thin line finally arrived at "T" (Figure 4d), the AWS recorded the same qualitative changes observed in the other AWS, concurrently with the thin line arrival (Figure 5a). By this time, the three AWS were being influenced by a cooler and moister airmass than before. These observations showed that the thin reflectivity line that was identified on low-level reflectivity was, indeed, coherently associated with the propagation of a SBF. The findings were similar to those documented by Hanley et al. (2013). This behavior confirmed the forecasts of the ECMWF and highlighted the fine performance of the model for this event (Figure 3).

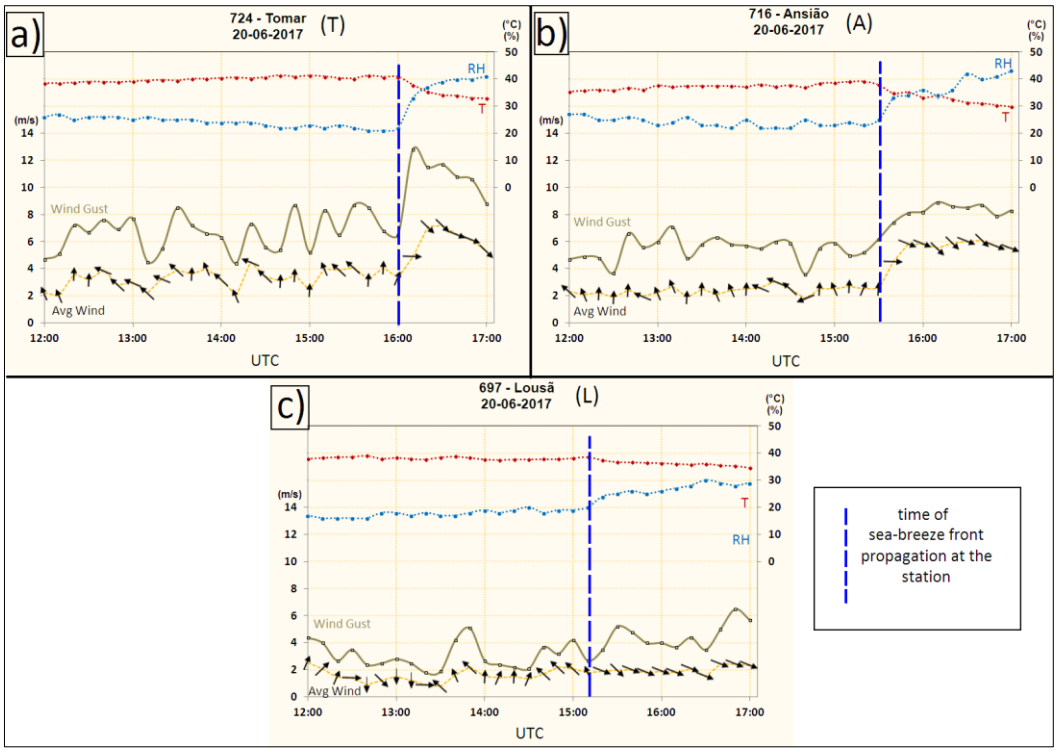

Figure 5- Weather observations at the AWS (a) Tomar ("T"), (b) Ansião ("A"), (c) Lousã ("L"). 2m air temperature (T, red), relative humidity (RH, blue), magnitude of 10 m wind gusts (green cyan), magnitude of 10 m average wind (dotted black line) and direction (arrows) observed during 12:00-17:00 UTC, 20 June 2017.

3. Influence of the sea-breeze front over the fire plume: pyroCumulus formation

The magnitude of low-level reflectivity close to buoyancy sources was monitored according to a method described in Pinto et al. (2022). The monitoring for the southwest fire (Figure 4) yielded magnitudes of 9-16 dBZ for the period 14:50-15:50 (Figure 4a,b,c). Then, from 15:50 to 16:00, an increase from 16 to 21 dBZ was noticed for this fire. At 16:10 a similar value was observed and slightly lower values were found afterwards (not shown).

Miller et al. (2003) show a diagram (their figure 9) of the simplified two-dimensional flow of a gravity current such as a SBF. Their study refers to a SBF head that may extend for more than 2000 m above the surface and explains that the flow of the pre-frontal area may promote convective activity due to the favored vertical motions. On this concern Hanley et al. (2013) have noticed that the reflectivity of a smoke plume increased substantially when a SBF was approaching the fire, but still 5-7 km upwind of it (their Figure 7.3) and considered that this was the result of enhanced low-level convergence and vertical motion ahead of the front.

The increase observed in reflectivity at 16:00, however seeming small in dBZ units, it equates to a large difference in base linear reflectivity units, since the factor is logarithmic due to its dependency on the sixth power of the scatterers diameter. Thirty minutes before this increase has occurred, the SBF was 15 km to the west of the buoyancy source (Figure 4c) but at 16:00 it was only 5 km to the west of it (Figure 4d). This sudden and transient increase on low-level reflectivity by 16:00-16:10 is considered as a result of the direct influence of the approaching SBF over the plume, similar to the case studied by Hanley et al. (2013). The SBF continued to propagate eastwards and at 17:50 was still detectable on radar but displaced to the east of the fires (Figure 4e).

The pyroconvective plume was observed in low-level reflectivity at 500 m above the fires, as a V-shape pattern extending northwest of the buoyancy sources, driven by the flow at that level (Figure 4, Figure 6). Two independent plumes were identified as departing from each buoyancy source, but merged downwind of them due to fires proximity (Figure 4, Figure 6). The plume of the southwest fire looked discontinuous due to strong clutter cancelation effects over the mountainous area located to the northwest of the buoyancy source. This can be seen with the C/CL radar (Figure 6) but also with the A/PG radar (Figure 7). Still, it can be observed a larger

magnitude of the reflectivity in the area of the plume slightly downwind of the fire, close to "L" at 16:30 (Figure 6a), when compared to the value observed at 16:00 (Figure 4d). At 16:40 an even larger reflectivity (41, 5 dBZ) was observed in the same area of the plume (Figure 6b).

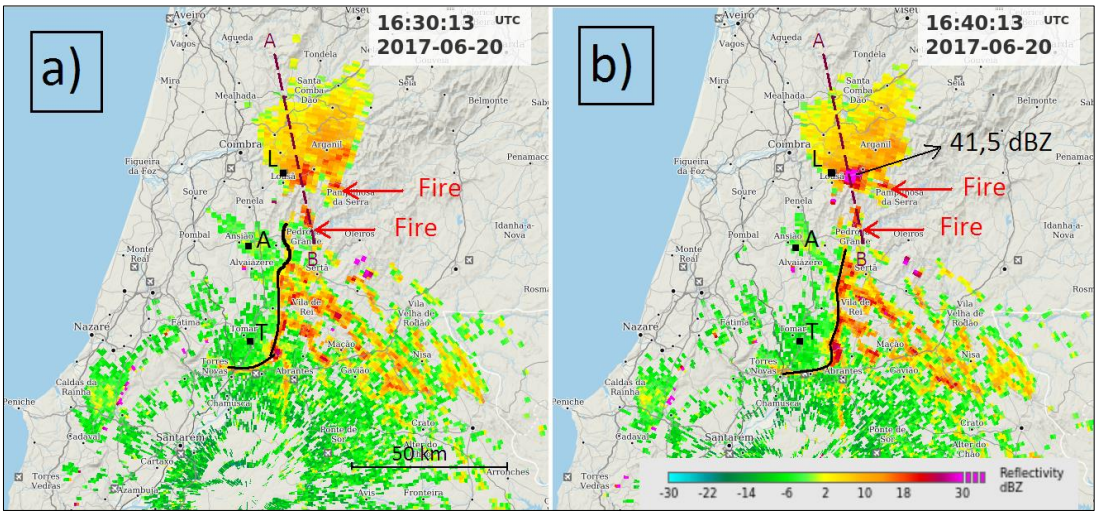

Figure 6- PPI of reflectivity, 0.1° tilt, 20 June 2017, C/CL radar. (a) 16:30 UTC, (b) 16:40 UTC. "L" Lousã, "A" Ansião, "T" Tomar AWS's. Buoyancy sources are represented by red arrows and "FIRE". "AB" dashed segment in (a) represents transect of the vertical section represented in Figure 7(c). "41,5 dBZ" highlights large magnitude reflectivity.

A sequence of static vertical sections of reflectivity and ρhv illustrates the vertical growth of the smoke plume and its transition to a pyrocumulus cloud (Figure 7). At 16:00 the smoke plume top was at 6000-7000 m a.m.s.l., as in previous observations (not shown). Its reflectivity (Figure 7a, upper) was produced by pyrometeors (ρhv ≤ 0.7, greenish colors in Figure 7a, lower), without significant condensation. This was consistent with the observed LFCV (Level of Free Convection from virtual temperature) at 5600 m a.m.s.l. at 12:00 (Figure 2). However, as the SBF started to influence the plume, it was noticed a vertical expansion of it, so that by 16:30 the top was at 9000 m (Figure 7b, upper). By then there were signs of condensation/glaciation in upper levels (ρhv > 0.7; yellowish colors in Figure 7b, lower). At 16:50 its top was at 12500 m, reflectivity attained 50.5 dBZ in the convective core (3500 m a.m.s.l.), 40 dBZ at 1200 m altitude (Figure 7c, upper) and condensation arrived at low levels (Figure 7c, lower). The hydrometeor algorithm (not shown) classified as *rain*, *graupel* and *hail* large fractions of the pyrocumulus transect, suggesting that some precipitation may have reached ground levels but there was no ground truth to verify it. This pyrocumulus peaked at 13000 m by 17:00 (not shown) and started to lose buoyancy afterwards, lowering as observed at 17:20 (Figure 7d). A photograph taken from Coimbra, 25 km to the west, shows the outstanding pyroCu at 16:48 (Figure 8).

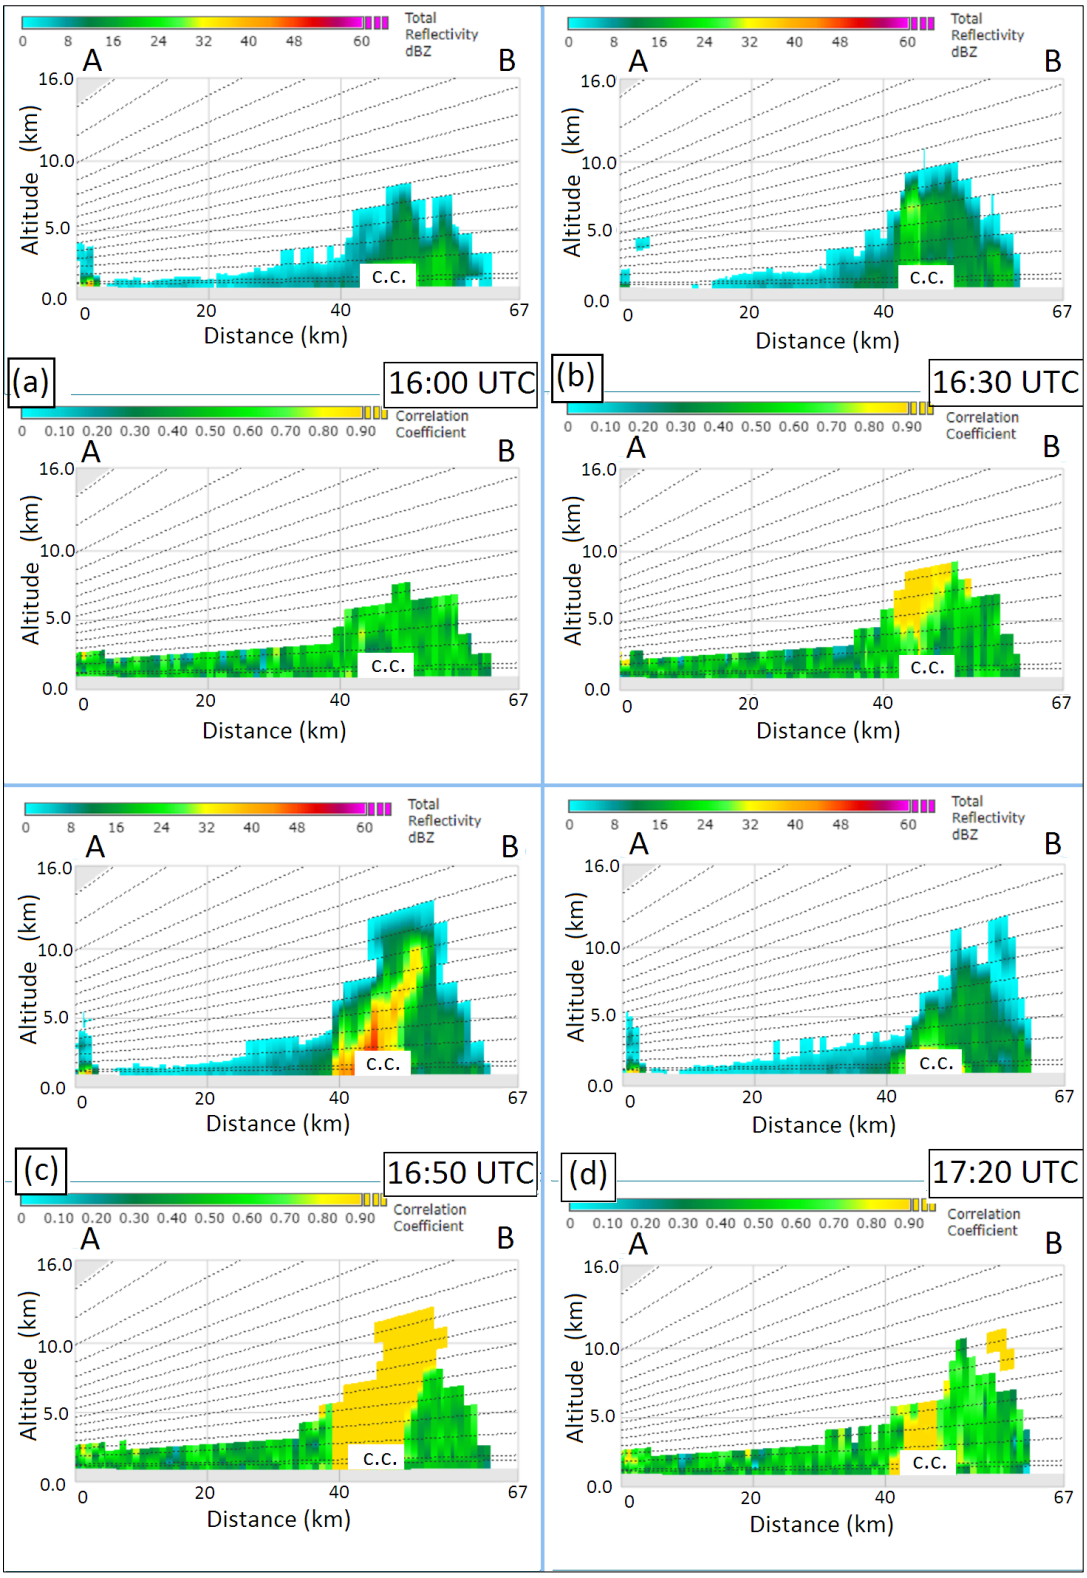

Figure 7- Vertical sections of reflectivity ((a), (b, (c), (d), upper) and of ρhv ((a), (b), (c), (d), lower), 20 June 2017, A/PG radar. (a) 16:00 UTC, (b) 16:30, (c) 16:50 UTC, (d) 17:20 UTC. Horizontal axis with distance marks every 20 km up to 67 km. Vertical axis with distance marks every 5 km up to 16 km."C.C." white rectangle depicts the area contaminated by strong clutter cancelation. Greenish colors represent smoke, yellowish colors represent condensation/glaciations of pyrometeors. (see figures 4 and 6 for reference of the transect location).

Figure 8- Photograph of the pyrocumulus cloud taken from Coimbra, at 16:48 UTC, 20 June 2017 (note: confront with Figure 7c). Extracted fromViegas et al. (2017).

Abstract

Evacuation is a critical part of wildfire emergencies. Emergency managers must be prepared to issue evacuation notices to areas that could be in the path of a wildfire to protect lives. There are methods of establishing when an evacuation should be called for any given urban area. One option is the creation of trigger boundaries around populated areas. This boundary is formed so that, should the wildfire cross it, a triggered evacuation will be complete before the wildfire becomes a threat to the area by threatening the community.

Models already exist for calculating the trigger boundary around an area, and each have their strengths and limitations. WUIVAC by Li et. al. (2015) is a robust tool that can calculate the trigger boundary of an urban area, for any one simulated fire. However, it can only model trigger boundaries for one wildfire at a time and thus cannot capture the susceptibility of the area to any possible wildfire. Ramirez et. al. (2019) created a tool to calculate the probabilistic trigger boundary of an area by simulating all possible fires that may threaten the urban area. This tool is effective for management and planning, but is incredibly resource-intensive and limited in terms of letting the user specify which area is most likely to suffer from a wildfire.

To address this, the k-PERIL algorithm was developed to calculate the trigger boundary of an urban area, as an upgraded version of the PERIL algorithm (Mitchell et. al, 2019). The user can load a single simulated wildfire, through software like FARSITE, and an evacuation time and get an exact trigger boundary for a specified urban area. The user can also load multiple wildfire simulation results for a given area, and K-PERIL will then generate a probabilistic trigger area. The user can then choose to retrieve a singular boundary of the area based on a probability value; It was made as part of the WUINITY project, by Ronchi et. al (2020), a self-contained wildfire simulation and evacuation planning tool.

To introduce k-PERIL as a tool of calculating trigger boundaries, this paper presents the a study on creating trigger boundaries for Roxborough Park, an urban area near Denver, CO, USA. A fire ignition area was specified and a number of wildfires with varying weather inputs were created, and a probabilistic boundary was created. The testing program allowed the user to specify the average weather values and standard deviations of their area of interest, specify an area where ignition is most likely, and specify the number of simulated wildfires. Testing for single-wildfire boundaries will be conducted in the full paper.

The results show that the results follow the current understanding of wildfire propagation. The resulting shapes are more accurate when more test cases are loaded, and are wider when the input variables are more varied. K-PERIL can thusly be used to create both specific and probabilistic boundaries around an inhabited area, either for immediate response or long-term planning.

1. Introduction

Wildfire emergency managers currently rely on their experience and intuition to call an evacuation when a Wildlife-Urban Interface (WUI) area is at risk [Pyne, Andrews, Laven 1996]. If the evacuation is called too soon, critical resources may be diverted from an area that needs them more; if it is called too late, lives may be at risk [Thomas, McAlpine 2010]. Trigger boundaries are a method of calculating the ideal time to trigger an evacuation, by coupling the decision-making process with the physical position of the fire.

1.1. Trigger Boundaries

Trigger boundaries set an area around an urban area at risk. For a given Wildfire Required Safe Egress Time (WRSET), the boundary is formed so that, when the fire reaches any point in the boundary, the urban area has

an ASET amount of time before the fire reaches the urban area. This can be explained schematically using Figure 1.

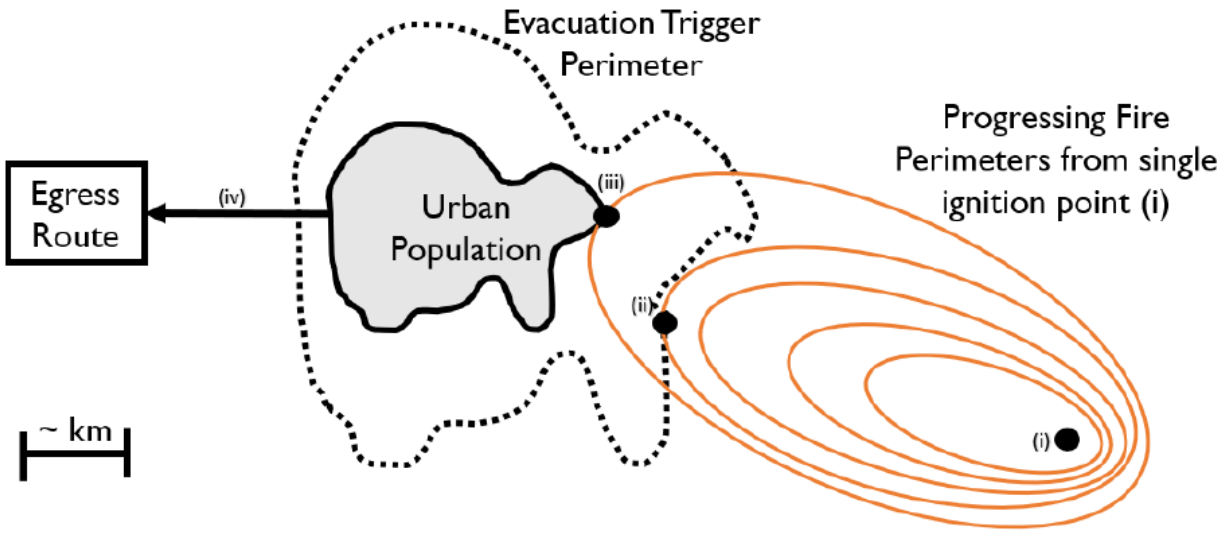

Figure 1- Schematic of the function of trigger boundaries (here referred to as trigger perimeters) [6]. A fire starts at timestep (i). At timestep (iii) the fire has reached a designated urban population. An ASET amount of time before timestep (iii), the fire was at timestep (ii). The locus of all the points where the fire is an ASET amount of time away from the urban node is the trigger boundary.

Currently there is no universally used method of analytically deducing trigger buffers by practitioners, but there is a number of models that attempt to calculate the safety boundary. The most popular such model is HURREVAC [A Hurricane Decision Support Tool For Government Emergency Managers] although it is made to calculate trigger boundaries for hurricane-prone coastal areas. Below is a presentation of trigger boundary calculation programs created specifically for wildfire risk.

1.2. Previous models

1.2.1. WUIVAC

WUIVAC [Dennison, Cova, Mortiz 2007] [Li, Cova, Dennison 2015] is an open-source model that uses Rate of Spread data from wildfire simulations to calculate the trigger boundary for any given urban area. WUIVAC has been used in applied test cases such as one involving the 2003 Cedar Creek fire [Larsen et. al. 2011], though none of them have been experimentally validated. One setback of the program is it can only be used to create one boundary at a time, so if a sensitivity or long-term planning study was needed, the program would be cumbersome to use.

1.2.2. Ramirez et. Al.

Ramirez et. Al [Ramirez et. al. 2019] calculate safety buffers using a different approach. They simulate wildfires as well, but set the simulated time duration equal to WRSET, and then run one hundred simulations, with normally distributed starting conditions. While this method is very thorough, it is also computationally expensive and inefficient. It also does not account for the acceleration phase of wildfires or other effects that fully developed wildfires may induce [Thomas, McAlpine 2010]. It also cannot run a study for a singular fire, should that need arise.

1.2.3. PERIL and K-PERIL

PERIL [Mitchel, Rein 2019a] [Mitchell et al. 2019b] is a program created based on the working principles of WUIVAC. It too uses wildfire simulations to calculate arrival times, and then creates a weighted point network to find the trigger boundary. The long-term goal of PERIL is to be integrated in the greater WUINITY project [Mallick, 2021] [Ronchi et al. 2020] [Wahlqvist et al. 2021]. WUINITY is a project aiming to provide a coupled wildfire-evacuation model that accounts for wildfire propagation, pedestrian and vehicular evacuation.

k-PERIL is the next iteration of the PERIL program, which enables the running of both single-fire studies and probabilistic studies. It uses the same core algorithm as PERIL but outputs a matrix of all the points that are inside the trigger boundary. It can then compound each output matrix for multiple cases and thus create a probabilistic boundary based on how many boundaries include each point. PERIL has been used in a real case before, but k-PERIL has only been verified in simple cases, when compared to PERIL. This is the first study where k-PERIL is used in a real-life situation.

2. Objectives

In this study, we set out to test k-PERIL in a real-life case. The urban area selected for the test is an area around Roxborough Park, an urban area south of Denver, CO, USA (figure 2) that has undergone extensive evacuation testing and documenting thereof as part of the WUI-NITY studies [Mallick 2021]. The primary risk of fire considered is ignition in the shrubland south of the area, with southern winds guiding the fire towards the urban area.

3. Methods

For this analysis, a custom testing suite was created, that generated several custom FARSITE [Finney 1998] simulations and run them through a command-line version of FARSITE [Fire Behavior Applications and libraries 2021]. The results were then given to k-PERIL and the boundary of each simulation was calculated. The boundaries were then summed to a probabilistic overall boundary around the urban area. FARSITE was used here because of its position as a universally accepted accurate wildfire simulation model, and because of the availability of the command line version. However, any wildfire simulation software (or, in fact, any Rate of Spread data) can be used to create the inputs, such as WFDS or Prometheus.

The inputs to FARSITE were specified assuming a normal distribution of all the available weather input values. A sample of the normal distribution of the input data for a test case is given in Figure 3. The fuel moisture was specified as constant and identical for all fuels, as fuel moisture data is difficult to obtain. The wind direction was made to always point towards the urban area to ensure the simulated wildfire would always reach the urban area (this was in accordance with the average wind direction given by the closest Remote Automatic Weather Station (RAWS)). The temperature and moisture data were extrapolated to a diurnal profile. The ignition location was chosen randomly from a specified area in the raster (figure 2). The WRSET time was set at 110 minutes, from [Mallick, 2021].

The parameters used for the fuel moisture are:

- Fuel models: 0 -245
- 1-Hour Fuels: 4 tons m^{-2}
- 10-Hour Fuels: 6 tons m^{-2}
- 100-Hour Fuels: 13 tons m^{-2}
- Live Herbaceous moisture content: 30%
- Live Woody moisture content: 60%

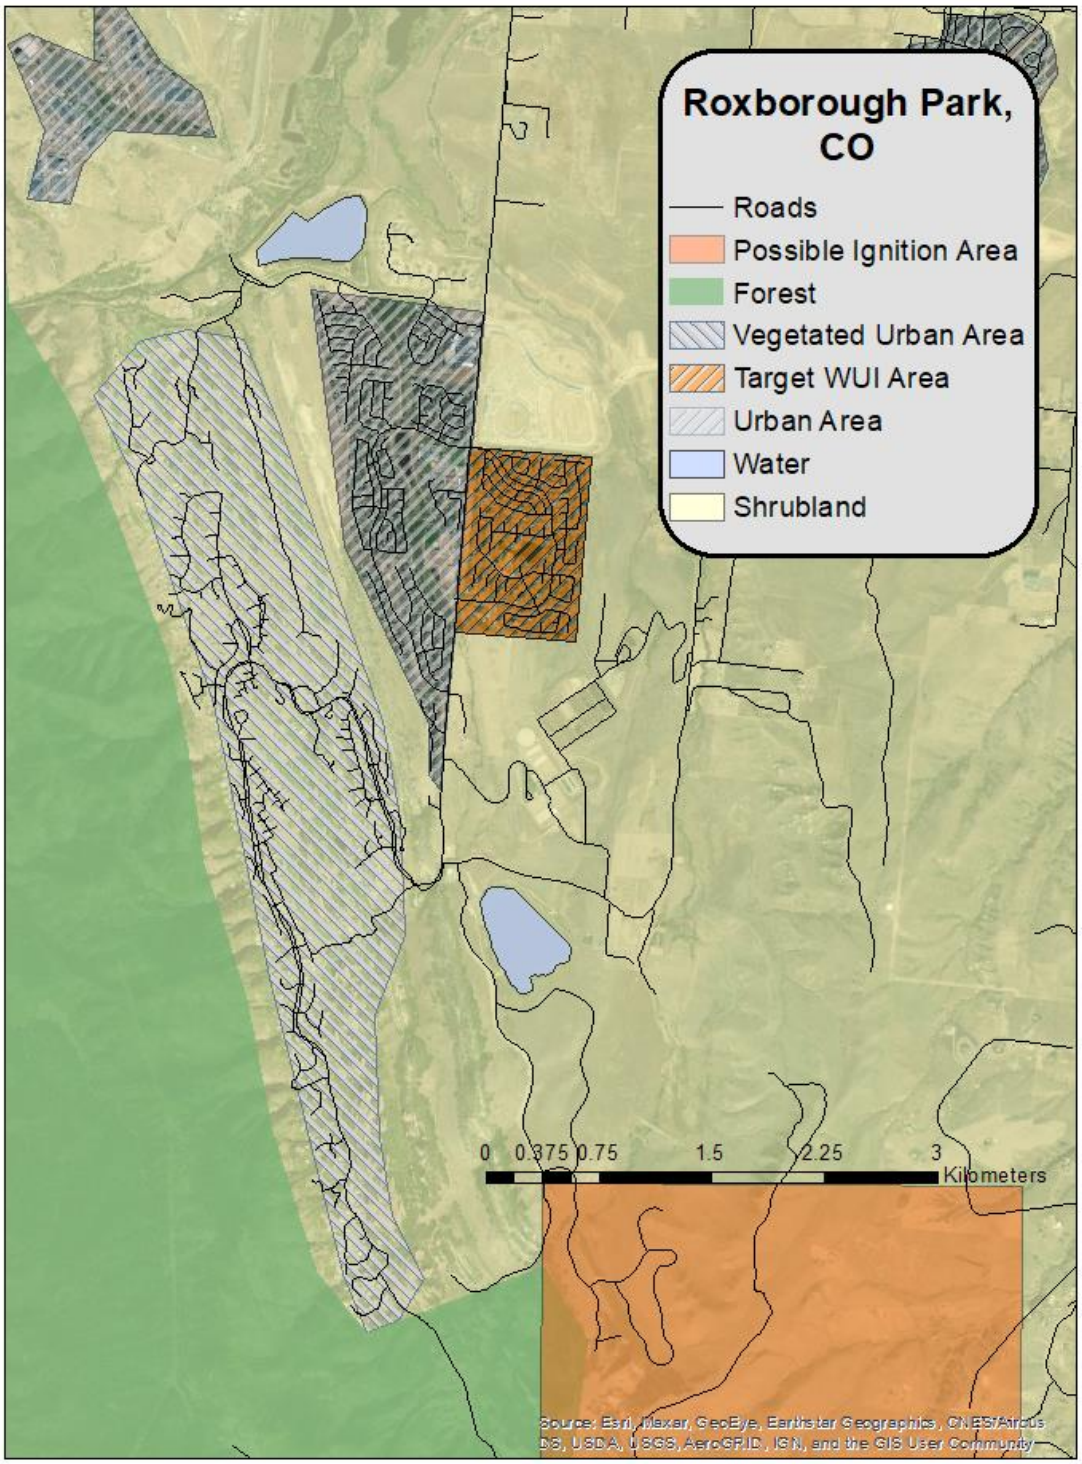

Figure 2- ArcGIS map of area selected for this study - a neighbourhood in Roxborough Park, CO, USA. Target urban area is highlighted in Pink. A populated region of Roxborough Park was chosen as the at-risk community. The fire risk has been identified as any fire starting on the south, with northwards winds.

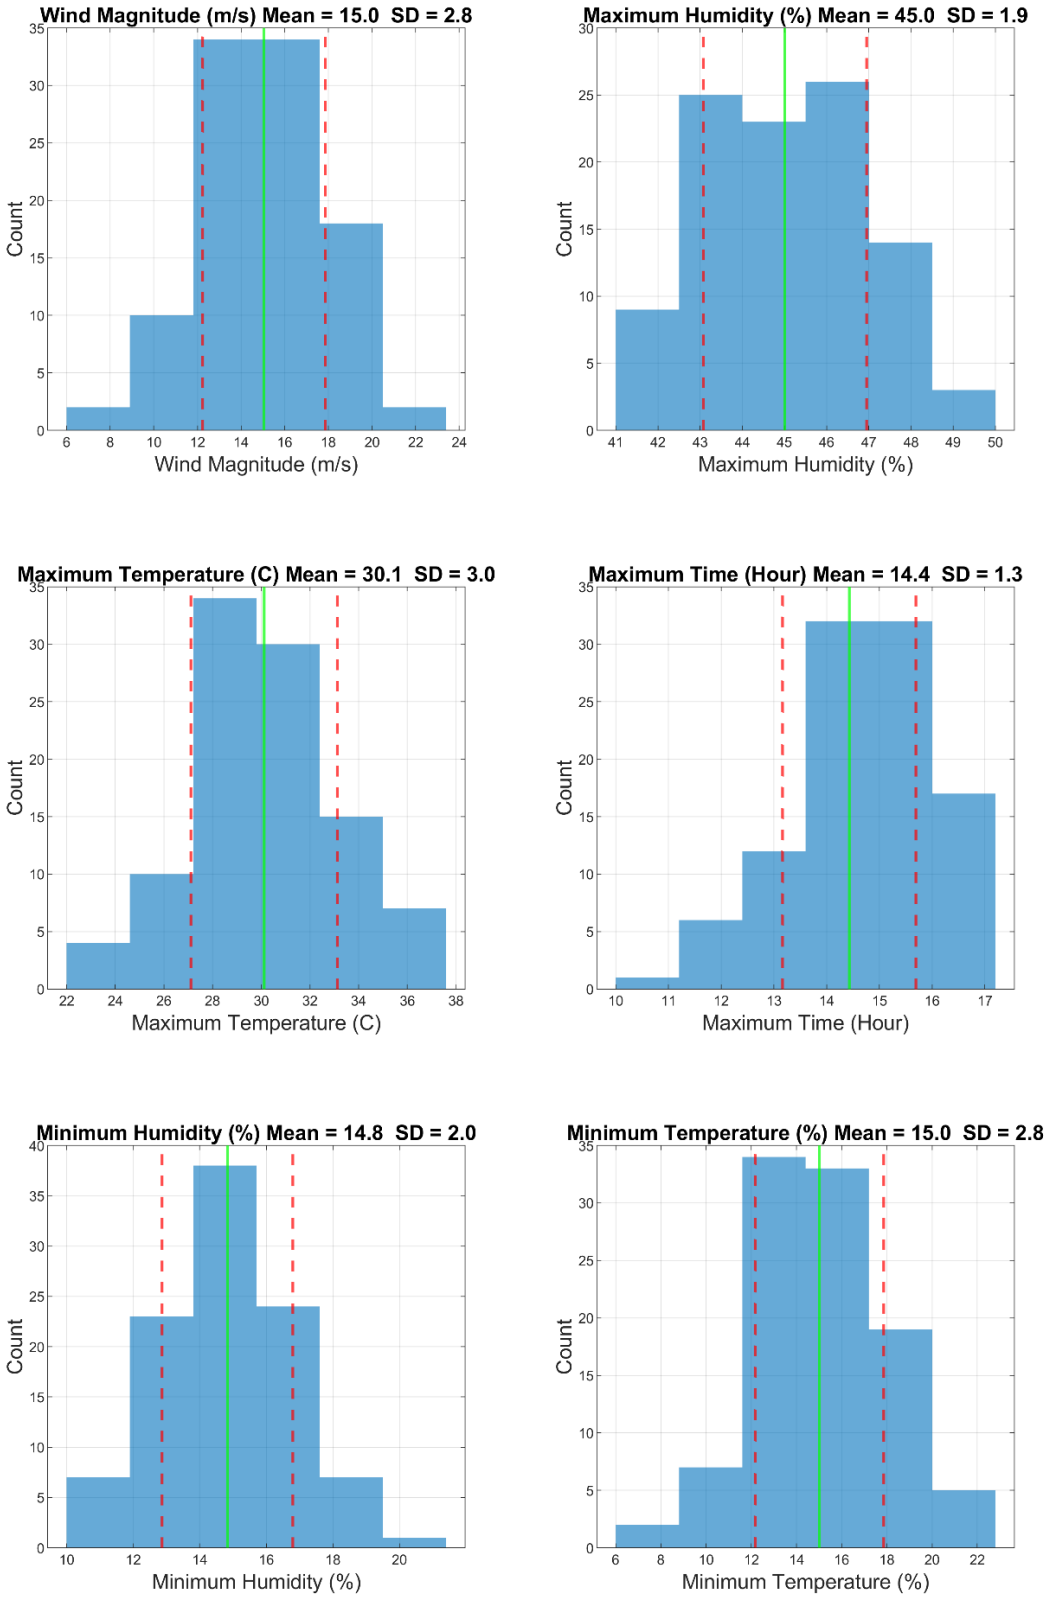

Figure 3- All the weather related values are given as normally distributed values. This data is plotted above for a simulation with 100 cases.

4. Results

A number of studies were conducted with varying input data, as shown in table 1. The first three sets of tests examine the effect of number of simulated cases to the probabilistic boundaries. The latter three cases test the effect of wind magnitude (both average value and standard deviation) for a larger ASET, to exaggerate the effect of the change.

Table 1- Input variables for the simulated cases.

Case No.	ASET (min)	Wind Magnitude (ms^{-1})	Wind Standard Deviation (ms^{-1})	Simulated cases
1	110	15	3	10
2	110	15	3	25
2	110	15	3	100
3	300	15	3	100
4	300	35	3	100
5	300	35	15	100

The results of the studies are shown in Figures 4, 5, and 6. Specific discussion on the results and what they suggest is given in the Discussions section.

The probabilistic boundaries are given as probability values on a raster. One can choose whether to keep all the nonzero cells as their trigger boundary, and get a conservative boundary that would cover all simulated cases. One could equivalently choose the boundary where 90% of all the boundaries meet, to exclude any outliers or one-off glitches. The user could ultimately even choose the 0% boundary value, which only shows the area common to all the boundaries. To illustrate the shape and gradient of the trigger boundaries, values ranging from 100% inclusion to 0% inclusion are shown in figures 4 and 5.

5. Discussion

The studies ran in this paper have a level of uncertainty due to uncertainties in the input data. While the wind data is consistent with the average readings of the nearest RAWS station, said RAWS station is more than 20 miles away from the target area. The generated wind magnitude and direction data are also considered temporally uniform which is inaccurate for any area.

For all the reasons above, it is challenging to tell whether the probabilistic or direct results of k-PERIL are accurate to the target area. What can be done is a qualitative analysis of the boundaries based on their characteristics and their change based on changing input variables. In this analysis, the formed boundaries seem to agree with the expected results. In figures 4, 5, and 6 the boundaries are uniform which stems from the fact that the fire spread is steady and uniform in a uniform shrubland. The boundary's southern border is thicker as it is meeting the faster-spreading head of the fire. On the northern border there is a large area on the north-western corner, which also makes sense since the fire turns when it is past the urban area as it is spreading upwards and to the unburned area. Figure 4 shows that more simulations form a better boundary as they filter out outlier simulations; 25 to 100 simulations are enough for a consistent 75% Boundary. Figure 5 shows that a larger ASET does result to larger boundaries as expected, but larger wind or deviation thereof does not seem to affect the probabilistic boundaries. This might be because the wind magnitude is not as strong an influence for

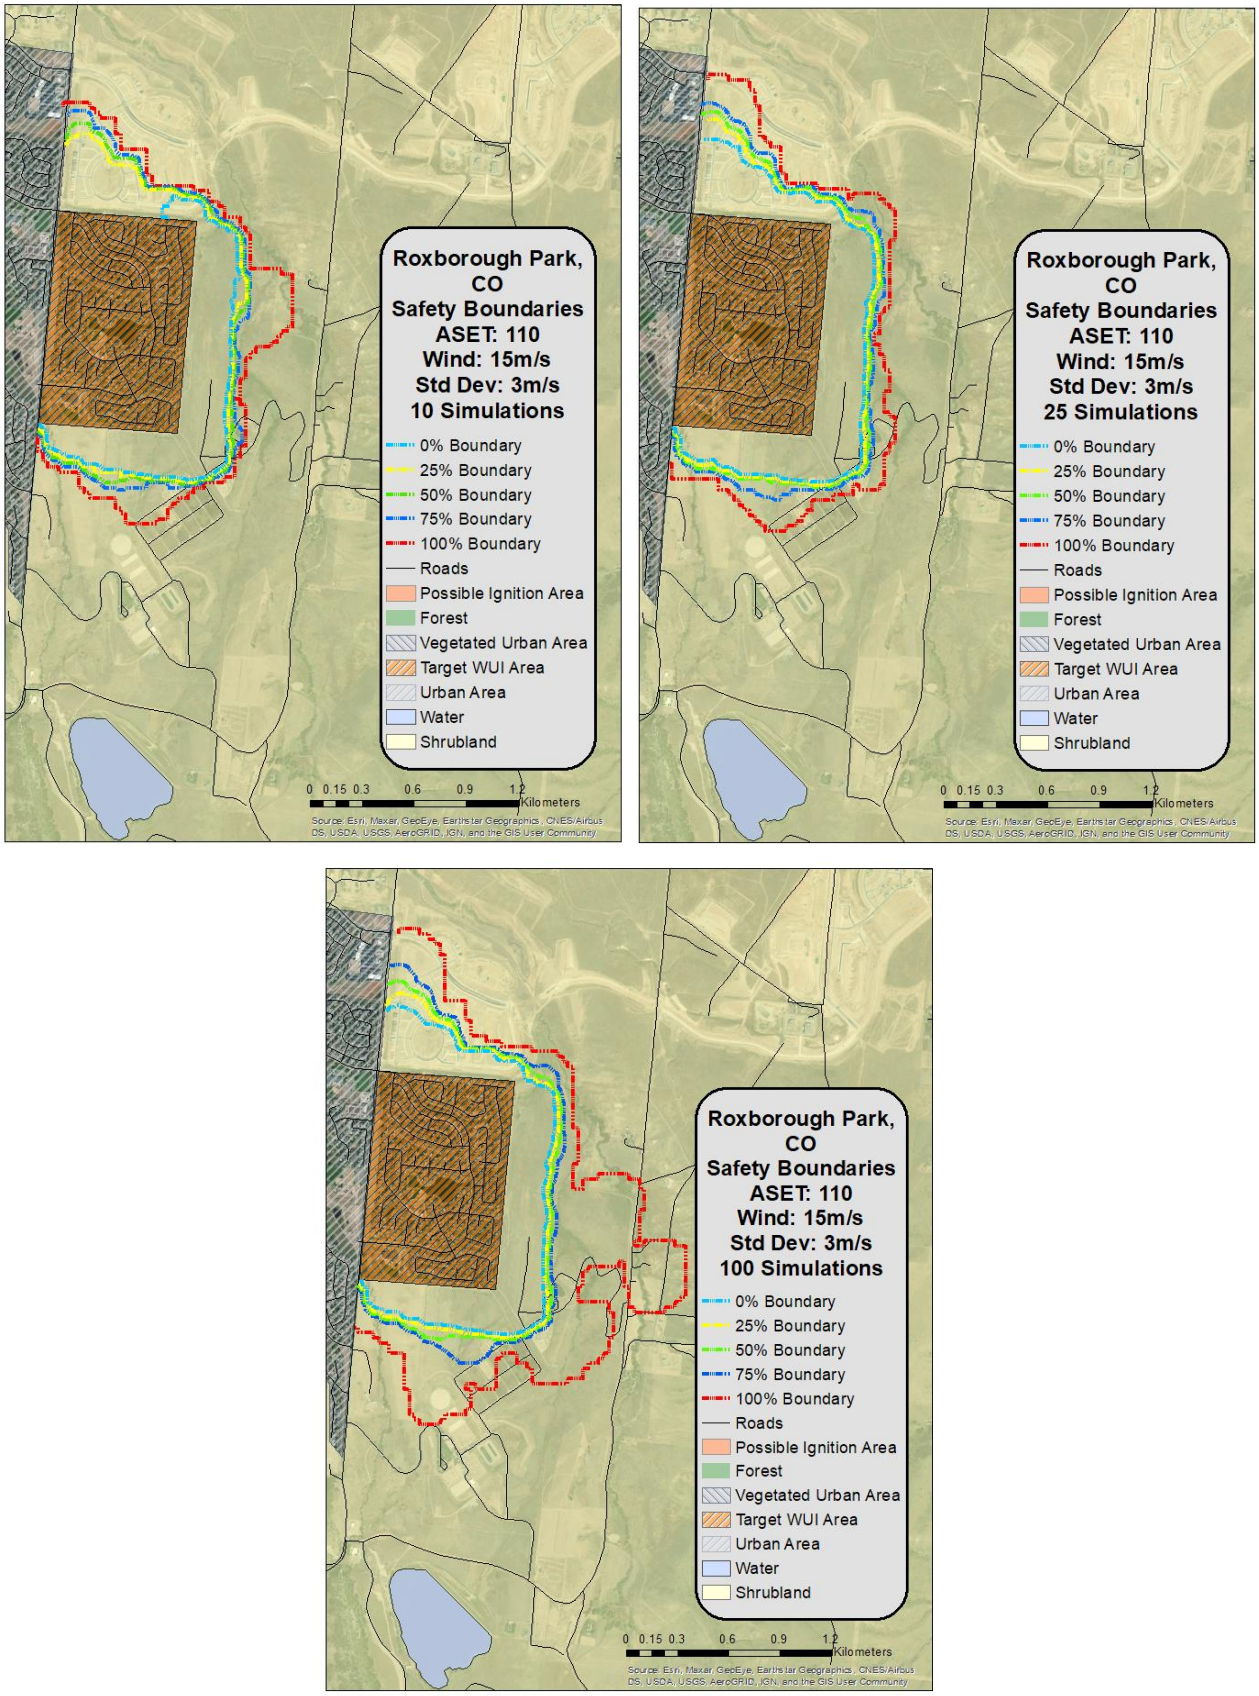

Figure 4- Top Left: Probabilistic safety Boundary for an ASET of 110 minutes, wind magnitude of 15 ms^{-1} with a standard deviation of 3 ms^{-1} and 10 simulated cases. Top Right: Safety boundary for the same case as the Left, with 25 simulated cases. Bottom: Safety boundary for the same case as previous, with 100 simulated cases.

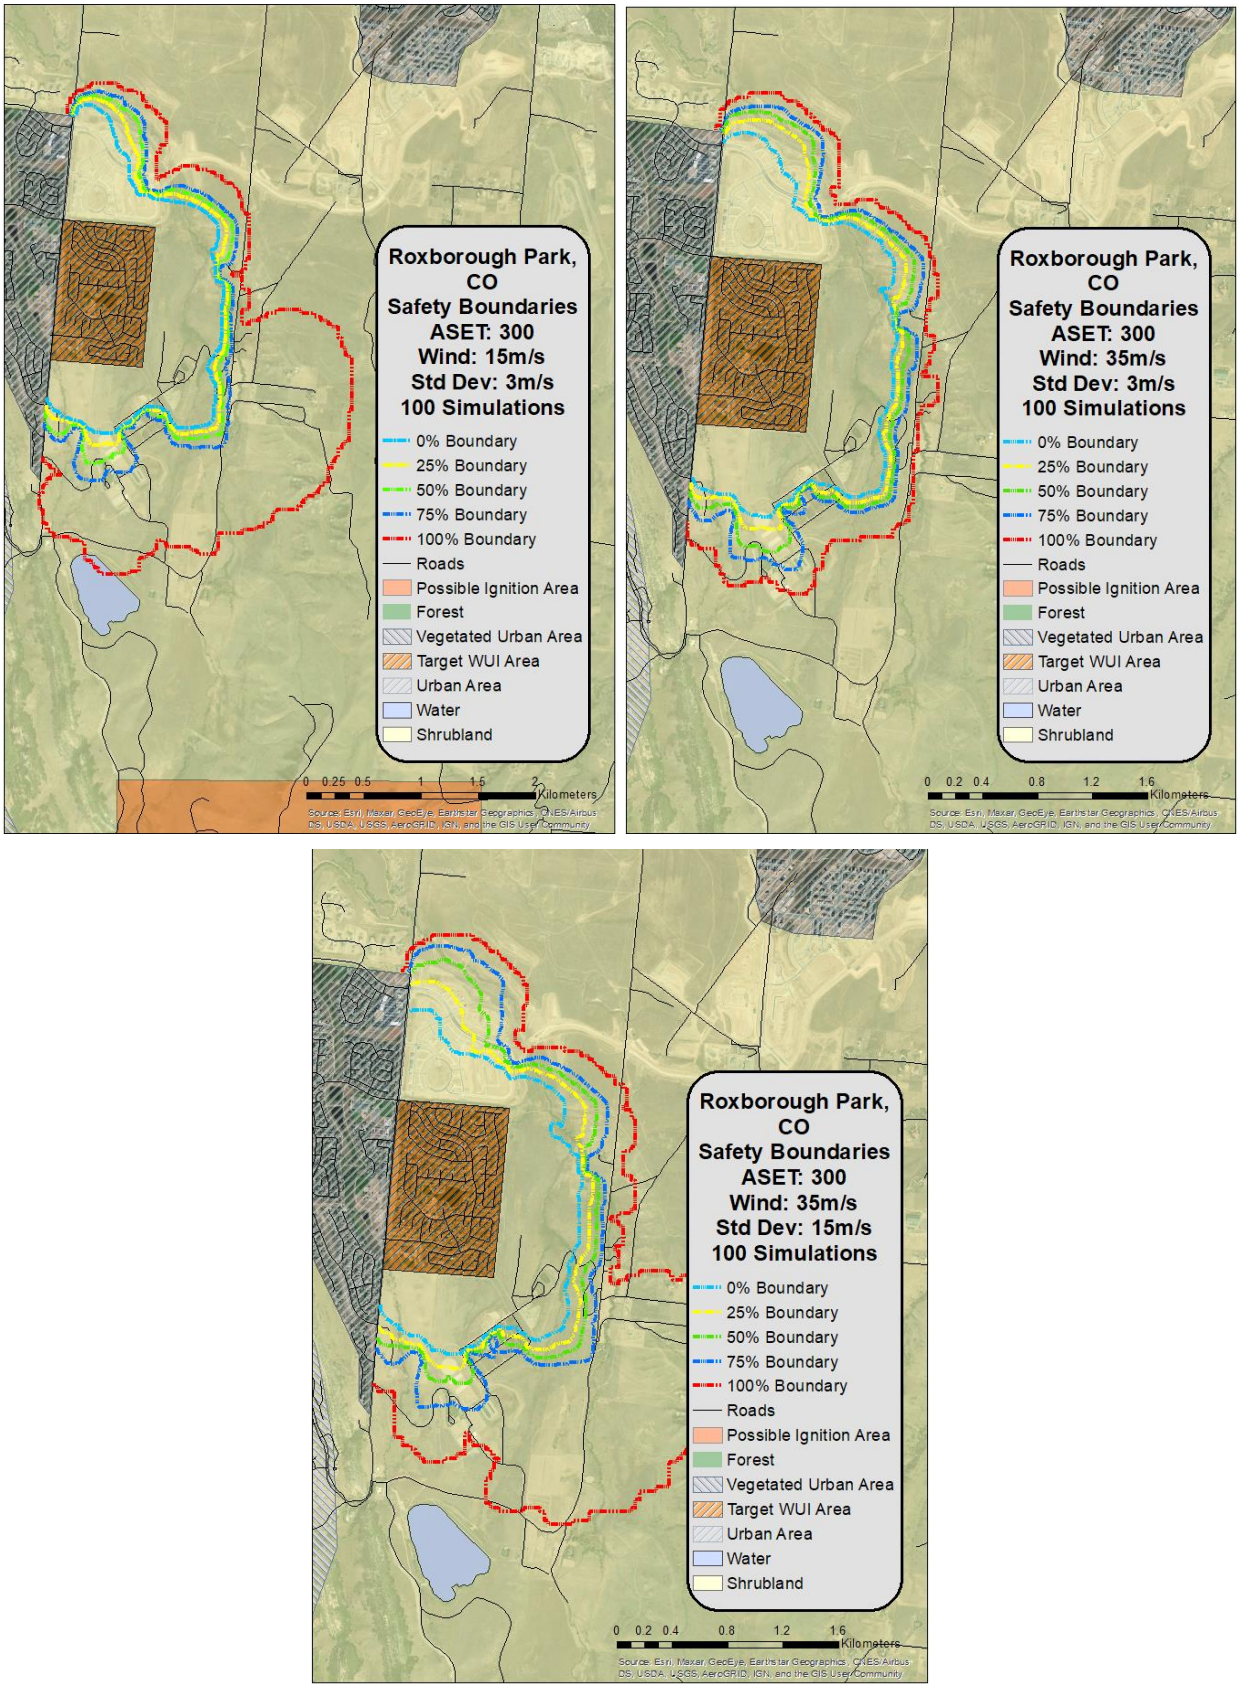

Figure 5- Top Right: Safety Boundary for an ASET of 300 minutes, wind magnitude of 15 ms^{-1} with a standard deviation of 3 ms^{-1} and 100 simulated cases. Top Left: Similar case to A with a wind magnitude of 35 ms^{-1}. Bottom: Similar to B with a wind magnitude standard deviation of 15 ms-1.

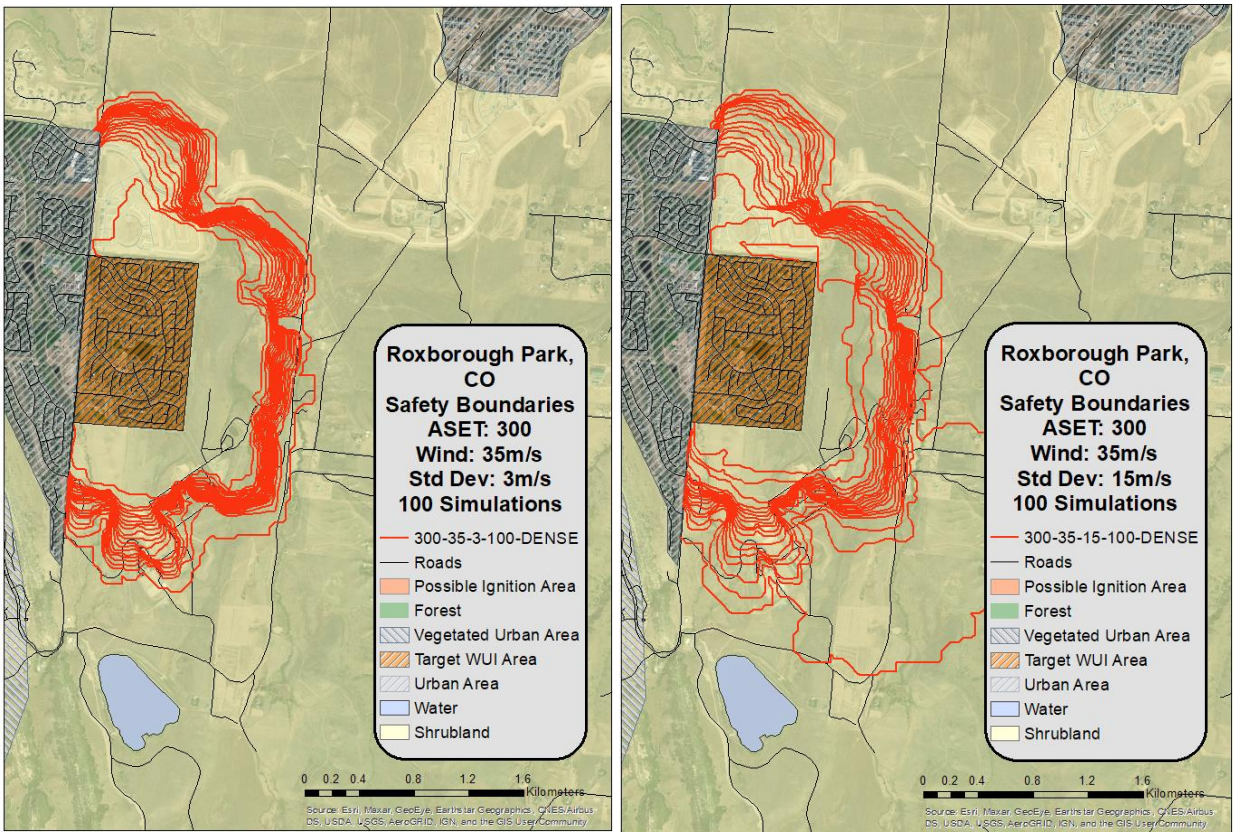

Figure 6- Right: Safety Boundary for an ASET of 300 minutes, wind magnitude of 35 ms^{-1} with a standard deviation of 3 ms^{-1} and 100 simulated cases. Left: Similar case to A with a standard deviation of 15 ms^{-1}. Both plots have equal isoprobabilistic boundaries.

this type of vegetative fuel. From Figure 6 it is evident that a greater standard deviation in wind input results in wider probability boundaries, although the magnitude of the change is small compared to the change in standard deviation. The difference in output between the last two cases can be better appreciated when more probability lines are drawn, as in Figure 6.

6. Limitations

Although k-PERIL is an upgrade compared to previous versions, it is still limited in many aspects. One critical limitation is that verification and validation can only be done with real wildfire data. Using simulated wildfire data to validate k-PERIL would only verify that the program is self-consistent, since these data are an input layer to the algorithm. To truly verify k-PERIL, the trigger boundaries would need to be generated for a real area, then a wildfire should be initiated, and the propagation of the fire and time of arrival should be recorded and compared with the predicted trigger boundary. The accuracy of k-PERIL will then be limited by the accuracy of the modelling engine used to obtain the simulated spread data. A point of future work is to find recorded rate of spread data of a real wildfire, and use it to test the validity of k-PERIL.

Another critical limitation of k-PERIL is that its results are limited by the accuracy and abilities of the wildfire model used to create the ROS input data. Most such programs can model surface fires, crown fires and spotting effectively. However, most models cannot model complex physical effects, such as long-range spotting, plume collapse, sudden wind shift, or other eruptive fire events. These are avenue of future work but may require radical changes.

7. Future work

Two future work possibilities have been discussed on the Limitations section above. Another critical area of improvement is expanding the coupling between the wildfire propagation and the evacuation simulations.

Currently the model reduces the entire evacuation procedure into one number (WRSET) and cannot account for event such as egress route blockage, probability of traffic accidents, or lane reversals initiated while the fire has crossed the trigger boundary. There is little real-time interaction between evacuation modelling and wildfire modelling; k-PERIL is supposed to be a link between the two, but at its current form it does not provide a robust coupling of the two models.

8. Conclusion

The above analysis shows that the boundaries are reasonable according to current wildfire behaviour understanding, and as such k-PERIL creates boundaries appropriate for future application. K-PERIL's results are as close to verified or tested as they can feasibly be, and as such k-PERIL has been proven to produce actionable results.

Abstract

Our general objective in the present study is to develop tools to better describe the coupling between solid phase and gas phase processes that control the dynamics of flame spread in wildland fire problems. We focus on a modelling approach that resolves processes occurring at flame scales, i.e., the formation of flammable vapors from the biomass vegetation due to pyrolysis, the subsequent combustion of these fuel vapors with ambient air, the establishment of a turbulent flow because of heat release and buoyant acceleration, and the thermal feedback to the solid biomass through radiative and convective heat transfer. The modelling capability is based on a general-purpose Computational Fluid Dynamics (CFD) library called OpenFOAM and an in-house Lagrangian particle model that treats drying, thermal pyrolysis, oxidative pyrolysis and char oxidation using a one-dimensional porous medium formulation that allows descriptions of thermal degradation processes occurring during both flaming and smoldering combustion.

The modelling capability is calibrated for pine wood and is first applied to simulations of fire spread across a surrogate vegetation bed corresponding to thin, monodisperse, cylindrical-shaped sticks of pine wood with prescribed particle and environmental properties (i.e., bed height, surface-to-volume ratio, packing ratio, moisture content, and wind velocity). While the model can be used in sloped terrain, the present simulations are limited to a flat ground surface. The current emphasis is on determining threshold conditions for successful spread, differences between the plume-dominated and wind-driven flame regimes, possible transitions to a steady or time-dependent flame structure, and differences in the relative weights of the flaming and smoldering regions.

1. Introduction

The dynamics of wildland fires involve multi-physics phenomena occurring at multiple scales. Computational Fluid Dynamics (CFD) models have the potential to provide detailed information on the interactions between physical phenomena occurring at all these different scales. However, because of computational cost, the domain of application of CFD models is typically limited to a particular range of scales. Thus, current CFD-based wildland fire models are scale-specific and belong to one of the following three classes: combustion solvers aimed at describing the coupling between pyrolysis, combustion, radiation and flow occurring at the vegetation and flame scales (Porterie *et al*. (2000), Morvan and Dupuy (2001), Morvan and Dupuy (2004), Fire Dynamics Simulator (FDS), Verma *et al.* (2022)); wildfire solvers aimed at describing the coupling between combustion and flow occurring at fireline scales and/or geographical scales (Linn and Cunningham (2005), Canfield *et al.* (2014), Mell *et al.* (2007)); and atmospheric boundary layer solvers aimed at describing the coupling between combustion and flow occurring at meteorological scales (Clark *et al.* (2004), Mandel *et al.* (2011), Kochanski *et al.* (2013), Coen *et al.* (2013), Filippi *et al.* (2009), Filippi *et al.* (2013)).

We focus in this study on the development of a combustion solver aimed at describing the physics of wildland fire spread at flame scale. The solver couples a one-dimensional, Lagrangian-based, solid particle model that describes the biomass vegetation phenomena (drying, pyrolysis, char oxidation) with a three-dimensional, Eulerian-based, CFD model that describes the gas phase phenomena (flow, combustion, radiative and convective heat transfer processes). The gas phase model uses a Large Eddy Simulation (LES) approach and is based on a general-purpose CFD library called OpenFOAM. The Lagrangian particle model uses an in-house solver developed both for fast one-dimensional simulations of flame spread (Forthofer *et al.* (2022)) and for

detailed LES simulations of the flame structure in wildland fire configurations. The model considers the particle as thermally-thick and composition-thick and includes descriptions of thermal degradation processes occurring during both flaming and smoldering combustion.

2. Numerical Model

The vegetation bed is treated as a population of porous particles, which can have different geometries and different sizes. Each porous particle is described as a system with a solid phase and a gas phase, which allows for a detailed treatment of the particle-to-external-gas outflow of volatile mass and the external-gas-to-particle diffusion of oxygen mass; this detailed treatment is required to account for in-depth oxidative pyrolysis and char oxidation. We consider here thermally-thick and composition-thick particles featuring in-depth variations of temperature and composition. The particles geometry can be modelled as rectangular (leaves or sticks), cylindrical (needles or stems) or spherical (embers or firebrands).

2.1. Lagrangian particle model

In the Lagrangian viewpoint, the thermo-chemical degradation of each porous particle is tracked individually in space and time. We consider each porous particle to experience four heterogenous (gas/solid) reactions: a drying reaction; a thermal pyrolysis reaction; an oxidative pyrolysis reaction; and a char oxidation reaction. We follow the work of Lautenberger and Fernandez-Pello (2009) by describing the particle as a matrix of pores featuring a solid phase and a gas phase. We discretize the porous particle into a set of one-dimensional control volumes that contain information about the porosity, thermophysical properties, chemical composition, temperature and pressure. In the following case studies, we consider thermo-chemical degradation and flame spread of pine sticks. We combine the thermophysical properties of pine wood provided in Lautenberger and Fernandez-Pello (2009) with the reaction kinetic parameters provided in Anca-Couce *et al.* (2012); this combination was found to achieve a good fit of experimental data at both micro-scale and bench-scale, as shown in the next section.

The governing equations of mass, momentum, and energy conservation inside each control volume of the porous particle are solved numerically using an implicit approach that treats convection and diffusion through a second-order, Crank-Nicolson method and chemical reaction through a first-order, backward Euler method. An in-house object -oriented C++ solver of this Larangian particle model was developed. This code can serve as a stand-alone solver of thermo-chemical degradation of solids, or it can be implemented into larger frameworks to model fire spread over vegetation as discussed in the following section. This code also features an adaptive time-stepping technique (for speed, stability, and robustness) and a re-meshing capability (for deforming particles due to swelling or shrinking).

2.2. Vegetation bed model

In order to describe gas-solid mass, momentum and energy exchanges in simulations of fire spread across a given set of porous vegetation layers, ambient air conditions and a given terrain, we developed a LES solver that couples the open-source C++ library OpenFOAM and the Lagrangian particle solver presented in the previous section.

The LES solver adopts a multiphase formulation similar to previous work proposed by Porterie *et al*. (2000), Morvan and Dupuy (2001) and Morvan and Dupuy (2004). In the current work, the Favre-filtered reactive-radiative Navier-Stokes equations are solved using a low Mach number approach. Source terms are added to the governing equations to represent the contributions of solid particles to the mass production or consumption of gaseous species, the flow momentum through a drag force, and the energy exchange through radiative and convective heat transfer. These source terms are treated as subgrid-scale (SGS) terms using the Lagrangian particle model and are accumulated to account for multiple particles existing inside each elementary control volume of the vegetation bed. The number of particles is determined from the fuel loading and the geometric parameters of the vegetation bed. A three-dimensional representation of a typical computational configuration is shown in Fig. 1.

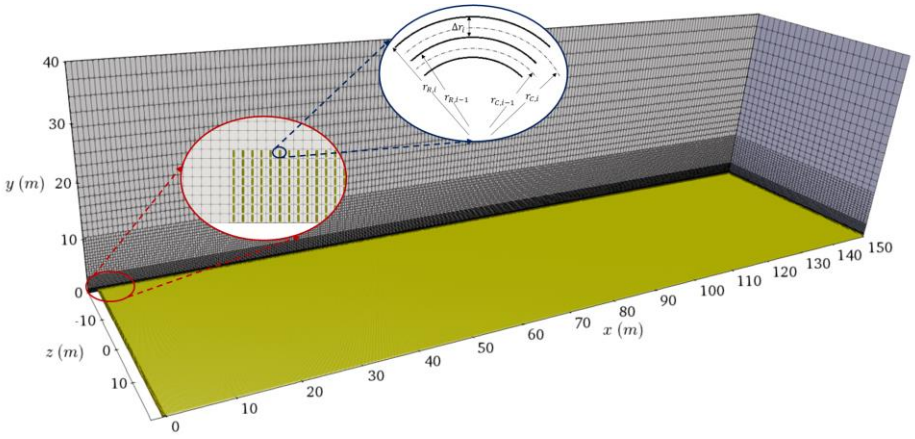

Figure 1- A view of the computational domain used in spreading line fire simulations. The solid particles are colored in yellow. A zoom into the 1D cylindrical mesh used for individual solid particles is shown.

The solver can leverage various SGS turbulence models implemented in the native OpenFOAM library. We use the WALE model proposed by Nicoud and Ducros (1999). The homogenous combustion of the gaseous fuel produced by pyrolysis reactions is treated by assuming a global reaction equation and using a modified version of the Eddy Dissipation Model (Magnussen and Hjertager (1976)) that we recently developed to account for the variations of the laminar diffusion characteristic time with LES filter size. The solver also features a radiation model based on a multi-phase radiative transfer equation (MRTE) that includes absorption/emission by the solid particles and by the gases (Consalvi *et al.* (2002)); the MRTE is solved using the finite volume Discrete Ordinate Method (DOM) implemented in the OpenFOAM library. The radiation absorption/emission by the gases is modeled by either a Prescribed Global Radiant Fraction (PGRF) approach or a Weighted-Sum-of-Gray-Gases (WSGG) model (Ahmed and Trouvé (2021)). The PGRF approach is adopted in the present study in the flame region, while the absorption and emission in the plume region are calculated using Plank-mean absorption coefficients of CO_2 and H_2O. Convective heat transfer is modeled using empirical Nusselt number correlations developed for a wide range of Reynolds numbers under no blowing conditions (Churchill and Bernstein (1977)). The blowing effect due to outflowing volatiles is accounted for through a Couette flow approximation (Lautenberger and Fernandez-Pello (2009)). The vegetation bed drag force is modeled using a drag coefficient that has been determined experimentally for isolated particles in crossflow (Mueller (2012)). It should be noted that there might be some uncertainties in the choices of the drag coefficient and the heat transfer coefficient, and more elaborate models that represent actual vegetation patches may be required.

3. Results and Discussion

3.1. Bench-scale validation of the Lagrangian particle model

We present here validation results of the Lagrangian particle model introduced in section 2.1. Numerical simulations were performed for a single particle exposed to prescribed heating conditions. The spatial resolution inside the particle is 0.1 mm. The first set of simulations corresponds to the experiment of Anca-Couce et al. (2012) in which a micro-scale pine wood sample is exposed to a heating rate of 5 K/min, while the second set of simulations corresponds to the experiment of Kashiwagi *et al.* (1987) in which a 3.8 cm-thick white pine sample is exposed to an irradiation intensity of 40 kW/m^2. Both sets of experiments consider different nitrogen-air atmospheres and thereby evaluate the ability of the model to correctly describe the contributions of oxidative pyrolysis and char oxidation. Figure 2 shows that the model predictions in terms of particle mass evolution and spatial distributions of temperature inside the particle are in very good agreement with the experimental data at both micro- and bench-scales.

3.2. Flame scale simulations of quasi-infinite line fires

We now turn to LES of a quasi-infinite line fire over a surrogate vegetation bed corresponding to vertical cylinders made of the same pine wood material tested in the previous section. A computational domain with periodic boundary conditions on the lateral sides is used to mimic quasi-infinite line fires. As shown in Fig. 1, the computational domain has a cross-section of $40 \times 40\ m^2$. The vegetation bed of pine wood cylinders starts

at 2 m from the domain entrance and extends to a length of up to 150 m to achieve steadily-propagating line fires. Preliminary tests show that a shorter domain that extends to only 50 m is sufficient to achieve steadily-propagating plume dominated fires. The pine wood cylinders have a diameter of 2 mm and a total height of 0.4 m. The packing ratio and the surface-to-volume ratio of the vegetation bed are 0.005 and 2000 m^{-1}, respectively, which give a radiation absorption length-scale of about 0.4 m (Consalvi *et al.* (2002)). The initial moisture content of the fuel bed is 5%. The composition of the gaseous fuel produced from thermal and oxidative pyrolysis reactions is assumed to be $C_{3.4}H_{6.2}O_{2.5}$ with a heat of combustion of 15.6 MJ/kg and a global radiant fraction of 0.35. External wind velocity is imposed at the domain's west boundary using a power-law profile with a nominal velocity evaluated at an elevation of 2.0 m. Turbulence fluctuations are introduced corresponding to 10% intensity. Ignition is achieved using a hot plate placed underneath the fuel bed. The plate has a length of 0.5 m and a temperature of 1600 K and is activated for 5 seconds.

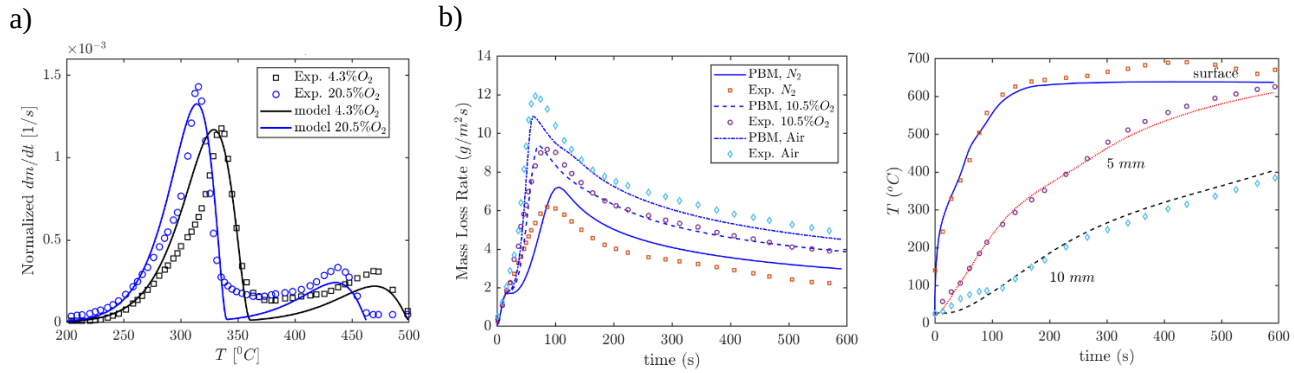

Figure 2- Series of validation tests of the Lagrangian particle model calibrated for pine wood: a) Mass loss rate in different atmospheres in micro-scale experiments taken from Anca-Couce et al. (2012) (5 K/min heating rate); b) Mass loss rate and surface/in-depth temperatures in different atmospheres in bench-scale experiments taken from Kashiwagi et al. (1987) (40 kW/m² irradiation).

The computational domain is divided into 4 regions with cells of equal size in the *x*- and *y*-directions: the grid resolution in the vegetation bed region from the ground to 0.8 m elevation is 0.1 m; the grid resolution in the flame region between 0.8 and 3 m elevation is 0.2 m; and the grid resolution in the plume region between 3 and 10 m elevation is 0.4 m; the grid resolution in the far-field region above 10 m elevation starts from 0.2 meters and is slowly decreased with elevation through stretching. The grid resolution in the span-wise direction (z-direction) is twice that in the *x*- and *y*-directions. The total number of grid cells is about 3.6 million with approximately 1.2 million particles. The time-step is controlled using a Courant–Friedrichs–Lewy condition and is of the order of ~0.001 s. The radiation field is updated every 5 time-steps using 144 solid angles. The simulations are carried out on a distributed-memory parallel cluster using Message Passing Interface (MPI) technique. A simulation of 60 seconds fire spread requires 96 hours using 160 processors (~15 kCPU hours).

We present here results from two cases corresponding to nominal wind speeds of 1.0 and 5.0 m/s. The corresponding Byram's convection number is 79 and 1.5, respectively. These two conditions are representative of the plume-dominated and wind-driven flame regimes. The corresponding values of the rate of spread (ROS) as predicted by the classical Rothermel model are 0.09 m/s and 0.34 m/s, respectively. A three-dimensional rendering of the simulated cases is presented in Fig. 3. The comparison between the left and right plots in Fig. 3 shows the expected differences between a low-wind-velocity flame that is vertical and develops above the vegetation bed and a high-wind-velocity flame that is horizontal, is attached to the ground and develops mostly within the vegetation bed. It also shows that the simulated fires feature a peak-and-trough structure (and a finger-like structure) similar to those observed in wildland fires.

Figure 4 shows the time evolution of the locations of the flame front (defined as the maximum *x*-location where the mixture fraction is greater than the stoichiometric mixture fraction), the back and front edges of the pyrolysis region (defined as the minimum and maximum *x*-locations where the pyrolysis reactions take non-zero values), and the smoldering front (defined as the maximum *x*-location where the char oxidation reaction takes non-zero values). The flame front location predicted by the Rothermel model is included for comparison. The simulation results show that the fireline intensity is 0.56 MW/m for the plume-dominated flame and 4.3 MW/m for the wind-driven flame; the corresponding values of the ROS are 0.082 and 0.52 m/s, respectively.

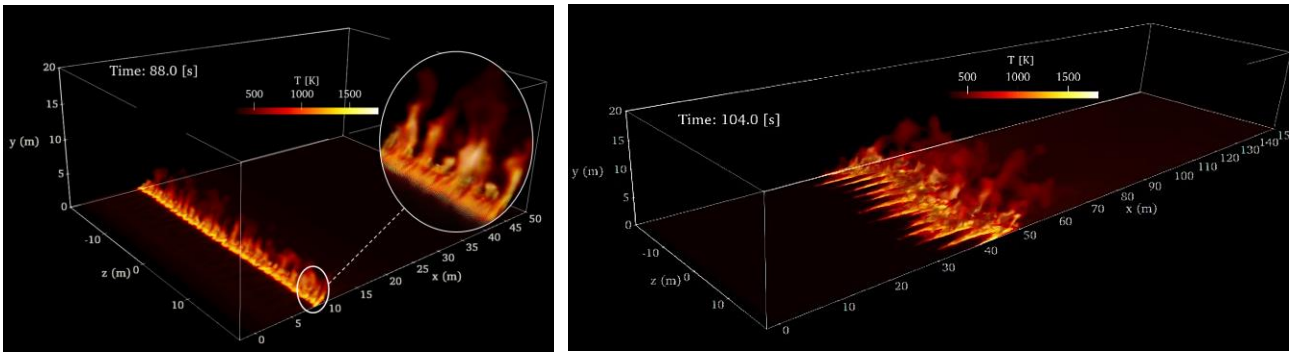

Figure 3- A 3D rendering of the structure of the line fire at a wind velocity of 1 m/s (left) and 5 m/s (right). The fire is visualized using an iso-volume of the region where the gas temperature is above 450 K.

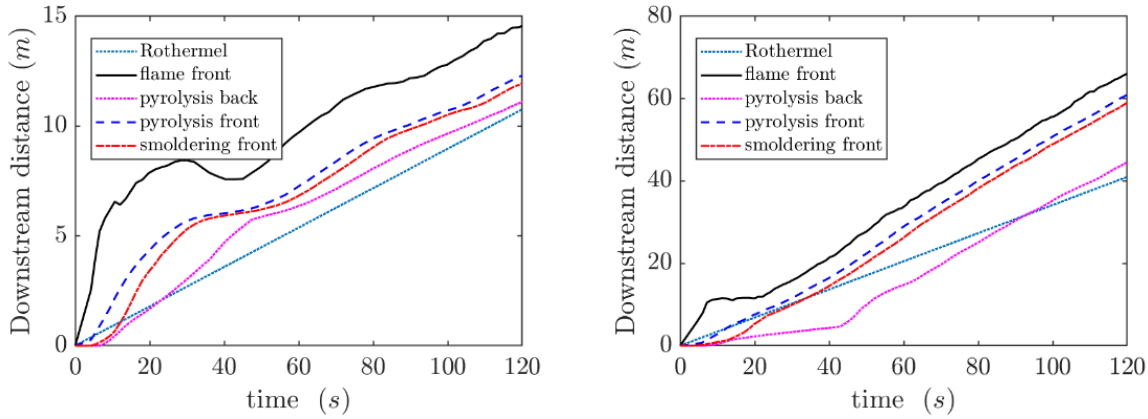

Figure 4- Time evolution of the position of the line fire at a wind velocity of 1 m/s (left) and 5 m/s (right).

4. Conclusion

This paper presents preliminary results obtained with a new modelling capability aimed at bringing fundamental information on the coupling between solid phase and gas phase processes that control the dynamics of flame spread in wildland fire problems. This modeling capability uses sub-millimetre-scale spatial resolution in the solid biomass solver and centimetre-scale spatial resolution in the gas phase solver and thereby resolves the exchanges of mass, momentum and heat associated with pyrolysis, combustion, radiation and flow at flame scales. The modeling capability is based on the OpenFOAM CFD library and an in-house Lagrangian model that treats particles as a one-dimensional porous medium and includes descriptions of thermal degradation processes occurring during both flaming and smoldering combustion.

Wildfire, risk metric, risk characterization, clustering, data-driven approach

Abstract

Fire authorities have started widely using operational fire simulations for effective wildfire management. These fire simulation outputs, when aggregated on a massive scale, create an opportunity to apply the evolving data-driven approach to closely estimate wildfire risks even without running computationally expensive simulations. We explored this opportunity in one of our previous works where we proposed a probability-based risk metric that gives a series of probability values for fire starting at a location under a given weather condition, to fall into different risk categories. The metric considered each fire start location as a unique entity, which could face scalability issues when the metric is used for a larger geographic area and make the metric hugely compute-intensive. As spatial clusters are significantly fewer than fire start locations, such spatial clusters may leverage the metric by reducing the computational requirements. In this work, we investigate if the spatial clustering of fire start locations based on historical fire areas can address the scalability issue without significantly compromising the accuracy of the metric.

1. Introduction

With an increased understanding of phenomena and advancements in computing technologies and observational sciences, natural disasters can be modeled and studied with greater detail (Razavi et al., 2012, Kaizer et al., 2015). Several wildfire models and tools have been developed that can estimate the wildfire behaviors and propagation accurately. Consequently, fire authorities have started widely using operational fire simulations for making better-informed decisions for wildfire management. These fire simulations when aggregated on a massive scale have created a unique opportunity to apply the evolving data-driven approach to closely estimate wildfire risks even without running a single computationally expensive simulation amidst the process being highly compute-intensive otherwise.

In one of our previous works (KC et al., 2022), we validated the application of the data-driven approach to facilitate rapid wildfire risk using a Bayesian probabilistic model. The wildfire risk metric detailed in the study gave a series of probability values for fire starting at a location under a given weather condition to fall into different risk categories. Despite the application of the model being computationally inexpensive, building the inference model was tedious and comparatively compute-intensive as each possible fire start location was considered a unique entity and the probability values conditioned on fire start location had to be calculated for each location. Such a consideration can face serious scalability issues when the geographical area undertaken for wildfire risk estimation is large and has a significantly large number of possible fire start locations. As such, in this work, we investigate if the spatial clustering based on historical data (the data used to build the inference model) could address this scalability issue of the risk metric without significantly compromising the accuracy of the metric. The concept of spatial clusters was envisioned to leverage the risk metric as the number of spatial clusters is significantly lower than the number of possible fire start locations in a geographical area, which could further reduce the overall computational requirements of the metric.

2. Methods and Procedures

2.1. Study Area

We chose Tasmania as the study area to validate the proposed idea of characterizing geographical regions into different risk zones using spatial clustering. The choice was made for several reasons - frequent occurrences of wildfires in the region, the prevalence of readily available high-quality land data sets for the region usable in operational wildfire simulation tools, and a well-studied and systematic grid configuration of fire start locations in the region (Service, 2019; KC et al., 2020a). Tasmania Fire Service (TFS) has maintained a grid configuration of 68,048 possible fire start locations at an interval of 1 km irrespective of land. Any start locations falling on the water bodies are shifted to the nearest land location.

2.2. Wildfire Simulation Tool – Spark

We used the Spark framework (Miller et al., 2015) to run wildfire simulations. Spark offers a flexible platform to simulate the progression of wildfires and their behaviors in different vegetation types. Each wildfire simulation in Spark requires input data sets for fire behavior models, maps of land classification, fuel load, topographical data sets, and weather data to produce output metrics such as total area burnt by fire, the intensity of the fire, and the number of urban cells burnt. All the calculations in Spark are parallelized using the OpenCL framework. All the simulations and their outputs used in this study are available in (KC et al., 2021).

2.3. Fire simulations inputs

We chose four weather inputs - temperature, relative humidity, wind speed, and wind direction for this study following the experimental setup of one of our previous works (KC et al., 2020a, KC et al., 2020b). The ranges for these inputs considered for spatial clustering for risk zones are listed in Table 1. Five equally spaced discrete values of each weather input (except wind direction) were considered along with four distinct directions (east, west, north, and south) for wind directions. Wildfires grow aggressively under weather conditions characterized by high values of wind speed, temperature, and low values of relative humidity when the wind is pushing the fire away from the water bodies. All other static inputs to fire simulations were used as per the configurations and records maintained by TFS and the Tasmanian Government (Tasmania, 2021). All fire simulations were run for five hours, and the cumulative areas burnt by fire in the period were reported as a simulation output.

Table 1 - Range and discretization of the factors for fire weather

Parameters	Range	Labels with Interval
Air Temperature	[10, 40]	Low (L) [10,18] Medium (M)(18, 33) High (H) [33, 40]
Relative Humidity	[10, 90]	Low (L) [70,90] Medium (M) (30, 70) High (H) [10, 30]
Wind Speed	[10,60]	Low (L) [10,23] Medium (M) (23,48) High (H) [48, 60]

2.4. Wildfire risk zones assignment using spatial clustering

We employed spatial clustering enabled by k-means clustering (Likas et al., 2003) based on the values of area burnt by fires starting at the location to assign a risk zone to the fire start location. It should be noted that for any fire start location closer to any water bodies, the information on the fire burnt areas should be interpreted carefully. For example, under a given weather condition, a fire starting at a location with a water body to its east with the wind driving the fire towards the east ceases immediately giving an unburnt landscape, while any fire starting at the same location with the wind driving the fire in other directions not east, may burn a significant area of land. To overcome such circumstances, we adapted the clustering mechanisms based on the mean and median values of fire burnt areas for all locations. The characteristics of the clusters obtained from clustering mechanisms were interpreted to label all fire start locations in Tasmania under three risk zones - low, medium, and high.

3. Experimental setting

3.1. Computing environment for wildfire simulations

All the wildfire simulations used for this study were run using the cloud-based frameworks as designed in (KC et al., 2020) over the cloud infrastructure of Nectar Cloud (Nectar, 2018) and Google Cloud (Google, 2020). Several types of Cloud instances were used as this study does not include any time-related evaluation metrics.

3.2. Evaluation metrics

We compared the accuracy of the proposed clusters-based risk zone characterization against that of the baseline McArthur Forest Fire Danger Index (FFDI) (McArthur, 1967) and our previously proposed risk metric. We also compared the proportions of underfits (predicted area less than the true values) and overfits (predicted area more than the true values). The comparison was done for three and two risk zones as initially explained in our previous work (KC et al., 2022).

4. Results and Discussion

4.1. Risk zones characterization using spatial clustering

Figure 1 shows all possible fire start locations in Tasmania characterized as low, medium, and high-risk areas as given by the spatial clustering. Out of 68,048 fire start locations, about 66 % of the locations were characterized as low-risk zones while the compositions for the medium and the high-risk zone stood at about 24 % and 10 % respectively. Most of the fire start locations closer to water bodies were labeled as low wildfire risk zones while the fire-starting inwards were labeled as high-risk zones. The high-risk zone had a range of average fire area between 3,900 and 10,400 hectares while the low-risk zone had the same range between 2 and 1,700 hectares.

4.2. Comparison against the FFDI and the risk metric

Table 2 shows the comparison of the cluster-based risk metric against the baseline FFDI and the previous wildfire risk metric for three and two risk categories. The accuracy of the cluster-based metric for three distinct risk categories stood at about 70 % while the same for the FFDI and the previous metric stood at about 55 % and 75 % respectively. Similarly, for two distinct risk categories, the numbers stood at about 85 %, 88 %, and 77 % for the cluster based, FFDI, and previous metric respectively. As expected, the accuracy of the cluster-based risk metric is less than that of the previous risk metric. However, the accuracy is still better than that of the McArthur FFDI and is not considerably far from the accuracy of the previous metric. The cluster-based risk metric had more proportion of underfits than the previous metric which could be due to a wider range of fire areas for the low-risk zone compared to the original range of low-risk zone in our previous metric. Conversely, the overfit proportion with the cluster-based metric is marginally less than in the previous metric, which could minimize the overestimation of resources during wildfire management.

In this investigative study, we were able to cut down the location-specific probability calculations from 68,048 to a clustering mechanism and a significantly fewer number of 3 (clusters). Such a provision in the risk metric could theoretically reduce the computational requirements of the calculations of location-specific probability values by a factor in thousands. The most important fact in the findings is that the change in the accuracy of the metric is a mere 8 % and 3 % for three and two distinct risk categories respectively. A comprise of less than 5 % in accuracy at such a scale for a significant reduction in the computational requirements outlines the spatial clustering as discussed in this paper to be a good alternative for fire start location risk characterization in the data-driven probability-based wildfire risk metric.

Table 2 - Performance comparison against the McArthur FFDI

Evaluation metrics	**Three Categories**			**Two Categories**		
	Cluster-based	Previous metric	McArthur FFDI	Cluster-based	Previous metric	McArthur FFDI
Accuracy	66.81	74.55	51.99	84.87	87.43	76.03
Underfits	24.9	15.88	38.87	13.31	10.27	13.49
Overfits	8.2	9.66	9.14	1.81	2.3	13.49

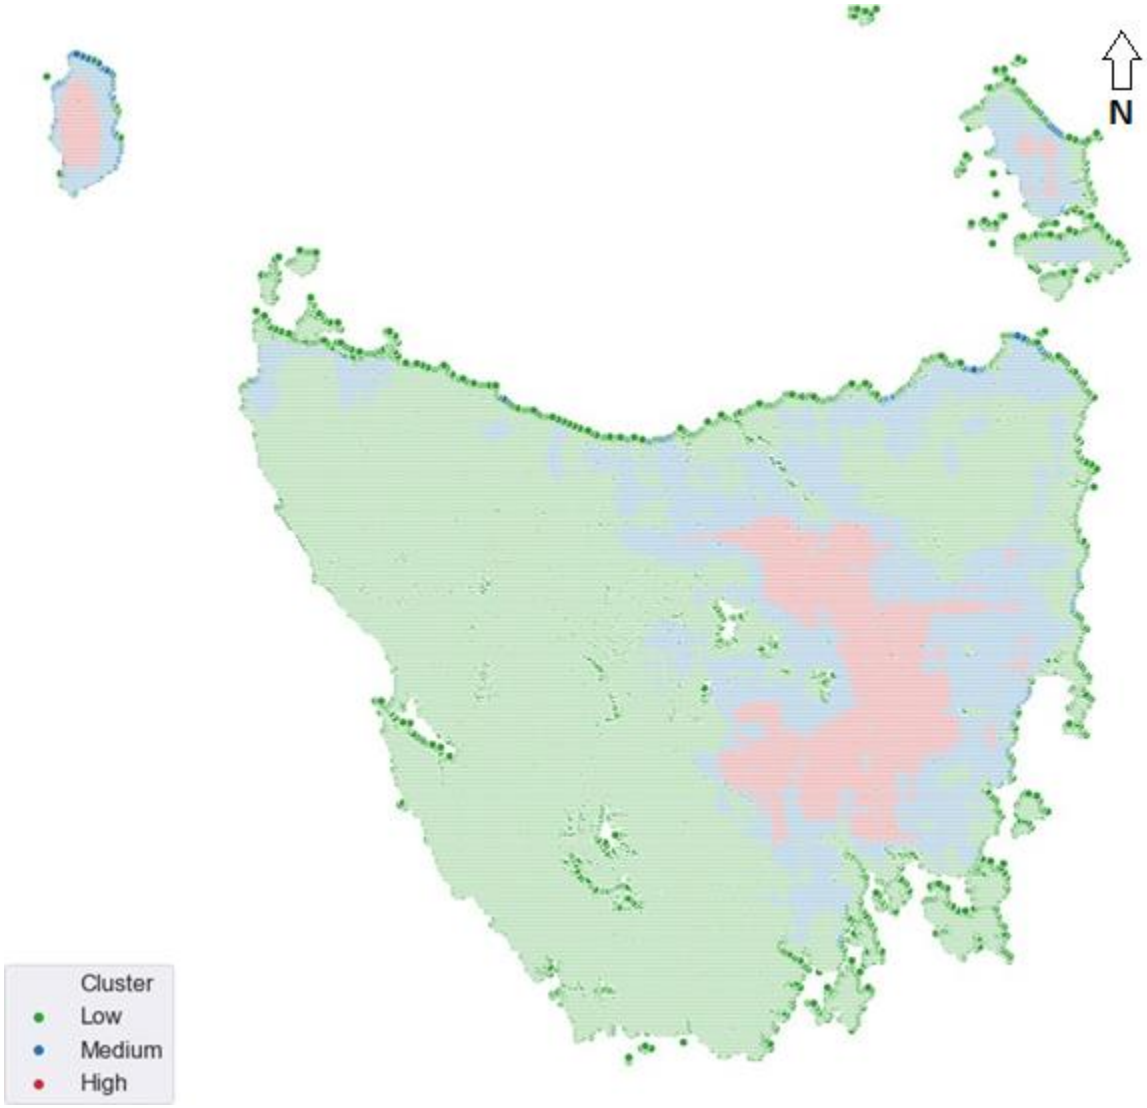

Figure 1 - Risk zone characterization of all possible fire start locations in Tasmania.

5. Conclusions and future research

The ever-evolving data-driven approach can be a computationally efficient alternative to rapidly estimate wildfire risks using several inference models. One such model was detailed in one of our previous works to build a probability-based risk metric, which was quite accurate in risk estimation. But the metric was subjected to scalability issues as each fire start location was considered a unique entity for location-related probability calculations. In this brief study, we investigated if spatial clustering could address the scalability issue of the metric without significantly compromising the accuracy of the metric. We found that the spatial clusters to characterize the risk of each start location could help solve the scalability issues by drastically reducing the number of calculations required by a theoretical factor in thousands with a mere compromise of about 5 % in accuracy. Such an inexpensive estimation of wildfire risk with a data-driven metric can help fire authorities to prioritize resource allocation and make better-informed decisions at various stages of fire emergencies to

minimize the possible losses. We expect future works to verify the numbers around the factor by which the computational requirements of the probability-based risk metric are poised to get reduced with spatial clustering. Similarly, the studies around the influence of the number of spatial clusters on the accuracy of the metric could also be studied further.

Keywords

Doppler lidar, fire dynamics, mobile Doppler lidar

Abstract

The California Fire Dynamics Study (CalFiDE) is a collaborative effort between the Chemical Sciences Laboratory (CSL) at National Oceanic and Atmospheric Administration (NOAA), Wildfire Interdisciplinary Research Center (WIRC) at San Jose State University (SJSU) and the University of Nevada Reno (UNR), to investigate wildfire dynamics in Northern California in late Summer and Fall 2022. Further information on the instrumentation and scope of this study can be found in the Valero et al. short paper. During CalFiDE, the contributing organizations plan to deploy four Doppler lidar systems in addition to infrared imaging and chemical measurements to quantify the fire dynamics and atmospheric coupling of large scale wildfires. These systems will be installed on a range of mobile platforms including; a Twin Otter aircraft, pickup trucks, and trailers. The mobile ground based installations allow researchers to rapidly deploy the systems to areas of interest during the study, while the aircraft installation will cover a larger range of spatial scales. Systems will operate in scanning modes to quantify 3D winds, vertical stares to resolve fine scale vertical velocities, and coordinated scans where the measurement volumes of nearby systems are overlapped to provide high resolution measurements of 3D winds. The coordinated scanning technique will be used to target fine scale features within fire plumes such as helical updrafts, counter-rotating vortices, and inflow/outflow dynamics. Collectively these lidar observations will provide validation data sets for simulated fire-generated winds.

1. Introduction

Doppler lidar is a proven technology to study atmospheric dynamics and recently has expanded its scope to measurements of wildfire dynamics (Charland et al. 2013, Lareau et al. 2017). These systems can provide measurements of 3D wind fields, boundary layer dynamics, and aerosol backscatter intensity allowing for characterization and ultimately a better understanding of the dynamics which govern wildfire behavior. Coupling Doppler lidars with mobile platforms enables measurements of both the spatial and temporal evolution of wildfires. Additionally, these mobile installations enable fast deployment of the lidar systems for time sensitive and dynamic deployments such as wildfires. Here we present the Doppler lidar instrumentation which will be deployed for the California Fire Dynamics Study (CalFiDE) in Northern California in August-September 2022. A total of four Doppler lidar systems will be deployed for this experiment consisting of; one aircraft based Doppler lidar, one ground based mobile Doppler lidar, and two ground based stationary Doppler lidars. The aircraft based measurement will primarily focus on profiling incoming winds and measuring plume structure. The ground based mobile system will perform continuous measurements while driving the periphery of the fire. The two ground based stationary systems will be located at the fire front to monitor fire generated winds.

Deploying multiple Doppler lidars within the same geographic region allows for more complete measurement coverage. Additionally, by overlapping measurement volumes from multiple Doppler systems, measurement resolution of 3D winds can be drastically improved (Newman et al. 2016, Choukulkar et al. 2017). This technique will allow for targeted measurements of smaller scale features such as entrainment/lateral mixing of core updrafts over wildfire fire plumes, and will help address the horizontal and vertical structure of the dynamics governing transport.

2. Aircraft Based System

2.1. Installation on the Twin Otter

Dynamics of the plume and wind fields surrounding the fires will be measured using a Doppler lidar installed on board the NOAA Twin Otter aircraft. The Doppler lidar is a microjoule-class pulsed Doppler lidar designed by the NOAA Chemical Sciences Laboratory (Schroeder et al. 2020). The lidar will provide measurements of turbulence intensity and 3-D winds around the fire as well as aerosol intensity backscatter distributions as seen in Figure 1b. The system has a maximum range of 7.2 km with a resolution of 60m. The lidar is paired with a partial hemispheric scanner which will extend out the port-aft window of the aircraft (Figure 1a) allowing for measurements below the aircraft as well as above the aircraft, which will be used when flying at low altitudes for in-situ sampling. The scanner can be operated in a scanning mode for measurements of 3-D wind fields around the fire. An inertial navigation system feeds back to the scanner for real-time stabilization of aircraft motion during the flight. This stabilization enables vertical stares and target tracking.

Ultimately these scanning data will provide the upstream wind profile impacting the plume development and thus important context for other plume rise observations. The motion compensated stares and target tracking will provide data on fine scale structures occurring within the plume and the surrounding flows.

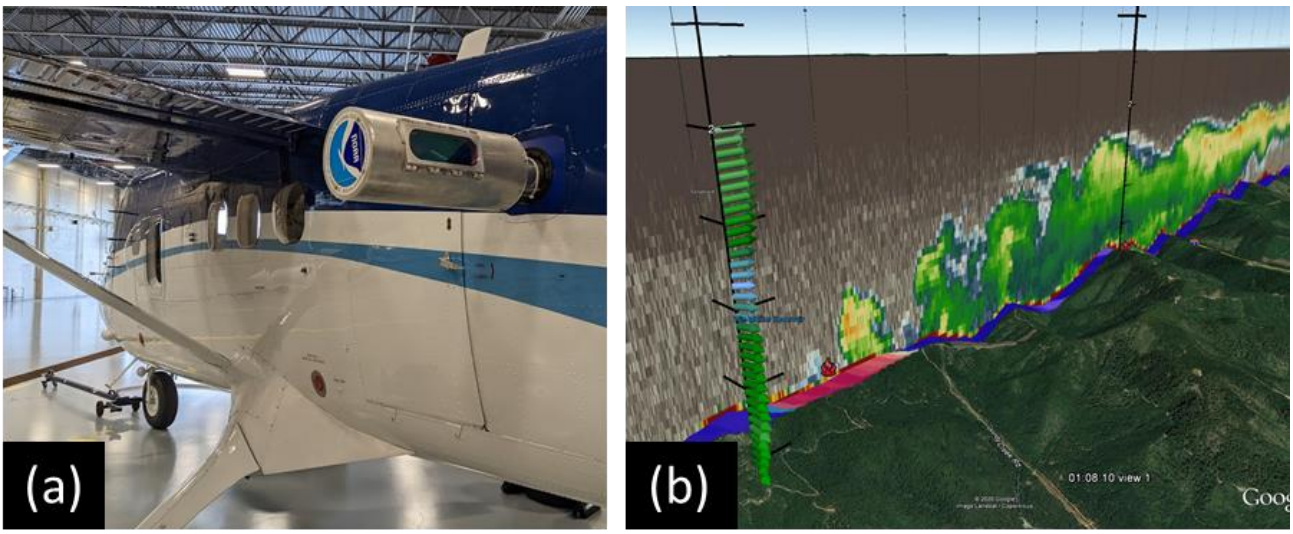

Figure 1- a) Doppler lidar scanner installed on the NOAA Twin Otter. b) Data from a wildland fire during a 2019 measurement campaign. The red area at the surface indicates the fire area. Arrows on the left axis indicate wind speed and direction. Coloration indicates aerosol backscatter intensity.

3. Ground Based Systems

In addition to the aircraft based Doppler lidar, there will be three ground based Doppler lidars deployed for the CalFiDE experiments. Fire-generated winds close to the fire front, including convergent and rotating inflow winds will be sampled by two Doppler lidar systems from UNR and SJSU. These data are critical for understanding the coupling of fire and atmospheric processes that can drive rapid fire spread and intensification.

A NOAA motion-stabilized truck-based lidar will measure convective boundary layer (CBL) depth, vertical velocity, and horizontal wind profiles proximal to the fire, but away from the fire front. The Doppler lidar installed in the NOAA F-250 pickup truck, known as the PickUp based Mobile Atmospheric Sounder (PUMAS), is shown in Figure 2. The Doppler lidar system itself has also been designed by the ARS group within NOAA CSL. The system has similar operating characteristics as the system installed on the Twin Otter, with an effective range of 7.2 km and 60m along path resolution. The unique characteristic of this system is it has two output beams. One beam is coupled with an optical wedge scanner for continuous scans for 3D wind fields. The second channel is directed vertically for continuous measurements of vertical velocities. The optical head of the lidar is housed in a motion stabilizing cradle which stabilizes the platform in both pitch and roll, enabling continuous measurements while the truck is underway.

Figure 2- Doppler lidar and scanner installed in the bed of an F-350 pickup truck.

4. 3-D Measurements of Wildfire Winds: Improved Scan Patterns and Multi-Lidar Systems

The NOAA airborne Doppler lidar system has previously flown on the Twin Otter for the 2019 FIREX-AQ campaign to study the impact of fires on air quality and climate. During this campaign, the system was outfitted with an optical wedge scanner which allowed for scans and motion compensated vertical stares below the aircraft, but did not allow for more complex scan geometries or upward looking measurements. The partial hemispheric scanner which will be deployed for CalFiDE was developed in response to this need for improved scanning strategies and coordinated scans between multiple lidar systems which was noted in the FIREX-AQ data.

The wildfires sampled from the Twin Otter during FIREX-AQ were done with a single Doppler lidar. While the vertical stare captured the spatial distribution of updrafts/downdrafts within a wildfire, the conical scan attempted to characterize the inflow/outflow structure near the fire front. Analysis of the data collected during FIREX-AQ revealed that features central to transport, such as rigorous updrafts centered over wildfire hotspots, offered an opportunity to study the structural variability of these updrafts and dynamics associated with lateral mixing during parcel ascent.

A key shortcoming of this dataset, however, was the lack of temporal information related to the evolution of the updraft as well as the rather narrow observation window associated with beam slice intersecting the updrafts/downdrafts along track. Measurements which were not completely centered on core updrafts/downdrafts made quantifying their role in transport challenging, and thus has led to the development of new and improved strategies that are planned for CalFiDE.

To address the temporal evolution of hotspots and the updrafts therein, an inverted triangle, either vertically pointing or off-angle, will be used to target specific core features over areas of high FRP as the Twin Otter flies within range of the fire front. The inverted triangle will have a denser cluster of points near the base of the updraft which will widen with height. Additionally, two ground-based mobile systems – one upwind and one downwind – will be used in conjunction with the inverted triangle scan to map out the 3-D structure in order to quantify the spatiotemporal characteristics and associated dynamics. Figure 3 shows a proposed configuration of the three Doppler lidar systems that would be coordinating in real-time, such that the beams from the respective Doppler lidar systems will intersect to construct the 3-D wind vector in a gridded format. The idea is not only to quantify the spatiotemporal characteristics over wildfires, but to determine the vortical structure associated with counter-rotating vortices at the flanks of updrafts, whether there is a helical component associated with certain core updraft features, and how the inflow/outflow dynamics assists in the spatial structure and temporal evolution of the most rigorous updrafts.

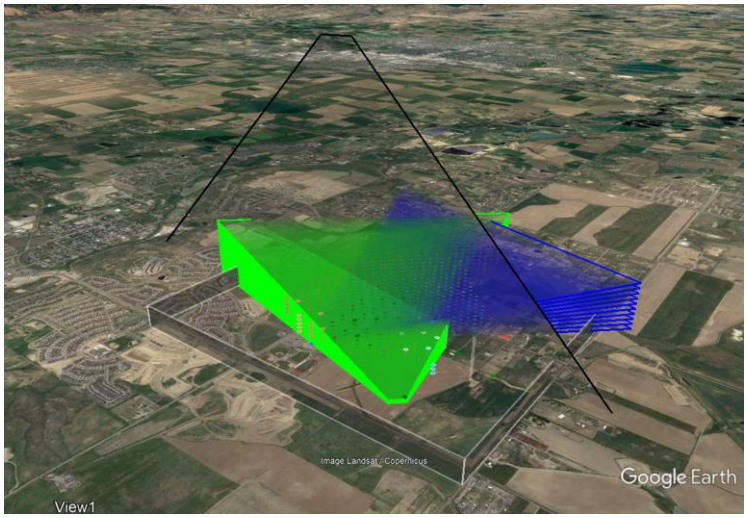

Figure 3- Demonstration of scan geometry for CalFiDE multi-Doppler coordinated scans.

Abstract

Portugal as a member of the European Union (EU) follows the air quality legislation regulated by Directive 2008/50/EC that states that "Member States shall ensure that timely information about actual or predicted exceedances of alert thresholds, and any information threshold is provided to the public". The southern European countries, have biogenic contributions, mainly resulting from the long-distance transport of particulate matter, originating in arid regions, and from large forest fires, whose pollutants loads cannot be imposed limits. These sources lead to an additional contribution of atmospheric pollutants mainly during the spring and summer season. Climate change is increasing the vulnerability of the environment to extreme events, such as those that enhance the likelihood of forest fires. Due to the predicted increase in temperatures, the decrease in precipitation and humidity, an increase in the frequency and intensity of forest fires is expected, namely in regions of the Mediterranean basin, as is the case of Portugal. Monitoring the concentration of particles (PM10 and PM2.5) in the network of air quality stations can be a way of detecting the dispersion of smoke and giving possible alerts to affected populations. The analysis of PM10 and PM2.5 of the air quality network stations, from 2010 to 2020 only for June to October, shows very high concentration values that are associated with to the periods of forest fires. These data were analysed for all seasons by districts, considering a daily average. The daily concentration average was performed by including the observations on the period spanning from two days before and after the registration of a fire with daily burned area larger than 500 ha by district. Trajectory analysis was performed to confirm the origin of the particles observed at the stations. It was verified that, for the period 2010-2020, the daily average value of PM10 concentration is variable and generally increases from the day before to the day of the event by an average percentage of 26%. This variation depends on the proximity of the forest fire, the burned area as an indication of its strength, the stability of the atmosphere and the height of the boundary layer. During the summer season, dust episodes also occur, originating in the Sahara, especially in the southern regions of Portugal, increasing the observed concentration of PM10 and PM2.5 particles. In this way, for the summer period, the days with high values of PM10 and PM2.5 that could have been originated by dust particles, with larger dimensions, were identified and separated from those which referred to smoke particles from forest fires, usually smaller. For this purpose, the relationship between the concentrations of PM2.5 in relation to PM10, in the studied period, was taken in to account. For the large fires of 2017, a more detailed characterization of these features was made, analysing the optical thickness of the aerosols and the Angstrom exponent of the VIIRS radiometer on board the Suomi NPP satellite.

1. Introduction

Climate change is increasing the vulnerability of the environment to extreme events, which happen more frequently, namely those likely to promote forest fires (EEA, 2021). Due to the expected increase in temperatures (Andrade et al., 2014, 2015) and decrease in precipitation and humidity, it is expected an increase in the frequency and intensity of forest fires in certain regions of the Mediterranean basin, considered climatic hotspots, such as Portugal. It is also expected an increase in the duration of the current forest fire season, revealed by the analysis of the last 30 years. Furthermore, the fire regime is expected to change almost everywhere in Europe, southern countries being the ones that concentrate most of the annual burned area (San-Miguel-Ayanz et al, 2018). In 2017 the burnt area in Portugal was 539921 ha, which represented 498% of the average of the

previous decennium. Indeed, the wildfires that occurred in 2017 in Portugal, and more recently in 2019 in Australia, have raised awareness towards the need for further studies on the many relevant impacts of wildfires.

Biomass burning is an important source of gases and particulate matters (PM) that can significantly change local, regional and global atmospheric chemistry, with impact on air quality, which can affect human health (Crutzen & Andreae, 1990). Smoke emissions from forest fires present a highly variable composition between wildfires and with time for the same wildfire, leading to different particle sizes distribution, particle light absorption, and spectral dependence on absorption based on the type of fuel, its amount, burning characteristics, and weather conditions (Dubovik, O et al, 2002; Shi, S. et al, 2019). The released particles and gases can affect the tropospheric chemistry and cause several respiratory and cardiovascular diseases (Cardoso de Mendonça et al., 2006; Reid et al., 2019). Exposure to wildfires pollutants has been associated with an increase in respiratory and cardiovascular hospitalizations (Cardoso de Mendonça et al. 2006; Finlay et al. 2012). Therefore, it is important to monitor the concentration of particles in the ambient air. Monitoring can be done by warnings based on observations of air quality network stations and complemented by observations of the aerosols optical thickness (AOD) for wavelength between 400 to 800 nm, together with the Angstrom exponent, which indicates the particles size distribution in the air column, or with the aerosol index (AI), which gives information on absorbent aerosols. Both aerosols may present high values of AOD (for 500nm), but with large differences in the Angstrom exponent (dust aerosol is characterized by low values, around 0.5, while forest burning aerosols are characterized by high values often higher than 1.5). It is known that the main absorbing aerosols in the atmosphere are dust and aerosols resulting from forest burning. In the great fires of June 17th and October 15th 2017 in Portugal, the coexistence of these two types of aerosols was observed.

2. Material and Methods

2.1. Study Data

In this study, PM_{10} and $PM_{2.5}$($\mu g/m^3$) observational data from surface air quality monitoring stations, was used, from June 2010 to October 2020. These stations are the responsibility of the Portuguese Environment Agency (APA) in coordination with the corresponding Commission for Coordination and Regional Development (CCDR). The data measured continuously at the various stations are reported, in near real time, and made available to the public by QUALAR online database (https://qualar.apambiente.pt/indices).

Back and forward trajectory performed by HYSPLIT Model, (https://www.ready.noaa.gov/hypub-bin/trajtype.pl)

Daily values of burned area in Portugal, by district, were accessed from June to October, 2010 to 2020. The days in which the daily burned area, for each of the districts, exceeded 500 ha were identified.

Optical thickness data from OLCI-SENTINEL3A, with the XBAER algorithm (product C3S from Copernicus) and satellite Angstrom exponent from VIIRS (NOAA) data were used for June 16th to 20th, 2017 and October 14th to 17th, 2017.

Two Doppler weather radars from the IPMA network were accessed to analyze several fire plumes as they were being tracked near ground air quality stations.

2.2. Methods

All PM_{10} and $PM_{2.5}$ concentration values were analyzed for forest fires with a burned area larger than 500ha. For each case, the period spanning from two days before the fire occurrence to two days after the fire suppression was considered. The variation of the daily average of PM_{10} between the days before and after was calculated. For stations where a positive variation was observed, the back trajectory was computed for 24h and 48h in order to verify the origin of the particles in order to confirm the areas they came. In the large fires of 2017, data from AOD 550nm and Angstrom exponent of aerosols were also used, the latter mainly for splitting dust and smoke from forest fires. Data from the IPMA radar network was also used to monitor smoke plumes from the large forest fires that occurred in Portugal in 2017.

One of the radars, Arouca/Pico do Gralheiro (A/PG), is a dual polarization (DP) system located northeast of the observed plumes, with a beam around 1100 m a.m.s.l.(above mean sea level), while the other, Coruche/Cruz do

Leão (C/CL), is a single polarization system located to the southeast of the plumes, with a beam around 200 m a.m.s.l.. Low-level plane position indicators of reflectivity (PPZ) were extracted every 10 min from the A/PG radar and used to identify fire plume patterns in the case of high PM10 values observed at the air quality station Ilhavo (number 2018) from 20UTC of 15th October to 01UTC of 16th October 2017, the radar beam being at approximately 800 m a.g.l. (above ground level). PPZs were also used to identify fire plume patterns in the case of observation of PM_{10} at station Ervedeira (number 2019) and station Montemor-o-Velho (number 2022), but in this case the C/CL radar was used, the beam being at approximately 400 m a.g.l., due to the lower altitude of the radar.

As fires intensify, heat flux increases combustion and buoyancy, and more pyrometeors are transported upward, according to Jones et al, (2010). Thus, the magnitude of low-level reflectivity observed near the fire site is a good indicator of the overall intensity of strong convective processes caused by fire. A/PG radar was additionally used to verify if the suspected plume patterns were, in fact, originating from fire activity, based in the magnitude of the correlation coefficient that is processed in DP mode (Balakrishnan et al. (1990), Pinto et al. (2022)). Within the range of 100 km, the spatial resolution of the radar observations was 1 km or better. The evolution of plume patterns observed in the low-level PPZ was followed in the vicinity of ground stations as shown on a georeferenced map. A comparison was made between ground station air quality observations and low-level radar observations. Every 10 min, the magnitude of the reflectivity value of the plume that was being observed was estimated, at each moment, in an area of 3 x 3 km^2 (in polar coordinates). The center of this area was selected to be 5 km upstream from the ground station in relation to the identified buoyancy source and for each instant an average reflectivity was derived.

3. Results and Discussion

The variation in PM_{10} concentration between the day before and the day of the forest fire, for the stations whose back trajectory indicated this origin, was on average, 26%, ranging between 22% and 31% for the 2010-2020 period.

The 2017 forest fire season in Portugal was considered as a complex of extreme forest fire events, with two noticeable events, one in June and the other in October, not only because of the amount of total area burned, but because of the high number of casualties (more then 100 in two days). We studied, in detail, the behavior of the air quality stations for these two events. These events were also characterized by having dust events associated.

During the forest fires episodes, the proportion between $PM_{2.5}$ and PM_{10} varies in the sense of increasing the percentage of $PM_{2.5}$, indicating an increase of smaller particles, with greater damage to health. In the case of the large fires in Pedrogão Grande, 17th to 22th of June 2017, Figure 1 shows this ratio for stations 3096-Chamusca, 3089-Mem Martins, 2020-Fundão. By analyzing the back trajectory for the Fundão station (2020) it appears that on the 16th, 20th and 21th, the concentration of PM were due to dust, coinciding with the periods in which the $PM_{2.5}/PM_{10}$ values were lower, while on the 18th and 19th they were due to large fires in the central region of Portugal, with higher values of the $PM_{2.5}/PM_{10}$ ratio, Figure1. In the intermediate periods, a mixing of particles may have occurred, with intermediate values of the ratio. With the same methodology applied to Chamusca (3096, in blue in Figure 1) it was confirmed that the concentration of particles was essentially due to the forest fires in Pedrogão Grande and Góis on the 17th to 19th of June and the variation in the type of particles from the afternoon of the 19th of June.

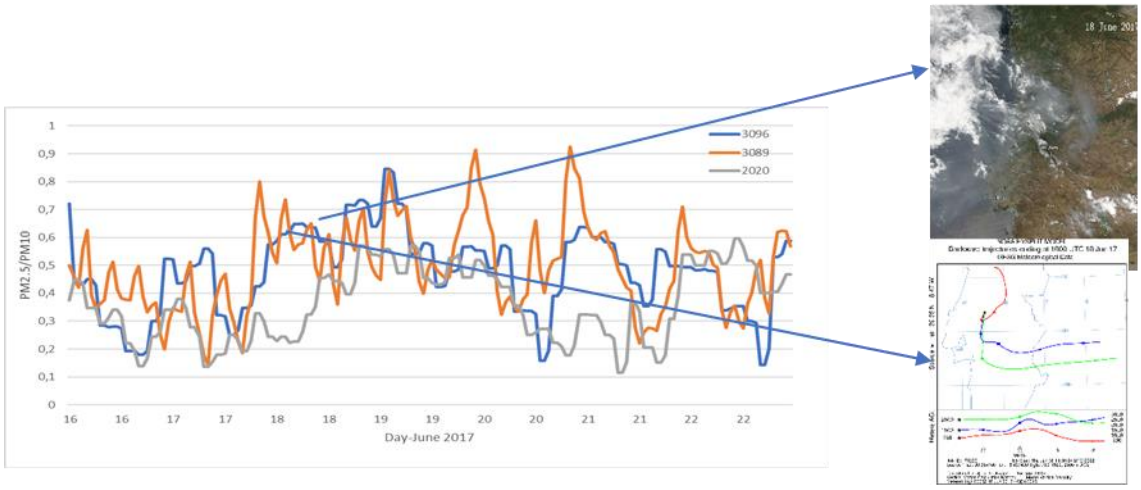

Figure 1- Hourly variation of the ratio between $PM_{2.5}$ and PM_{10} on three air quality monitoring stations (3096-Chamusca, 3089-Mem Martins, 2020-Fundão) the 16th to 22th of June 2017. Satellite image (MODIS/VIIRS) and backtrajectory for Chamusca Station for 18th June 2017.

Optical thicknesses of aerosols at 550nm allow a good identification of regions affected by smoke particles from fires (Figure **2**), when available.

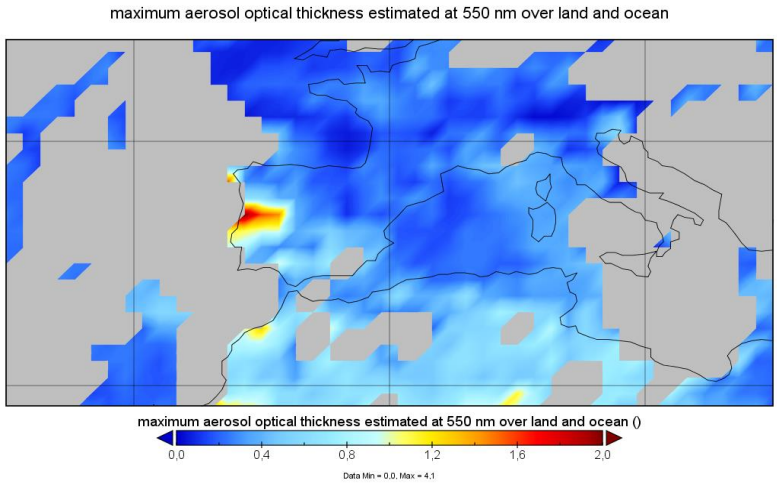

Figure 2- Maximum aerosol optical thickness estimated at 550nm on 18th June 2017(C3S from Copernicus)

Combining the optical thickness of the aerosols and the variation of the PM_{10} concentration (negative, in the direction of decrease, above 50% of variation, and positive with a variation above 50%), monitoring maps are obtained. These maps can allow the monitoring of the most serious episodes.

During the great fires of October, several stations had $PM_{2.5}$ observation´s gaps, especially the stations in the North and Central region of Portugal, where due to the location of forest fires and the predominant south-north flow will have been the most affected

In the wildfire events of October, the stations with PM_{10} observation located in the north and central region of Portugal were analyzed, jointly with the analysis of trajectories, dispersion of the point of fire and mainly with the analysis of smoke by radar observation. In the case of Ilhavo station (number 2018), two rapid increases in PM_{10} concentration were observed, one from 21UTC on the 15th to 2 UTC on the 16th and the other on the 17th of October, Figure 3. For the first PM_{10} observation period, low-level radar observations were analyzed every

10 minutes, monitoring the advection of the smoke plume from the forest fire, Figure 4. In the second period, no smoke was identified by the radar, being observed, by satellite, a mass of dust driven by a strong southerly flow.

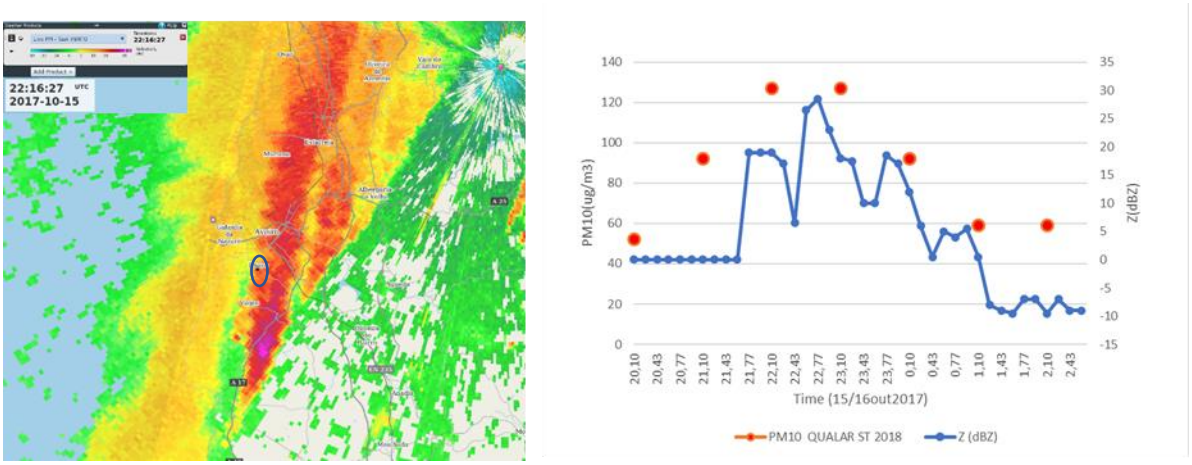

Figure 4- Low-level PPZ radar observation in an area matrix 3X3km² at 22:16 UTC of 15thOctober. The Ilhavo station is marked with a circle, (right). Hourly variation of PM_{10}, (red), on air quality monitoring station 2018 (Ilhavo), on October 15th at 20:00UTC to 16th at 2:00UTC, 2017, and low-level PPZ radar observation every 10 minutes in an area matrix 3X3km² between 15that 20:06 UTC and 16th at 2:36 UTC October (blue), (left)

4. Future Work

Combining multiple sources of information (RADAR reflectivity observations; surface air quality observations; AOD from remote sensors observations on board of satellite) we can early warn local authorities for atmospheric pollution events, caused by forest fires, in order to prevent population health issues.

As future work, this study should be extended to other severe forest fire events in Portugal, and it will also be necessary to study how to combine, operationally, all the existing information from observation.

Fire Weather, Adaptation, Fire Danger Rating Systems, Preparedness

Abstract

The Canadian Fire Weather Index (FWI) System has its origins in early Canadian fire research and resultant hazard rating systems dating back to the 1930s. Today the FWI System is one cornerstone of the larger Canadian Forest Fire Danger Rating System (CFFDRS), which is comprised of several sub-systems, each evaluating fire potential at different scales and resolutions. The other major sub-system in the CFFDRS is the Fire Behaviour Prediction (FBP) System, designed to give quantitative predictions of fire behaviour in specific situations under constant conditions. Whereas the FBP System requires information on fuels, weather and landscape features to calculate potential fire behaviour on variable timescales, the FWI System provides a set of six daily outputs derived from weather observations, each indicative of different aspects of potential fire activity useful in fire management planning.

The basic design of the FWI System and simple inputs has made it a popular choice for adaptation in other regions. The System outputs can be readily adapted to act as the foundation for a new fire danger rating system or as an enhancement to an existing system. Research exploring the utility of the FWI System for characterizing fire activity in a region often focus on the final indicator, the FWI (not to be confused with the System namesake). While the FWI (the indicator) is a highly useful indicator of potential fire intensity, it is not necessarily the most appropriate indicator from the System to capture specific fire management needs. In adapting the FWI System to a new jurisdiction to support fire management, each indicator from the System should be evaluated on how it informs specific fire management needs in a region; that is, which of the System's six outputs relate most closely to important aspects of fire activity. Furthermore, it is important to understand how the standard Canadian pine fuel type might differ from those in the region in question.

This paper will review examples of how each of the indicators of the FWI System are used in operational fire management planning in Canada, and present Canadian Forest Service (CFS) experience in adapting the FWI System to other jurisdictions. We will evaluate each of the six components of the FWI System and their use to describe different aspects of fire potential in the wildland fire environment. While grounding this discussion in the way the System outputs are used to inform operational fire management decision-makers in Canada, we will also discuss their potential adaptation to support fire management planning in other locations. We will touch on the question of adaptation of the System to different fuels, and how these might affect the interpretation of each component and, how these considerations can lay the foundation to building local fire behaviour predictors.

While there is no set recipe for adaptation of the FWI System to a new region, understanding what each element of the wildland fire environment the FWI System outputs are designed to track is a critical first step.

The Canadian Forest Fire Danger Rating System (CFFDRS) is the national system for fire danger rating used throughout Canada. The two main sub-systems of the CFFDRS are the Fire Weather Index (FWI) System and Fire Behaviour Prediction (FBP) System. The FWI System uses daily weather observations to create six indicators, each capturing different aspects of potential fire activity important in daily fire management planning. The simple design and use in Canadian fire management planning has made the FWI System a popular choice for adaptation to other regions. When adapting the FWI System to a new jurisdiction, each of its six

indicators should be calibrated to the regional landscape and evaluated with respect to how each can inform local fire management planning. In this paper, we discuss the fire management structure in Canada, the development of the FWI System and its outputs, describe fire management decision-aid tools and provide examples of the use and adaptation of each components of the FWI System to other regions.

1. Fire management and danger rating in Canada

Wildland fire management in Canada is largely the responsibility of its ten provinces and three territories, each organizing and operating a fire management agency independent of each other, conforming to policies and regulations specific to their jurisdictions. However, they engage collectively in risk-sharing by agreeing to share suppression resources during periods of heightened activity that overload the resource capacity in a specific geographic area. To support preparedness and response planning each agency relies upon its own internal fire intelligence capacity, running their own fire weather monitoring networks and fire danger calculation activities. The CFFDRS provides a 'common language' for characterizing potential fire activity in the wildland environment across the country; however, local interpretation and decision-making tools are as unique as each region.

2. International evaluations and adaptations

When considering the FWI System for adaptation to other regions outside Canada, a variety of methods have been used to evaluate its effectiveness and to adapt the System. Such studies tend to focus on evaluating the final component of the FWI System, also known as the Fire Weather Index (FWI). While the FWI component is a good indicator of general fire danger, evaluating the association between FWI and information about different aspects of the fire environment (e.g., number of fires, ignition date, weather or total area burned) may not identify the most useful relationships between different aspects of fire activity and the FWI System as a whole. Other components of the FWI System may be better suited to inform specific fire management decision-making needs (Table 1). When adapting the FWI System to new regions, the evaluation of how each indicator best reflect the different aspects of fire potential is an important first step in generating effective FWI System based decision-aids.

Table 1, Examples of each Fire Weather Index System indicator and their fire management decision-aid associations.

FWI indicator	Physical association	Primary association in fire management	Examples of fire management associations
FFMC	Forest litter moisture	Flaming ignition sustainability	- Human-caused fire occurrence - Spot fire ignition - Vigor of surface spread
DMC	- Duff moisture (F-layer) - Medium woody debris	Lightning fire ignition	- Depth of burn
DC	- Deep duff moisture (H-layer) - Logs, large woody debris	Sustained smouldering	- Depth of burn - Lightning fire holdover - Fuel consumption - Live moisture deficit - Suppression difficulty
ISI	Fire Spread	Fire spread rate	- Crown fire potential
BUI	Surface fuel moisture levels	Surface fuel consumption	- Depth of burn - Sustained smouldering - Fire intensity
FWI	Fire intensity	Suppression resource effectiveness	- Public facing assessment of fire danger - Flame size

Understandably, methods of evaluation and adaptation are dependent on a number of factors; analysis is constrained by data availability, such as historical weather data and accurate area burned datasets. While field campaigns can add invaluable information in the adaptation of the System, these are often limited due to resource or timeliness constraints. Evaluation may start as a data driven exercise and be re-evaluated as more

historical data and statistical methods for classification become available (e.g., de Jong et al., 2016, Dentoni, 2015). Strategies of calibrating the FWI System components over very different landscapes while maintaining a consistent calibration have been developed by the European Forest Fire Information (EFFIS) System by introducing additional layers to provide context (Camia and Amatulli, 2010). Others may have additional information from field data to examine the relationship between the different FWI System indicators and regional fuel composition (e.g., de Groot et al., 2007, Dimitrakopoulos et al., 2011, Fogarty et al., 1998) allowing local adaptations to be tailored to the specific effects of weather on forest floor fuel types. Re-evaluating each FWI System component after initial adaptation as data is collected can lead to better understanding and evaluation of each indicators use as a decision-aid. Fire management agencies in Canada have been developing the expert knowledge to use the FWI System over several decades and research continues to provide FWI System indicators and classification methods to reflect the changing demands in wildland fire management (Hanes et al., 2021).

3. The outputs of the FWI System and their use

The FWI System contains six indicators, calculated daily based on solar noon observations of temperature, relative humidity, wind speed and 24hr accumulated precipitation (Figure 1). The first three indicators of the FWI System are the moisture codes; they act as a bookkeeping system to track moisture in dead fuels in different layers of the forest floor. The three moisture codes are then used to calculate three fire behaviour indexes, which are general indicators of potential fire spread, fuel availability and fire intensity. The outputs of all indicators are on an increasing numerical scale, where higher numbers signify higher danger during the peak burning period of the day, generally late afternoon.

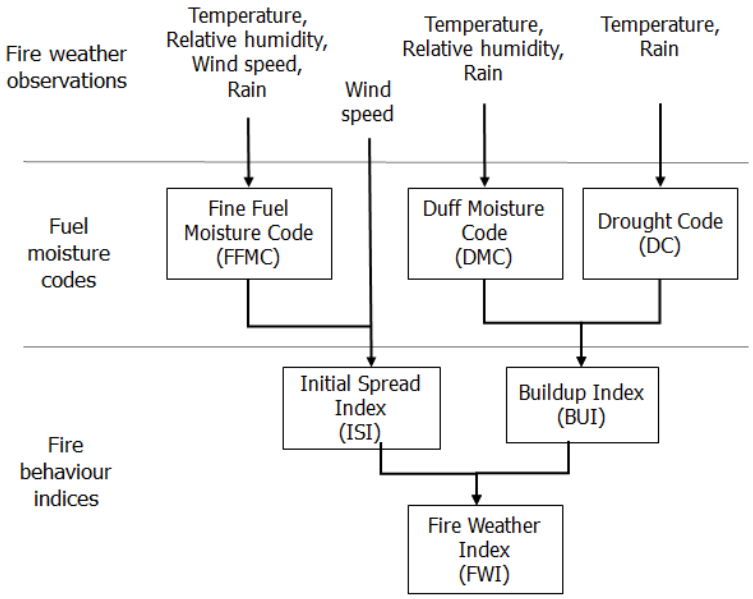

Figure 1: Structure of the Canadian Fire Weather Index (FWI) System.

The first of the three moisture codes in the FWI System is the Fine Fuel Moisture Code (FFMC), which tracks the moisture content of the fine dead fuels on the forest floor. Moisture content in fine fuels is a primary factor controlling the sustainability of a flaming ignition in fuel beds. The FFMC therefore plays a role as an indicator of the readiness of forest floor fine fuels to sustain flaming ignition; its utility in this regard has been demonstrated in many fuel types (e.g. Beverly and Wotton 2007). From the perspective of fire management agencies, this makes the FFMC well suited as an indicator of the day-to-day changes in the number of human-caused fires expected in regions with human activity in the wildland (this has been demonstrated throughout different fuel types in Canada). When the FWI System has been adapted to other regions, the relationship between FFMC and sustainable flaming ignition has been calibrated to other fuel types. For example, de Groot et al. (2005) calibrated dead grass fuel with FFMC using fuel moisture measurements and small-scale ignition

field experiments in three grassland sites of Indonesia. In this case, dead grass was chosen as the fuel type as it was a common fuel source and a fuel of concern for fire managers in Indonesia.

The Duff Moisture Code (DMC) tracks the moisture content in the loosely packed layer of decaying dead organic fuel directly beneath the fine litter (FFMC) layer. Moisture content in organic layers has been shown in both lab and field-based studies to indicate the sustainability of smouldering combustion; tracking moisture in this layer is of value for users looking to estimate the potential for consumption in this layer (i.e., depth of burning) or to estimate the ability of ignitions to 'holdover'. In day-to-day fire management planning in Canada, the DMC is used to indicate the potential for ignitions from lightning, (a significant cause of wildfires throughout most of the country).

The Drought Code (DC), tracks the compact decaying organic material deep (typically >10cm deep) in the forest floor, often associated with the humus layer of the organic horizon. While such deep layers are not always present throughout mature upland pine forests in Canada, tracking the impacts of drought is considered an important part of understanding conditions in the wildland fire environment. Operationally the DC is considered in lightning fire ignition and when examining the potential for deep burning and requirements for extended periods of suppression resource utilization for mop-up and the mitigation of the risk of restarts. In Canada, the DC has been studied in fen and bog peatlands to explore a relationship with the water table and volumetric moisture content (Waddington 2012). In South East Asia fire danger rating system applications, the DC has been calibrated to track drought in peatlands where fire activity has caused major haze disasters affecting health and industry (Field et al. 2004). In other more arid regions without deep organic layers the DC might have most utility as an indicator of drought effects on live fuel moisture.

The three moisture codes: FFMC, DMC, and DC are inputs used to calculate the three remaining FWI System indicators, which reflect different aspects of fire behaviour. The Initial Spread Index (ISI) provides an indication of the potential rate of spread of a fire by capturing the interaction between the dryness of fine dead surface fuels (which carry flaming) and the wind. The FBP System provides explicit characterization of the relationships between spread rate and ISI over a wide range of fuel types found in Canada; ISI is a good indicator of spread in all these types. In other regions, where grass fuel type is the main concern for wildland fire activity, the ISI has been adapted as an indicator for general fire intensity. For example, fire management guidelines in Indonesia indicate difficulty of wildfire control (and suppression resource effectiveness) as associated with the ISI (de Groot et al., 2007).

The Build-Up Index (BUI) is a weighted average of the DMC and DC and is a general indicator of the potential heavier fuel available for consumption by a passing fire. The FBP System uses the BUI as the primary variable influencing surface fuel consumption across a broad range of forest types. Because of this association with surface fuel consumption, as a daily planning aid the BUI is used to inform fire managers about the potential for increased fire intensity due to the long-term dryness of surface fuels. Because it provides a weighted indication of moisture content throughout the forest floor, it can also be used as a general indicator of potential below surface smoldering.

The final primary fire behaviour output of the FWI System is the Fire Weather Index (FWI). In the scaled, unitless world of the FWI System the FWI is an expression of Byram's fireline intensity concept, capturing the interaction between spread rate (ISI) and fuel consumption (BUI) in a relative way (Van Wagner 1987). In Canada, many agencies use the FWI when communicating 'fire danger levels' to the public, because it combines information from other parts of the system on ignition potential, spread potential, and the difficulty of suppression of a fire, into a single number. However, in operational fire management planning, the different elements of the FWI System that more directly influence each of those separate aspects of fire activity are used directly.

The FWI System remains an important tool for daily planning at the regional scale, providing fire management personnel an overview of potential fire activity over large landscapes. Increased fire activity, which increases demands for resources along with changing priorities in managing fire in Canadian forests has made decision-making in wildland fire planning increasingly challenging across the country. To support these complex demands and new technologies, updates to the CFFDRS are underway to incorporate new data sources and new modular, process-based approaches. Updates to the FWI System include a modification to the fire danger calculations to better reflect peaks in daily fire weather, and new fire danger indicators specific to grasslands and peatlands (Canadian Forest Service Fire Danger Group, 2021). The addition of the grassland and peatland

moisture codes and intensity indexes will widen the adaptability of the FWI System in other regions outside Canada. As the threat from wildland fire increases in many parts of the world, the FWI System indicators can be a foundation for local decision-support tools. Evaluation of the adaptability of the System to any new region must start with an evaluation of the information needs specific to fire management decision-making and then an evaluation of how the different indicators within the FWI System structure can inform those fire management decision-making needs.

Forest management, fire spread simulation, mixed integer programming, decision making, software.

Abstract

We propose a method for forest management in which wildfire is modelled explicitly through the integration of optimisation and simulation. Given a forest, the decision problem is to select a plan (i.e. a prescription and a periodicity for shrub cleaning) for each of its stands. Each plan is associated with values for a set of criteria for each period of the temporal horizon. Considered criteria are net present value, biodiversity, carbon stock, and erosion. The problem is modelled by a mixed integer programming (MIP) with the objective of maximizing the net present value and imposing limits for the remaining criteria.

A fire spread simulator, based on shortest path algorithms following the minimum travel time principle, is responsible to identify sets of plans that are not acceptable together as they result in a high rate of fire spread. That information is included in the MIP as constraints. This cycle optimization-simulation is repeated until the plans provided by the MIP are acceptable in all scenarios.

Data from a real landscape case-study has been collected and processed to obtain management and fire parameters required to validate the proposed method, which is being implemented in Python (with Gurobi as a MIP solver, GeoPandas for managing and processing geospatial data, and NetworkX implementation of graph algorithms).

1. Introduction

Forest management problems have been addressed with optimisation techniques for decades as surveyed in Kaya et al. (2016).

We consider the forest management problem of deciding which prescription and shrub cleaning periodicity to apply in each stand. Different variants of this problem have been approached before with mixed integer programming, being harvest scheduling with spatial constraints one of the most studied (for a broader view, see Yoshimoto (2018) for the problem with constraints on clearcut area and Neto (2020) for the problem with habitat fragmentation concerns). Recent works (e.g. Marques et al. 2017) consider, among the net present value, carbon stock and others, fire resistance indicators.

Our main contribution is to explicitly incorporate fire spread simulation in forest management. Optimization is used to select promising plans with respect to forest management indicators (net present value, biodiversity, carbon stock, erosion). Fire spread simulation is used to exclude plans that, taken together, may lead to wildfires with high damage potential.

We consider two modules: an optimization module and a fire spread simulation module. The optimization module, which consists in a mixed integer programming (MIP) model, is responsible for the selection of a global plan, i.e. the calendar of silvicultural operation including shrub cleaning periodicity for each stand, further called prescription, that maximizes the net present value taking into account limits on the biodiversity, carbon stock,

soil erosion, standing timber volume, and harvested timber fluctuations between planning periods. The first three limits are imposed to ensure a certain quality of the respective ecosystem services and soil functions. The last constraints aim at maintaining the availability of timber in the forest and simultaneously a stable timber supply.

The fire spread simulation module represents the landscape as a grid network and, using the minimum travel time principle (MTT) (Finney 2002) and an all-pair shortest paths algorithm (Ahuja et al. 1993) allows to obtain the fire paths and fire arrival times at each node of the network for any ignition node. The assessment of the fire potential damage is made by the distance travelled by fire in the quickest path (in a given time interval, i.e. the rate of spread (ROS) of fire is measured in all nodes that have the same fire arrival time) in a set of scenarios.

The interaction between the two models occurs in both directions. The optimization module provides to the simulation module the current plan of each stand. The simulation module generates a set of scenarios that share the fuel model and canopy characteristics derived from the current plan of each stand and have different wind and ignition locations. For each scenario, the fire transmission time between each pair of adjacent nodes is obtained and the ROS is calculated. If the ROS of a fire path is higher than a given threshold, the path is termed unacceptable. The set of stands belonging to an unacceptable path cannot have the current plan because lead to a ROS higher than the acceptance threshold. In that case, a corresponding constraint is inserted in the MIP model. If the simulation module does not identify an unacceptable fire path, the global plan is optimal with respect to all fire scenarios considered.

This paper is organized as follows. In section 2 we detail the optimization module. In section 3, we detail the fire spread simulation module. In section 4, we provide an overview of a landscape being used as a case-study, describe the data gathered, and how the proposed approach is being implemented. In section 5, conclusions are drawn, and extensions are discussed.

2. Optimizing plans

We consider a forest divided into stands. The set of stands is denoted by S. For each stand $s, s \in S$, we represent its area (in ha) with a_s and its set of available plans by P_s.

A plan p, $p \in P_s$, is defined by a prescription and by a brush cleaning periodicity. For example, for an eucalyptus stand, available plans may be characterized by an harvest periodicity (e.g., 10, 11 or 12 years), and a shrub periodicity (e.g, 5, 10 years or never, resulting in nine plans).

We denote by T the set of periods of the planning horizon, being the number of periods of the planning horizon its cardinality $|T|$.

The consequences of applying a plan p to a stand s are measured for each time period, which is indexed by $t, t \in T$, and are the following:

npv_{sp}^{t} − net present value (€);
bd_{sp}^{t} − biodiversity (*index*);
es_{sp}^{t} − soil erosion (ton);
cb_{sp}^{t} − stock of carbon (ton) ;
vol_{sp}^{t} − volume (m^3) of timber removed by thinning and harvest.

For the end of the planning horizon, we define:

$stv_{sp}^{|T|}$ − standing timber volume (m^3).

We consider the following limits that cannot be violated in each period:

b_{min} − biodiversity index;
c_{min} − carbon stock (ton/ha);
e_{max} − soil erosion (ton/ha).

Two further parameters are considered:

$stv_s^0 -$ standing timber volume (m^3) in stand s at the beginning of the first period;
$\Delta -$ deviation allowed from the reference volume of timber removed.

The decision variables are:

$$x_{sp} = \begin{cases} 1, \text{if stand } s \text{ is managed with plan } p \\ 0, \text{otherwise} \end{cases}, s \in S, p \in P_s;$$

$w -$ reference level for the volume of removed timber over the planning horizon.

The model is:

$$Max \sum_{s \in S} \sum_{p \in P_s} \sum_{t \in T} npv_{sp}^t x_{sp} \quad (1)$$

$subject\ to$:

$$\sum_{p \in P_s} x_{sp} = 1, s \in S \quad (2)$$

$$\frac{\sum_{s \in S} a_s (\sum_{p \in P_s} bd_{sp}^t x_{sp})}{\sum_{s \in S} a_s} \geq b_{min}, t \in T \quad (3)$$

$$\frac{\sum_{s \in S} \sum_{p \in P_s} es_{sp}^t x_{sp}}{\sum_{s \in S} a_s} \leq e_{max}, t \in T \quad (4)$$

$$\frac{\sum_{s \in S} \sum_{p \in P_s} cb_{sp}^t x_{sp}}{\sum_{s \in S} a_s} \geq c_{min}, t \in T \quad (5)$$

$$\sum_{s \in S} \sum_{p \in P_s} vol_{sp}^t x_{sp} \geq (1 - \Delta) w, t \in T \quad (6)$$

$$\sum_{s \in S} \sum_{p \in P_s} vol_{sp}^t x_{sp} \leq (1 + \Delta) w, t \in T \quad (7)$$

$$\sum_{s \in S} \sum_{p \in P_s} stv_{sp}^{|T|} x_{sp} \geq \sum_{s} stv_s^0 \quad (8)$$

$$x_{sp} \in \{0,1\}, s \in S, p \in P_s \quad (9)$$

$$w \geq 0 \quad (10)$$

The objective function (1) states the management objective of maximizing the net present value. Constraints (2) state that each stand is managed with one and only one prescription and shrub cleaning periodicity, i.e. one plan. Constraints (3) ensures a minimumfor the average biodiversity index value of the forest for each period. Constraints (4) guarantees a maximum for the average erosion of the forest for each period. Constraints (5) imposes a minimum for the average carbon stockage of the forest for each period. Constraints (6) and (7) impose a limit on the fluctuation of the volume of timber removed in each period in relation to a reference value. Constraint (8) states that the volume of standing timber of the forest at period T is greater than or equal to that at the beginning of the first period. Constraints (9) and (10) define the domain of the decision variables.

After the optimization of the model just introduced, a global plan is obtained. This plan is provided to the fire spread simulation which is responsible to identify stands belonging to unacceptable paths. Let U represent the stands belonging to an unacceptable fire path, and, with a slight abuse of notation for clarity, $s\bar{p}$ represent stand s and its current plan, $\bar{p}$. Constraint (11) excludes the use of the current plans of the stands in U together:

$$\sum_{s \in U} x_{s\bar{p}} \leq |U| - 1 \quad (11)$$

At a given iteration, the MIP model to optimize is (1-10) plus the set of all constraints (11) identified in the previous iterations.

Feasibility issues may arise in the first MIP if the limits are too narrow or the plans are not suited. After the insertion of constraints on unacceptable paths, the MIP may become infeasible – meaning that no global plan respecting the unacceptable path criterion can be found. In that case, the identification of the path may be used to drive other fire related measures (e.g. implement fire barriers).

3. Simulating fire spread

Fire spread simulation is based on the minimum travel time principle (MTT) (Finney 2002) which states that fire arrival time at any location is given by the duration of quickest path from the ignition to the location.

We define a grid network representing the landscape. Nodes are associated with locations and arcs are associated with potential fire transmission between adjacent locations. Each arc has a fire transmission time, which depends on the slope, wind and fuel model. The set of transmission times, together with one ignition location, defines a scenario for which the quickest path in a given period is identified.

After the optimization module obtains a global plan, i.e. as a set of plans, a set of fire scenarios is considered. The slope and fuel moisture are the same for all scenarios. For each period, the fuel model and canopy measures are constant (given by the plan selected for each stand). Different transmission times are obtained by varying the wind. For a given set of transmission times, all-pairs quickest paths are determined efficiently. Based on those transmission times, for each potential ignition location, the quickest fire path (in a given period, with a minimum length) is identified and checked against a pre-defined threshold. If the ROS of the fire path is greater then the fire path is unacceptable, and its plans and the corresponding stands are returned to the optimization module which will derive the constraints as (11).

4. Implementation and case-study

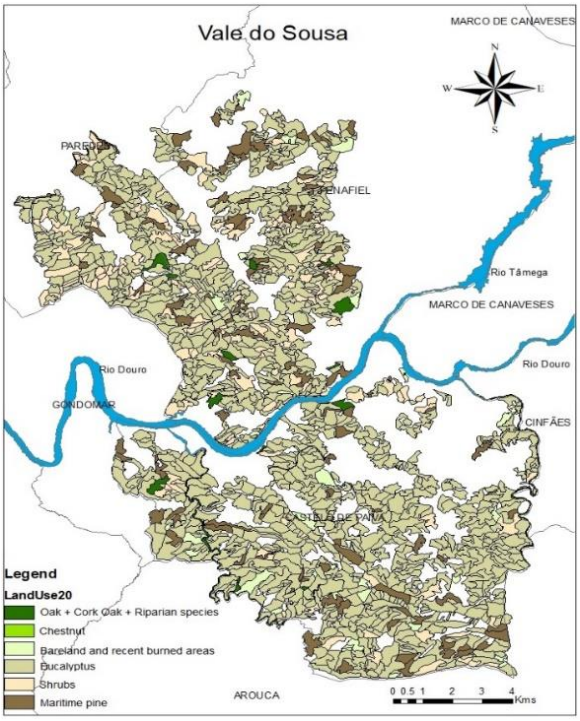

Figure 1 – Case study area location and land occupation in 2020.

The proposed approach is being implemented and validated with data from the Zona de Intervenção Florestal (ZIF) Paiva and Entre-Douro e Sousa in Portugal.

ZIF is a forested landscape located in Northwest Portugal, 100 Km from Oporto. The Associação Florestal do Vale do Sousa, a forest owners association, is the entity responsible for developing the management plan for the whole area. ZIF is divided in 1406 stands with a total area of 14313 *ha*. Data required for the approach was collected and estimated as follows.

The wSADfLOR decision support toolbox was used to automate data processing (Marto et al., 2019). The prescription writer and simulation modules were used to generate the prescriptions and their outputs according to the management planning criteria (Table 1). We also computed several ecosystem services provided by the forested landscape (Barreiro et al 2016, Botequim et al 2021, Marques et al 2021, Rodrigues et al 2021). We considered a planning horizon extending over ten years, with a period corresponding to one year.

A fuel model for each stand from the set of national fuels models proposed in (Cruz and Fernandes 2008, Fernandes and Loureiro 2021) was identified and assigned to each prescription each year of the planning horizon

Table 1- Silvicultural models characteristics and growth models used in simulation.

[1]Pre-commercial thinning; [2]Stool thinning in 2nd and 3rd coppice cycles, with 1.6 intensity; [3]Prunning; [4]Debarking (cork extraction).

Examples of three attributes of the landscape are given in Figure 2 (altitude, fuel models, and canopy cover).

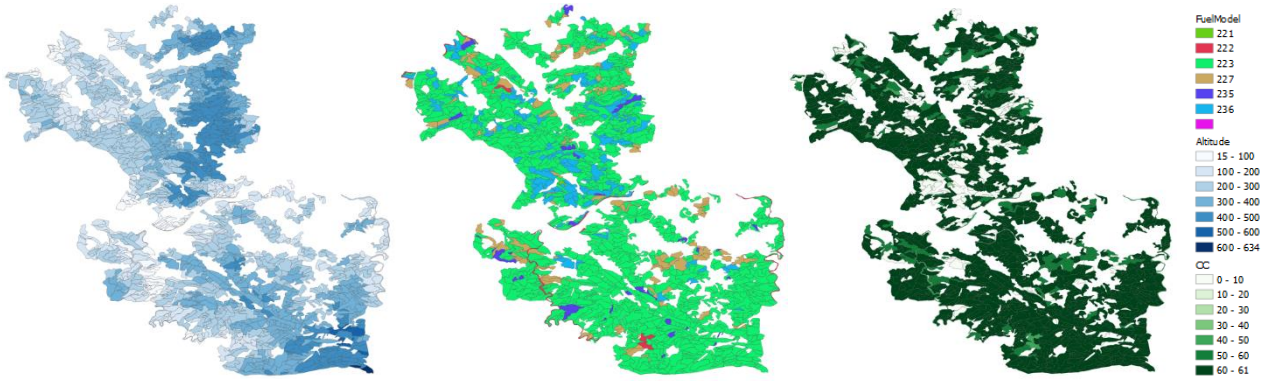

Figure 2- Altitude (600 meters amplitude), fuel models and canopy cover for ZIF.

Geographical information is processed and managed with GeoPandas, Transmission times are calculated with the Rothermel model (with R_0 obtained with BehavePlus6 for each portuguese fuel model and following Andrews (2018) to derive the slope and wind factors in any direction), NetworkX is used for shortest path calculations and visualization, and Gurobi / Gurobipy is used for optimization.

5. Conclusions

We proposed a method for fire-aware forest management based on the interaction of optimization and simulation. Optimization suggests plans respecting limits for different criteria (e.g. biodiversity) and maximizing the net present value, while simulation asserts the plans are acceptable for a different set of scenarios or identify which plans cannot be selected together. In the latter case, the optimization model is updated taking into account that information and the process is repeated. Short-term future work includes the validation with a case-study.

At the time of writing, most of the parameters required for validating the approach in a real landscape are gathered and an implementation in Python is being conducted.

Extensions of the proposed approach may explore four relevant issues:
i) include fire suppression resources and their optimized positioning (Alvelos 2018, Mendes and Alvelos 2022) in the fire spread model;ii) characterize unacceptable scenarios with other measures (or combinations), e.g, fire perimeter, fire area, and average ROS;

iii) address strategic plans where the planning horizon covers several decades;
iv) consider multiple objectives (in fact, the described model can be seen as the one of an iteration of the

epsilon-constraint method for multi-objective optimization) and additional spatial constraints (e.g. clearcut related).

6. Acknowledgments

This research was supported by project PCIF/GRF/0141/2019 ”An Optimization Framework to reduce Forest Fire” and in the scope of Norma Transitória—DL57/2016/CP1382/CT15 both funded by FCT – Fundação para a Ciência e Tecnologia. We thank Paulo Fernandes for providing us the files with the Portuguese fuel models.

Abstract

The process of modelling and replicating extreme fire behaviour like junction fire, which is the intersection occurred between two contiguous fire lines, is essential for understanding the phenomena associated with extreme fires. Numerical simulations of junction fires, replicating laboratory-scale experiments, with no imposed wind, were performed for a shrub fuel bed with slopes ranging from 0° to 30°. The simulations of junction fires were conducted for two junction angles 30° and 45°. For each scenario, the sensitivity to a range of numerical parameters was investigated.

The rate of spread (ROS) is a key parameter for assessing risks from vegetation fires. Experimental spreading junction fires, conducted at laboratory scale at Coimbra University (Portugal), were simulated using FIRESTAR3D −a three-dimensional physics-based fire model. To ensure the robustness of simulations, sensitivity analyses were carried out by varying the grid resolution, domain size and fuel characteristics −using two descriptions levels of the shrub: the vegetation was represented using only one cylindrical-shaped solid-fuel type (excelsior fuel using the characteristic parameters for Erica shrub), or two fuel by adding the contribution of twigs of various diameters up to 6 mm while keeping the same packing ratio. Finally, the validation of FIRESTAR3D simulations was achieved through the comparison of predicted and experimentaly-measured ROSs.

The experimental trends of the compared quantities were well reproduced by the simulations. Accelerating and decelerating propagation phases were observed in all simulations, with a dependence on the slope angle, while the maximum ROS depends critically on the junction angle. As it was the case of other wildfires simulated by FIRESTAR3D, it was found that this physics-based model is capable of simulating junction fire propagation.

There are several processes associated with the development of a junction fire behaviour, in which dramatic changes in fire behaviour can occur with little change in various fuel, weather and topographical parameters. In a subsequent study, we aim to develop an understanding of junction fire behaviour taking into account essential parameters that affect the behaviour, namely: slope, junction angle, and driving wind velocity.

1. Introduction

Fire behaviour in extreme form is one of the major natural disasters in many parts of the world given their devastating effects. The intersection of multiple fire lines is among the strongest form of extreme fire behaviour. A junction fire, also called jump fire or eruptive fire, is the case of merging of two fire fronts, enhancing their propagation speed through strong interaction that occurs between the two fire lines. A particularly serious example took place during the 2003 Canberra (Australia) fire, where fire merging led to a devastating intense fire which spawned the first known pyrogenic tornado (McRae, et al., 2013). To mitigate the impact of this natural hazard, there is a need to better understand the wildfire behaviour. Simulation tools are designed to forecast fire behaviour and the course of a fire front over landscapes on a broad scale, while describing the intricacies of the interaction between flames and possible targets on a smaller scale (houses, vegetation, etc.).

The present study is focused on the specific eruptive fire mechanism of the merging of contiguous fire fronts, called junction fires. The analysis and the estimation of the evolution of the junction fire fronts were conducted using a physics-based model FIRSTAR3D (Morvan, et al., 2018). This three-dimensional model, developed in close collaboration between Aix-Marseille University, the Lebanese University, and Toulon University, is based on a multi-phase formulation and solves the conservation equations of the coupled system formed by the vegetation and the surrounding gaseous medium. The model takes into account the vegetation degradation processes (drying, pyrolysis, and combustion), the interaction between the atmospheric boundary layer and vegetation (aerodynamic drag, heat transfer by convection and radiation, and mass transfer), and the transport in the gaseous phase (convection, turbulence, and combustion).

There has been limited research into the interactions of junction fires especially using a physics-based model, and it is desirable to count this study as an endeavour to replicate the behaviour and examine the influence of the critical parameters: slope and junction angle.

Physics-based modelling is a very complex approach and the complexity comes also from the numerous thermo-physical and numerical parameters used in the simulations. The sensitivity of the simulations to the grid resolution, domain size and fuel description level were investigated in this study. Sensitivity analysis to numerical parameters has been carried out with a twofold objectives: to assess the suitability of the numerical implementation of the junction fire configuration and show the advantage of considering several fuel types to represent the vegetation, and to determine the most appropriate grid resolution to be used within the vegetation, as well as the acceptable size of the computation domain.

2. Methodology and Numerical modelling

Raposo, et al. (2018) conducted a large series of experimental junction fire tests at laboratory and field scales. The laboratory experiments were carried out at the Forest Fire Research Laboratory (LEIF) of the University of Coimbra, Portugal. The experiments reported in Raposo, et al. (2018) provide many experimental measurements that could be used to validate the present simulation results. The rate of spread (ROS) is the quintessential parameter to quantify the dynamic behaviour, although other simulation outputs such as fire intensity, dominant heat transfer quantities, and flame geometry are also important.We examined the capability of FIRESTAR3D to reproduce the results of such experiments for slope angles ranging from 0 to 30°, and for two values of the junction angle (30° and 45°), and for multiple values of fuel moisture content (see Table 1). Additional simulations were carried out (simulation 6 in Table 1) as a part of the parametric study. Simulations of this kind, are computationally expensive due to the high spatial resolution (grid size of 5 cm in the propagation direction) and temporal resolution (10^{-3} to 10^{-2} s) required to accurately solve the governing equations of the problem.

Table 1- Physical parameters of the junction fires cases considered in the validation study.

Simulation Number	ID in (Raposo, et al., 2018)	Fuel moisture content, m_f (%)	Junction angle, Θ (º)	Slope angle, α (º)
1	10-L48	23.91	45	30
2	11-L49	23.91	30	0
3	12-L50	21.65	30	30
4	13-L51	18.76	30	20
5	17-L56	13.63	30	30
6	-	20	60	30

Numerical simulations were conducted using a V-shaped vegetation region immersed inside a larger computational domain (29 m long, 29 m wide, and 12 m high) as shown in Figure 1. The homogeneous fuel bed, of height 0.15 m, is 5 m long and is located 12 m away from the inlet boundary and at least 12 m (depending on the junction angle) away from the lateral boundaries. Solid-fuel particles are assumed to have a cylindrical shape and to behave as a black body. Both the solid-phase and the fluid-phase grids are characterised by cells sizes below the extinction length scale (0.073 m) within the vegetation, given by $\frac{4}{\alpha\sigma}$, where α is the packing ratio and σ is the surface-to-volume ratio (see Table 2).

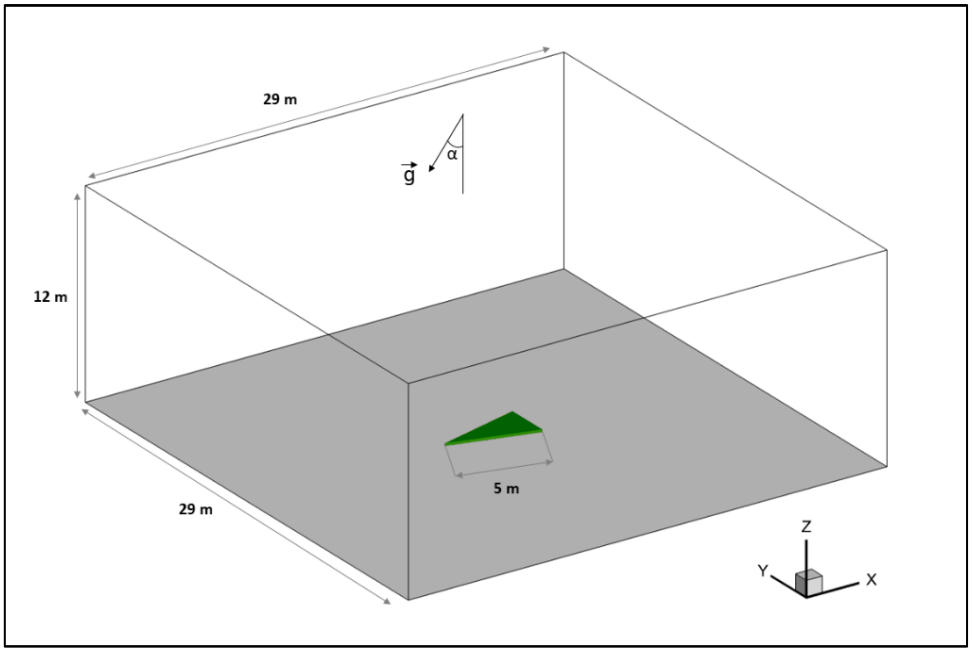

Figure 1 - Perspective view of the computational domain and the vegetation cover used to simulate the junction fire.

The fire lines are ignited in the model by activating a burner. A 10-cm wide burner is activated instantaneously along the entire ignition lines by injecting CO gas at 1600 K from the bottom of the computational domain for the duration of 5 s. Open boundaries are applied on the computational domain sides (except the bottom one), which allows the fire to create its own induced air flow. The main physical parameters that were used in all the configurations are tabulated in Table 2.

Table 2- Geometric and physical properties of the shrubland vegetation (Raposo, et al., 2018; Gilliers, et al., 2002).

Vegetation height δ	Solid-fuel volume fraction, α	Surface/Volume ratio, σ	Dry material density, ρ	Drag Coefficient, C_D	Thermal emissivity	Vegetation particles shape
(m)		(m^{-1})	($Kg.m^{-3}$)			
0.15	0.00784	6900	500	0.42	1	Cylindrical

The fuels used in this study were shrubs composed of a mixture of genus Erica, often called Heather, the fuel load was kept constant at the value of 0.6 $kg.m^{-2}$, used experimentally.

The physical properties of the shrub mentioned in Table 2 are characteristic properties (Pereira, et al., 1995). Realistic simulations should take into account the heterogeneity of fuel in terms of distribution of twigs and leaves, their percentages, as well as their specific surface-to-volume ratio. Most of the physical properties of shrubs used by (Raposo, et al., 2018) can be found in the literature (Fernandes, 1997) and a complex method of describing shurb (combination of leaves and twigs) is presented as Table 3. A simulation was carried out using this fuel description to observe any difference of fire behaviour compared to fuel of Table 2. For both descriptions, the same fuel moisture content was considered (same to experimental value).

Table 3- Geometric and physical properties of leaves and twigs of shrub vegetation (Fernandes, 1997).

	Surface/Volume ratio, σ (m^{-1})	Dry material density, ρ ($Kg.m^{-3}$)	Solid-fuel volume fraction, α
Leaves (d < 2.5mm)	7200	253	0.0108 (70%)
Twigs (2.5 < d < 6 mm)	920	970	0.001212 (30%)

Although the grid resolution is chosen below the extinction length, (Perez-Ramirez, et al., 2017) recommended to use a grid cell size three times less than the extinction length. Mesh and domain size sensitivity tests have been carried out by increasing and decreasing of the cell size by 30%. To that end, several simulations were carried out using cells of different sizes: 3.5, 5 and 6.5 cm. Moreover, three sizes of the computational domain with a distance from the vegetation region to the open boundaries of 10, 12 and 15 m have been considered, as detailed in Tables 4 and 5.

Table 4- Mesh parameters (for a computational domain size of 29×29×12 m^3).

Minimum cells size in the xy plane	3.5 cm	5 cm	6.5 cm
Mesh size of the solid phase	284×284×18	200×200×12	152×152×8
Mesh size of the fluid phase	202×202×163	160×160×160	136×136×158

Table 5- Domain size (with a cell size of 5 cm).

Size	***1***	***2***	***3***
Domain size	25×25×10 m^3	29×29×12 m^3	35×35×15 m^3
Mesh size of the fluid phase	150×150×134	160×160×160	176×176×199

3. Results and Discussion

In order to capture the effects of parameters and to consistently compare flame properties, quasi-steady regions of acceleration and deceleration were identified. These regions were duly identified for all selected simulations, similarly to the experimental work that proves a pattern of behaviour directly related to the selected parameters.

Six duly-chosen configurations (see Table 1 for details) were simulated using FIRESTAR3D. the comparison between the simulations and the experiments is based on the measurement of the ROS of the junction point assumed to lie in the mid plane of the computational domain.

3D views of the fire flame obtained for a simulation 5 is represented in Figure 2. These results show clearly the potential of FireStar3D in reproducing numerically the junction fire in shrubland.

Assuming a symmetrical propagation, we computed the ROS by tracking the local consumption of dry material in the central vertical plane along the streamwise direction inside the vegetation (at 5cm from the bottom). The ROS estimation was obtained from the time derivative of the position of the junction point.

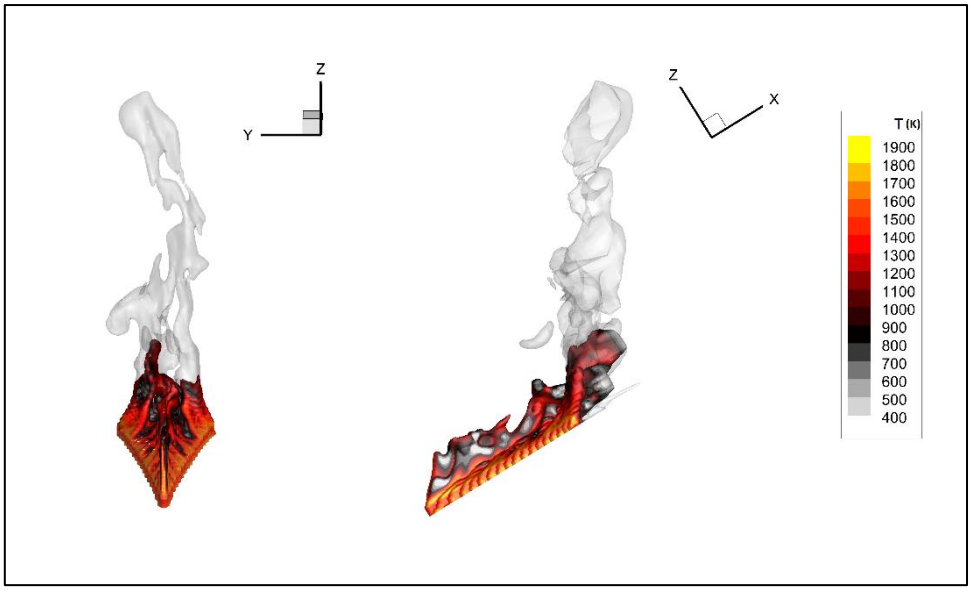

Figure 2- 3D front (left) and side (right) views of an isovalue surface of the soot volume fraction (1.6×10^{-7}) coloured by the gas temperature and an isovalue surface of the water mass fraction (9×10^{-3}) (in grey with 50% of transparency) obtained in the case of simulation 5, 10s after ignition.

3.1. Sensitivity analysis results

Figure 3 shows simulation results of junction point position as function of time from the cases listed in Tables 4-5. Minimal effects of the grid resolution and the domain size on the junction point propagation are observed. Consequently, the considered domain size and mesh (Size 2 – Mesh 5 cm) allow to obtain a solution that is quasi-independent of these parameters as far as global fire behaviour is concerned (ROS, fire intensity, etc).

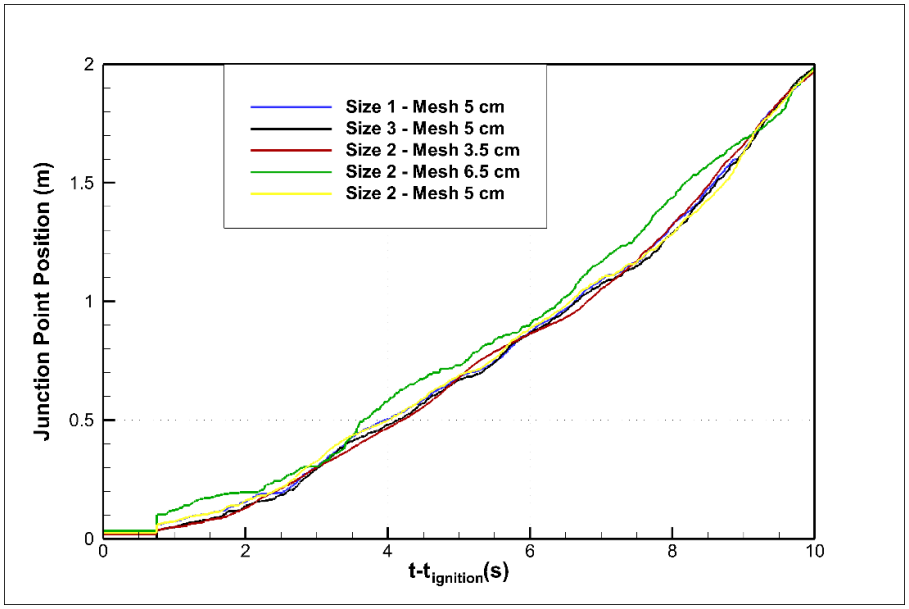

Figure 3- Junction point position for simulation 2 in five sensitivity tests.

Regarding fuel description level, the shrub was described using two methods. In both cases the total initial volume fraction and mass were kept the same (see Table 3) and they are identical to those reported in (Raposo, et al., 2018). A more realistic description of the vegetation (by accounting for different sizes of solid fuel particles) better reproduced the fire dynamics, especially the mass loss process.

Regarding the ROS, a good similarity of the junction point propagation for single and two types of fuel is observed (see Figure 4). The propagation is slightly quicker in the two-fuel case and we attributed that to the low percentage of large diameter particles and very small surface to volume ratio (diameter) of small particles comparing it to the characteristic value adopted first (6900 m^{-1}). Besides that, the limited information about moisture content of leaves and twigs, accounts for the slight overestimation. Overall, the use of multiple description level manages to estimate the ROS in a similar order of magnitude.

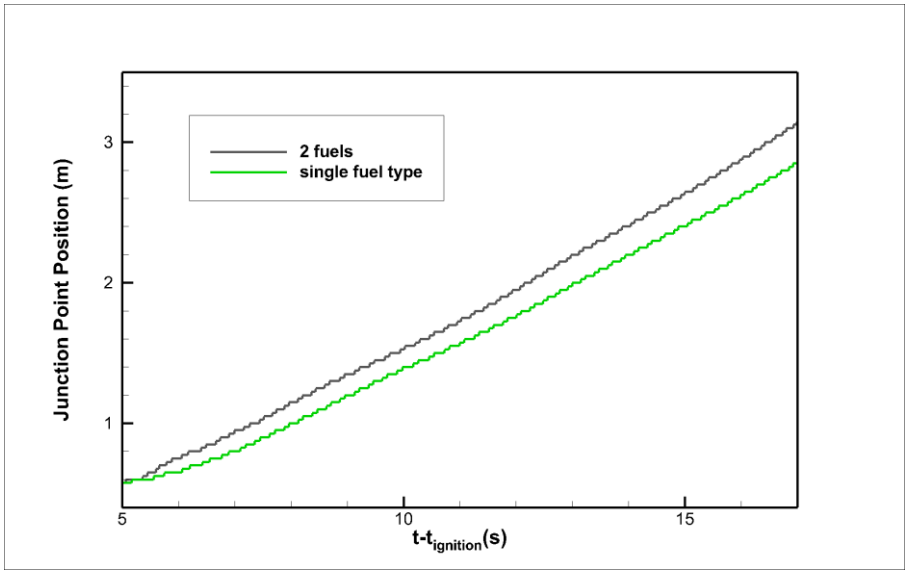

Figure 4- Junction point position for the different fuel combinations

3.2. Validation results

Figure 5 shows the evolution of fire perimeters. It can be observed that the junction fire angle is not fixed during the propagation, instead, it (on average) increases continuously.

The process of merging of these fires is not the closure of the space between the fire lines by a reduction of their respective angle, similar to the closure of scissors. On the contrary, it is the junction point that advances, tending to form a single straight fire line resulting from the two original fire fronts.

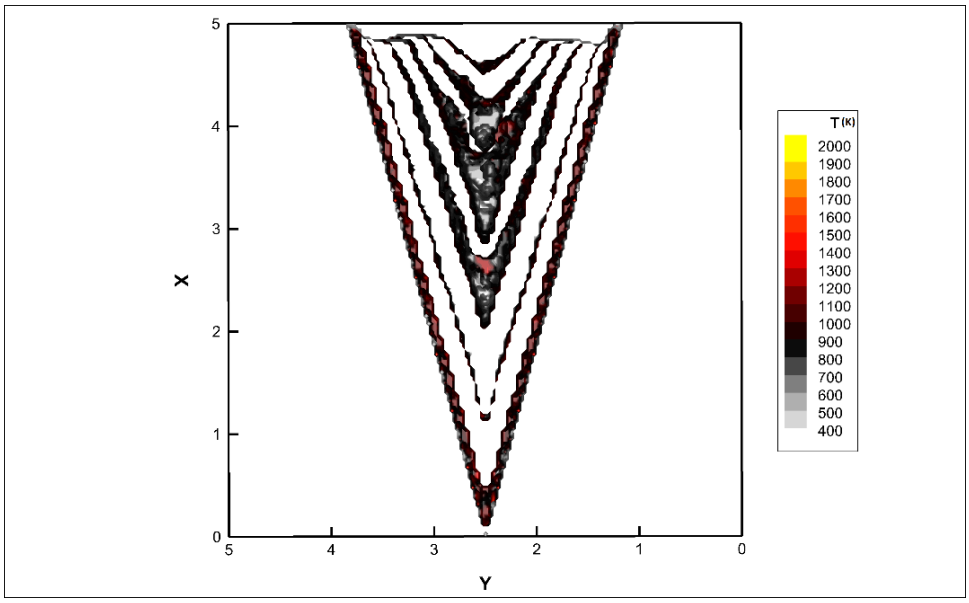

Figure 5- Evolution of fire perimeter according to pyrolysis edge (dry material 0.001 kg.m^{-3}) for simulation 2. The first perimeter is at t – $t_{ignition}$ = 5s and the time difference between each perimeter is 5s.

Simulations 2, 3 and 4 have the same junction angle (30°) and close fuel moisture content values (21.35±2.55%), whilst the slope angle varies (0°, 20° and 30°). Figure 6 shows the simulation and experimental results of ROS for these three simulations.

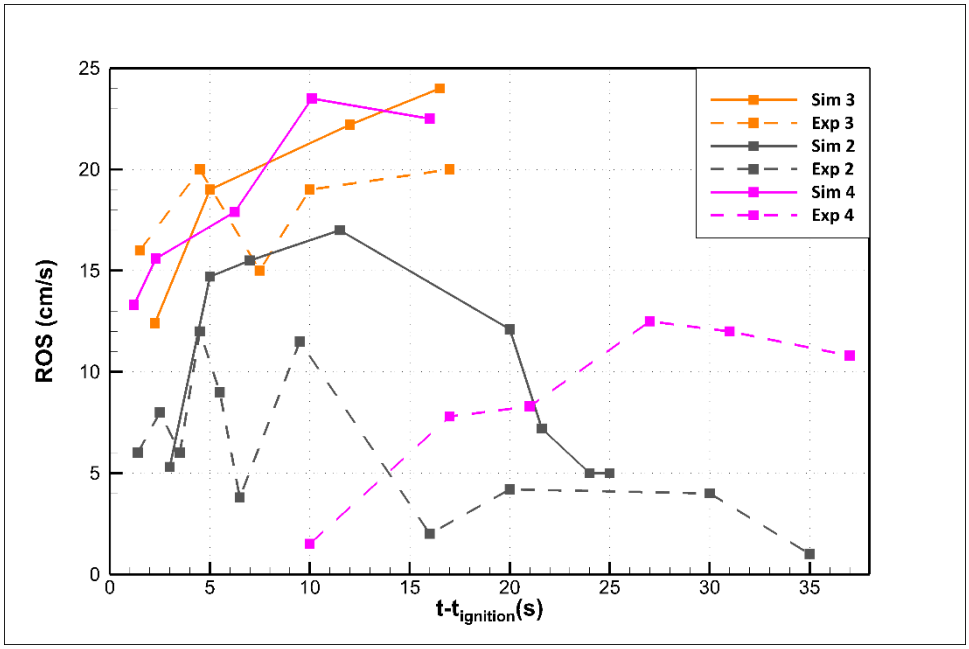

Figure 6- Evolution of the value of ROS for three different slope values (α) as a function of time.

First and foremost, the behaviour under the change of slope angle is prominent in the simulated ROS' results. Taking the maximum ROS into consideration, the value increases with the increase of slope angle (cm.s^{-1} for

slope 0°, 23.5 cm.s^{-1} for slope 20° and 25 cm.s^{-1} for slope 30°). Experimentally, case number 4 seems to be not reflecting this effect as the maximum value (12.5 cm.s^{-1}) is close to the maximum value for experiment 2 (12 cm.s^{-1}) and way far from 20 cm.s^{-1}, maximum value for case 3. This could be attributed to fluctuations that occurred in experiments or ROS measurement error.

The existence of acceleration and deceleration propagation phases has been observed in simulations as observed in experiments. The deceleration phase was significant in simulation 2 (α=0°), slight in simulation 4 (α=20°) and absent in simulation 3 (α=30°).

Experiments 3 and 5 were conducted with the same angles but the fuel in experiment 5 was drier (8% fuel moisture content difference). The simulations capture this difference only by a slight increase in the maximum ROS, however, the accelerative behaviour did not change.

3.3. Parametric study

In Simulations 1, 3 and 6, the slope is 30° and the junction angles are 45°,30° and 60°, respectively. The fuel moisture content values are close; therefore, the effect of junction angle could be deduced. The results are depicted in Figure 7.

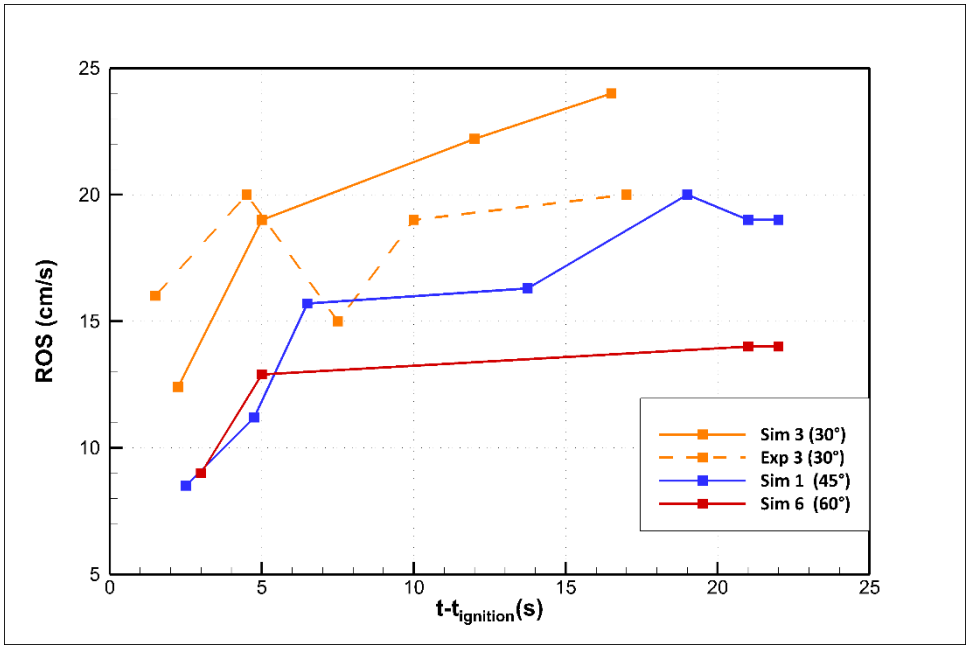

Figure 7- Evolution of the value of ROS for three different junction angles (θ) as a function of time.

Comparing Figures 6 and 7, it appears that the junction angle is more important parameter on the fire spread, consistent with the findings of (Viegas, et al., 2012) for non-slope conditions. A thorough investigation for the influence of critical parameters for a wider range were done in a full parametric study published in a forthcoming paper (Hassan, et al., 2022). Considering simulation 3 and 1, an increase of 15° of junction angle decreased the maximum ROS by 5 cm.s^{-1}, which correctly reflected the experimental results.

4. Conclusion

A set of junction fire simulations was conducted numerically using a physics-based model. The use of physics-based models to simulate extreme fires offers the possibility to study, in detail and at a low cost, the burning of vegetation according to a wide set of parameters that are difficult to control experimentally. FIRESTAR3D has been validated for junction fire simulations by comparison ROS estimation to an experimental data set, proving an excellent quantitative and qualitative accordance. The ultimate objective of the study is to investigate the effects of the slope, the junction angle and the wind speed on fire behaviour during the different propagation phases and on the ROS, endeavouring to build a better understanding of the junction fire phenomenon and its underlying physics.

Abstract

Fire managers often make decisions about wildfire incidents on a landscape scale. While several well developed models can predict fire behaviour at these scales, the limited data they draw upon restricts their range of validity. Other models explicitly represent the physical complexities of the fire environment, but with increased computational costs and increased sensitivity to boundary conditions. In this paper, we explore a middle ground between landscape level, data-driven fire behaviour predictions and physics-based, computationally expensive models. Machine learning is used to predict fire severity from a set of well recognized covariate features related to weather, fuel, and topography. A random forest is used for the classification task, and the model covariates are tested to determine their importance in the classification. The model demonstrates considerable skill in prediction of burn severity, with overall classification accuracy of 71%, and lower accuracy in moderate severity predictions. Our results are similar in accuracy to previous work, but distinctive in that we have made no attempts to train the model on specific ecoregions. We determine that topographic variables like elevation, slope, and aspect are the most important in this classification problem.

1. Introduction

Between 1985 and 2017, the Western United States experienced increases in both the severity and the area burned by wildfires (Center, 2017). During the same period of time, the wildland urban interface, WUI, became the fastest growing land use type in the United States (Radeloff et al., 2018), leading to increased economic consequences of wildfires (Center, 2017). Yet, wildfires have historically been an integral part of North American ecosystems, and by pursuing a policy of wildfire suppression since the early 20th century, land managers have altered fire regimes in much of North America, potentially driving some of the increases in fire frequency and intensity (Arno & Brown, 1991). In addition to a more complicated landscape from expanded WUI settlement and increased fuel loading, fire managers now have to account for a warming climate. Thus, the areas threatened by wildfires have increased, and are projected to increase still more under nearly all climate change scenarios (Flannigan et al., 2009).

Management practices aimed at mitigating the threat of wildfire have traditionally involved treatments of a landscape with a combination of thinning projects and prescribed burns (Arno & Brown, 1991). Assessment of the impact of these practices is a critical phase of planning, and involves predictive modelling of fire on the landscape being considered for treatment. Several predictive fire models exist, and have distinctive features that may be suited to requirements arising from operational use, predictive capabilities, computational cost, or model complexity (Sullivan, 2009a, 2009b, 2009c).

Sullivan (Sullivan, 2009a, 2009b, 2009c) divides existing fire models into six groups, organised by two broad classes. One class of fire models, data-driven models, are based on empirically derived formulas for fire spread, operate on large landscape level domains, are computationally efficient, and see broad operational use. The other class of fire models, called physics-based models, use physical principles to determine fire spread, operate on stand or individual fuel element levels, are computationally expensive, and are limited to research applications in fire science. Both classes of model offer various benefits and costs, and there is a lively debate to each class' relative merits (Cruz et al., 2017, 2018).

Nowadays, machine learning (ML) may offer a novel approach to fire modelling as it has the fast computation associated with data-driven models, yet may capture the complexities of fire physics. Several authors have applied ML techniques to predict fire behaviour from burn characteristics and covariates such as climate, topographic elevation and slope, and fuel descriptions (Jain et al., 2020).

In this paper we focus on predicting burn severity measured by the differenced normalised burn ratio (dNBR) (Eidenshink et al., 2007). We are not the first to apply machine learning methods to the problem of predicting burn severity. (S. A. Parks et al., 2018) predicted high severity fires using boosted regression trees using a suite of features (covariates) grouped into live fuel, topographic, climate, and fire weather. Moreover, they successfully predict high severity fires in 19 distinctive ecoregions of the American west and report that fuels descriptors have the greatest importance for prediction. S. Parks et al., 2018 predicted the probability of *low-severity* fires using a similar approach. More recently, Huang et al., 2020 carried out a similar analysis for Northern California's coastal mountains and achieved a 79% overall classification accuracy and found topographic features to have the greatest explanatory power.

Here, as in Parks et al., 2018, we set out to characterise landscapes by the severity of fire (Eidenshink et al., 2007) that would result if the landscape were to burn. Unlike Parks et al., 2018, but following Huang et al., 2020 we formulate our problem as a multi-label classification problem, using features to determine unburned, low, moderate, and high severity fires. We also include new features in our classification scheme by adding higher order products of features. Our region of interest is the state of Montana, which is broader and includes a greater variety of ecoregions than (Huang et al., 2020). In terms of data volumes, we evaluate 29 million pixels, which is 70 times the volume in (S. A. Parks et al., 2018) and more than 14 times more data than (Huang et al., 2020).

2. Methods

2.1. Collection of the Features and Training Data

Covariates considered in this work fit into three broad categories; topography, weather, and fuels. In Table 1 we detail the features, resolutions, and sources used in this analysis. To improve the classification, these 9 fields were multiplied by themselves and each other in order to create a total of 54 features (9 features plus 45 squares or products of features). The Monitoring Trends in Burn Severity (MTBS)(Eidenshink et al., 2007), provides fire perimeters and burn severity during the 35 year period from 1985-2020, totaling to 825 unique wildfires.

Table 1: The data used in the analysis, the resolution, and the source.

	Feature	**Resolution**	**Source**
Topography	Elevation	30 m, Constant	EDNA (Layers, 2005)
	Slope	30 m, Constant	EDNA (Layers, 2005)
	Aspect	30 m, Constant	EDNA (Layers, 2005)
Weather	Solar Radiation	4 km, weekly average	gridMET (Abatzoglou, 2013)
	Min Relative Humidity	4 km, weekly average	gridMET (Abatzoglou, 2013)
	Max Temperature	4 km, weekly average	gridMET (Abatzoglou, 2013)
	Precipitation	4 km, annual average	gridMET (Abatzoglou, 2013)
Fuels	Landfire Vegetation Type	30 m, 2014 Update	LANDFIRE (Rollins, 2009)
	Landfire Fuels Model 40	30 m, 2014 Update	LANDFIRE (Rollins, 2009)

2.2. Model Selection

The statistical modelling is done with Scikit-learn's RandomForestClassifier [17]. This method employs randomly created ensembles of classification trees. Through averaging of trees the variance of model output is reduced without a commensurate increase in model bias. This approach is well-suited to the large number of samples in the training dataset and the underlying physics of the classification problem, which is not overly dependent on spatial or temporal gradients in the feature set. The lack of gradient dependence justifies the decision to avoid convolutional neural networks (CNNs). It is also true that compared to deep CNNs, the RandomForestClassifier is easier to train and interpret, especially with regard to feature importance.

2.3. Model Training

For model training we split 75% of the pixel level feature vectors into training data with the remaining 25% reserved for testing. The test and training data were randomly sampled from the complete data set of 29,379,900 feature vectors. To avoid a class imbalance the training data are sampled in proportion to the number of records in each of the severity classes. Gini impurity was used for the loss function, and 100 trees were grown.

3. Results

To measure performance, we report the confusion matrix (Table 2), precision, recall and F1 scores for each category (Table 3), and a pair of summary statistics. Our classes are relatively well balanced and the summary statistics are a reasonable means of expressing our overall success. Tables 1 and 2 reveal the detailed structure of classifications.

The first summary statistic is the accuracy score for the classification, which was 0.711. The second summary statistic is the area under the receiver operating characteristics (AUROC) and was found to be 0.872.

An impurity method was used to evaluate the importance of the features. The results for the ten most important features appear in Table 4. We also map predicted and observed fire severities in Figures 1-3. These provide a means of visually inspecting fires to determine where predictions are failing. In considering these figures, it is important to note that the extent of the fire is determined by the outline provided in the MTBS data, our prediction method does not determine fire perimeters.

Table 2: A confusion matrix documents the performance of our classification algorithm. Diagonal elements represent instances of successful classification. Off-diagonal values indicate the number of times misclassification took place in each class.

	Low Severity	Moderate Severity	High Severity
Low Severity	**2,853,697**	**544,457**	**134,909**
Moderate Severity	**725,985**	**1,165,844**	**210,226**
High Severity	**120,313**	**285,448**	**1,204,096**

Table 3: A classification report summarises the values of various metrics for each class. Precision is true positives divided by the sum of true and false positives. Recall is true positives divided by the sum of true positives and false negatives. F1 is twice the ratio of precision times recall divided by the sum of precision and recall. Support refers to the number of labels in each class.

Category	Precision	Recall	F1	Support
Low Severity	**0.77**	**0.81**	**0.79**	**3,533,063**
Moderate Severity	**0.58**	**0.53**	**0.56**	**2,202,055**
High Severity	**0.73**	**0.75**	**0.74**	**1,609,857**
Accuracy			**0.71**	**7,344,975**
Weighted Average	**0.71**	**0.71**	**0.71**	**7,344,975**

Table 4: The fractional importance of the 10 most relevant features in the model.

Feature	Importance
Elevation × Annual Precipitation	**3.96%**
Elevation × Solar Radiation	**3.67%**
Elevation × Vegetation Type	**3.16%**
Elevation^2	**3.14%**
Elevation × Fuel Type	**3.05%**
Elevation	**3.00%**
Elevation × Minimum Daily Humidity	**2.83%**
Slope × Annual Precipitation	**2.59%**
Elevation × Aspect	**2.58%**
Elevation × Slope	**2.51%**

4. Discussion and Conclusions

A number of favourable outcomes were achieved in this work. First, we achieve nearly the accuracy reported in (Huang et al., 2020), which reported 79%. Our reported accuracies do not take into consideration the ecoregions used in both (Huang et al., 2020; S. A. Parks et al., 2018). We attribute our relative success within

the inhomogeneous state of Montana to the large volumes of data we used in training; nearly 29 million feature vectors for our work, compared to 462 thousand in (Huang et al., 2020) and 100 thousand per ecoregion in (S. A. Parks et al., 2018). (S. A. Parks et al., 2018) do not report accuracy, and have a boolean classification variable. This makes direct comparison difficult, however our AUC of 0.87 compares favourably to their value of 0.72.

We tested a large number of features and dropped ones determined to be less significant. So far as we know, we are the first investigators to use products of features in our analysis. The results show that some of these products have considerable explanatory power. The ability to account for some curvature in subdividing feature vectors appears to improve classification.

The lower scores for classification of moderate burn severity are noteworthy. We know burn severity suffers from classification errors due to the thresholding of its classification(Kolden et al., 2015), and expect those inherent difficulties to become prominent when classifying across inhomogeneous terrain, where the differences in severity might reflect changes in fuel composition and climate more than genuine thresholds in the classification.

We only classified low, moderate, and high because it is difficult to interpret land that burned but undisturbed. Nevertheless, we carried out analyses that included the unburned category and found overall classification accuracy fell to 65%. This is important to consider when comparing our results to (Huang et al., 2020).

Our software framework for carrying out these analyses is robust and highly scalable. We expect that the addition of more features such as primary productivity derived variables and climate data will improve our accuracy rates. It would also be a straightforward matter to begin identifying ecoregions and training a unique random forest within each of those. Our most significant advance may be to demonstrate that classification of burn severity can achieve near to cutting-edge results by simply increasing the volumes of data used in the analysis.

ALOS-2; nutrients; organic carbon; radar; wildfire

Abstract

The physical sense of synthetic aperture radar (SAR) backscatter data is of particular interest for characterizing soil spatial variability in burned areas. The objective of this study was to evaluate the potential of SAR backscatter data in L-band (Advanced Land Observing Satellite-2; ALOS-2) for assessing fire effects on soil organic carbon, total nitrogen and available phosphorous immediately after wildfire in a burned landscape of the western Mediterranean Basin. ALOS-2 backscatter coefficients were used to estimate soil properties measured in the field in immediate post-fire situation through generalized linear models. The retrieval of soil properties from ALOS-2 L-band SAR backscatter data featured a high overall fit (R2 = 0.37-0.59) and low error (nRMSE = 12.7%-22.5%). ALOS-2 co-polarized channel showed the highest sensitivity to spatial variation in soil properties, and there were no noticeable under and overestimation effects. These results support the applicability of SAR sensors operating at long wavelengths for monitoring fire effects on soil properties, reducing data gathering costs within large burned landscapes.

1. Introduction

Wildfires are a frequent disturbance in the Mediterranean Basin, entailing shifts in the multifunctionality of terrestrial ecosystems as a consequence of fire impacts on the (i) composition and structure of vegetation communities (Fernández-Guisuraga et al., 2019) and (ii) soil properties, among others processes. Fire effects on physical and biochemical soil properties have been widely documented from in-situ field research (e.g. Fernández-García et al., 2019; Huerta et al., 2020). However, the identification of fire effects on soil properties through conventional methods based on field trials is not functional for assessing large burned landscapes due to the fine scale of variation of soil effects, even more when dealing with high environmental variability in plant communities.

Remote sensing techniques (RST) based on multispectral and hyperspectral passive optical data, acquired from space-borne and aerial platforms, have been extensively used for retrieving soil properties in agroforestry systems (e.g. Mirzaee et al., 2016; Gholizadeh et al., 2018). However, the remote estimation of soil properties using multispectral and hyperspectral passive optical sensors might be limited to secondary correlations in vegetated areas, since the reflectance signal is mostly determined by top-of-canopy traits (Healey et al., 2020), and this behaviour may lead to soil properties overestimation (Angelopoulou et al., 2019). To deal with this constraint, active remote sensing data acquired by synthetic aperture radar (SAR) sensors are among the most

reliable RST for digital mapping of soil properties because SAR signal can penetrate the soil through vegetation canopy, especially with increasing wavelength (Jagdhuber, 2012).

In the field of fire disturbance, SAR backscatter data have been used to map burnt area (Belenguer-Plomer et al., 2019) and fire severity (Tanase et al., 2014) with high confidence. Nonetheless, the characterization of soil spatial variability in burned landscapes leveraging SAR strengths for this purpose, remains completely unexplored. For that reason, we aimed to evaluate the potential of L-band SAR backscatter data acquired from Advanced Land Observing Satellite-2 (ALOS-2) satellite for assessing fire effects on soil properties in a burned landscape of the western Mediterranean Basin.

2. Material and methods

The study site is located within the perimeter of a wildfire that burned 9,940ha of shrubland and forest communities in the Sierra de Cabrera mountain range (N-NW Iberian Peninsula; Figure 1) between 21th and 27th August 2017. The following plant communities were affected by the wildfire: (i) gorse shrublands dominated by *Genista hystrix* Lange; (ii) heathlands dominated by *Erica australis* L.; (iii) broom shrublands dominated by *Genista florida* L.; (iv) Pyrenean oak forests dominated by *Quercus pyrenaica* Willd.; and (v) Scots pine forests dominated by *Pinus sylvestris* L.

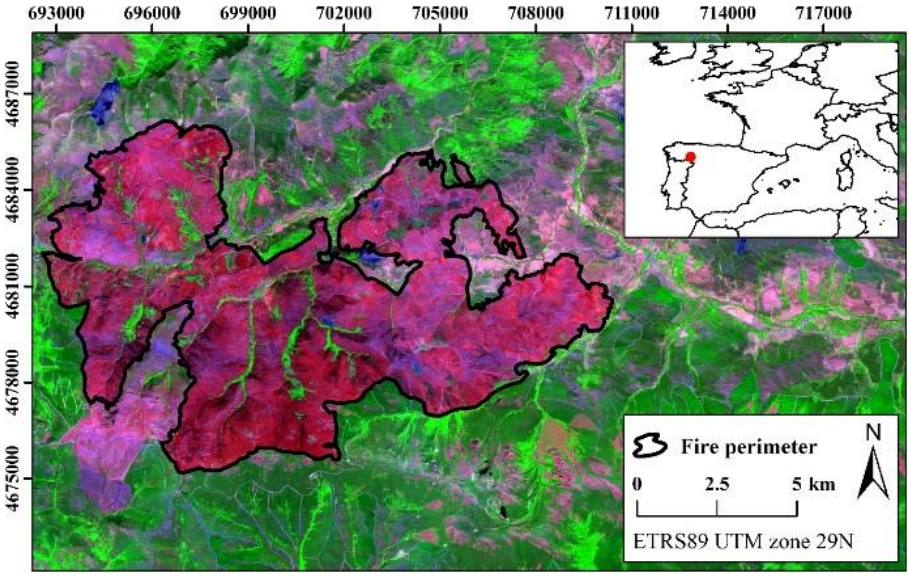

Figure 1- Sierra de Cabrera wildfire (NW Spain). Background image corresponds to a Sentinel-2 false-colour composite (SWIR-NIR-red) in immediate post-fire situation.

In September 2017, the month following the wildfire, a set of 35 plots of 30m x 30m were established in the field following a stratified random design using the dominant plant communities as strata. The area occupied by each plot was homogeneous regarding vegetation legacies and soil characteristics. Two composite soil samples were systematically collected at a depth of 3cm within the plots for obtaining a representative sample. Soil samples were homogenized, air dried and sieved in the laboratory (2mm mesh). Soil organic carbon (SOC; %) was determined following the combustion method (Dumas, 1831). We analysed soil total nitrogen (STN; %) by the Kjeldahl procedure (Bremner and Mulvaney, 1982) and available P (mg/kg) was determined through Olsen et al. (1954) method.

Remote sensing data used to predict soil properties in immediate post-fire situation consisted on ALOS-2 L-band SAR backscatter at dual polarization. ALOS-2 mission carries the Phased Array L-band SAR-2 (PALSAR-2) instrument, with a long operating wavelength of 23.6cm. Starting from 2015, the Japan Aerospace Exploration Agency (JAXA) has delivered 25m ALOS-2 global mosaics of Fine Beam Dual-polarization (FBD) SAR data strips (stripmap mode) acquired in ascending orbits with HH and HV polarizations. Mosaic data for the study site were acquired on 3rd October 2017 from JAXA Earth Observation Research Centre (https://www.eorc.jaxa.jp/). The product was pre-processed by JAXA using the mosaicking algorithm developed by Shimada and Ohtaki (2010), which includes (i) radiometric calibration, (ii) slope correction and

(iii) orthorectification. Product data stored in digital numbers were converted to γ^0 backscatter intensity in dB units. The values of ALOS-2 predictors (HH and HV γ^0 backscatter coefficients, as well as and HV/HH ratio) were extracted for each 30m x 30m field plot.

Soil properties in immediate post-fire situation were modelled by means of ALOS-2 predictors using generalized linear models (GLMs). The response variables were: (i) soil organic carbon, (ii) total nitrogen and (iii) available phosphorous, which were modelled following a Gamma error distribution with a log link function. Prediction performance of soil properties in immediate post-fire situation was evaluated through the coefficient of determination (R^2), the root-mean-squared error (RMSE) and the normalized RMSE (nRMSE). All statistical analyses were implemented in R (R Core Team, 2021).

3. Results and Discussion

ALOS-2 L-band SAR backscatter data featured a high overall fit (R^2 = 0.37-0.59) and predictive capacity (nRMSE = 12.7%-22.5%) for predicting each of the soil properties in immediate post-fire condition (Table 1). This could be attributed to the increased interaction of L-band SAR backscatter signal with soil surface properties because of the long operating wavelength of the instrument (Tanase et al., 2014), namely with soil moisture and surface roughness (Zribi and Dechambre, 2003), these properties being highly correlated with soil carbon and nutrients content (Moser et al., 2009). The soil property best predicted by ALOS-2 data was organic carbon (nRMSE = 12.7%), followed by total nitrogen (nRMSE = 14.1%) and available phosphorous (nRMSE = 22.5%). The slightly better predictive capacity of soil organic carbon content may be related to the lower carbon spatial variability in the plant communities of the study site immediately after fire relative to total nitrogen and available phosphorous content (Huerta et al., 2020).

Table 1- Soil organic carbon, total nitrogen and available phosphorous model performance evaluated through the coefficient of determination (R^2), root-mean-squared error (RMSE) and normalized RMSE (nRMSE).

	Organic C	Total N	Available P
R^2	0.59	0.48	0.37
RMSE	4.107	0.213	26.772
nRMSE	12.7%	14.1%	22.5%

All ALOS-2 predictors (HH and HV γ^0 backscatter coefficients and HV/HH ratio) featured a high signification in the models (*p-values* ≤ 0.01), being noticeable the strength of the correlation of the ALOS-2 HH polarization with all soil properties ($R^2 > 0.3$) (Table 2). This behaviour could be explained by the higher sensitivity of co-polarized SAR backscatter to soil dielectric properties as compared to cross-polarized data (Burgin et al., 2011).

Table 2- Relationship between ALOS-2 backscatter predictors and soil organic carbon, total nitrogen and available phosphorous evaluated through the coefficient of determination (R^2).

	Organic C	Total N	Available P
HH γ^0	0.30	0.33	0.31
HV γ^0	0.22	0.26	0.30
HV/HH	0.32	0.24	0.11

Soil organic carbon, total nitrogen and available phosphorous model predictions in immediate post-fire situation based on ALOS-2 fitted data were closely tailored to the 1:1 line, with the absence of under or overestimation effects for the entire range of field values of soil properties (Figure 2), which could be attributable to the lower attenuation of SAR backscatter signal in the L-band by vegetation canopies than in shorter wavelengths (Tanase et al., 2014).

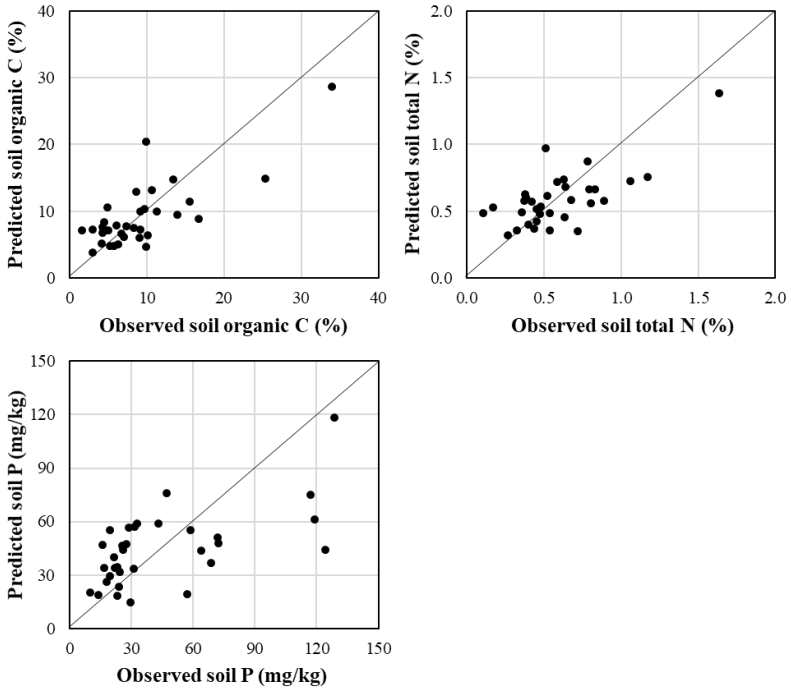

Figure 2- . Relationship between observed and predicted soil organic carbon, total nitrogen and available phosphorous in immediate post-fire situation from ALOS-2 backscatter data. The dotted black line represents the 1:1 line. Overall fit and predictive statistics are displayed in the Table 1.

The mean soil organic carbon, total nitrogen and available phosphorous content within the burned scar immediately after fire, extracted from spatially explicit prediction maps of GLM objects (Figure 3), were 4.78%, 0.65% and 34.13 mg/kg, respectively.

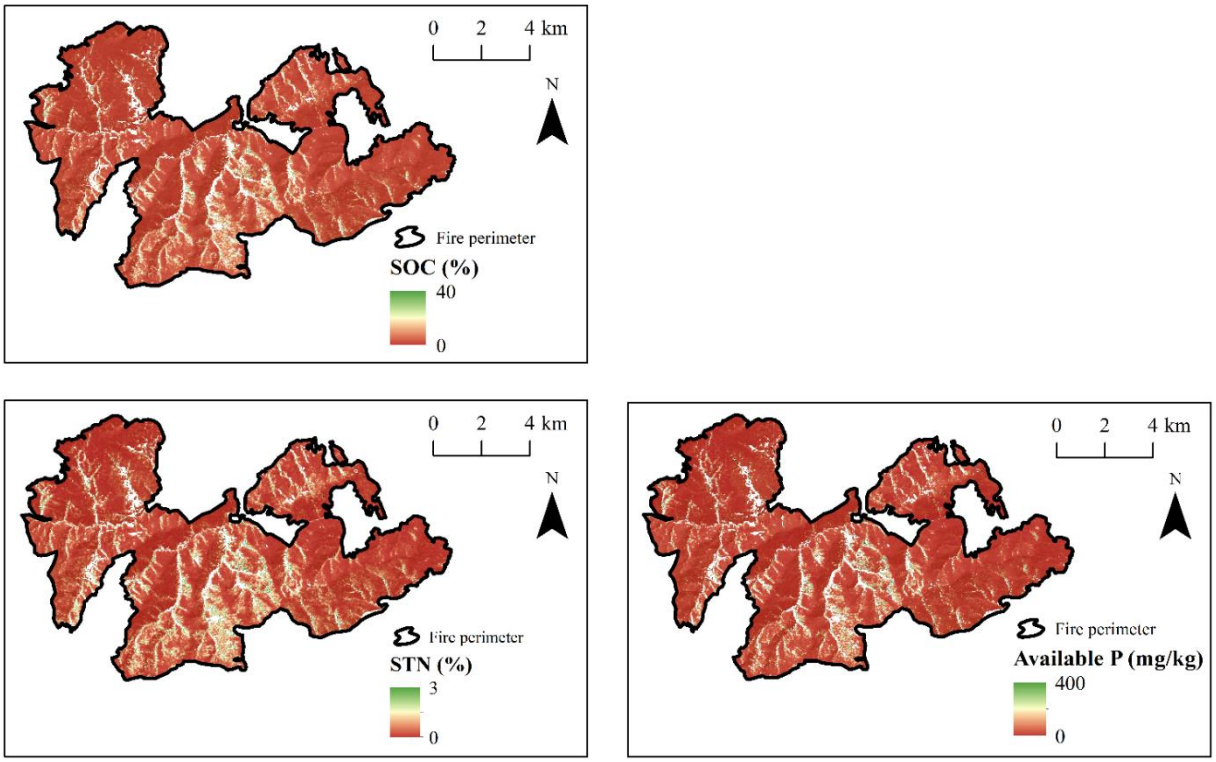

Figure 3- . Spatially explicit maps of predicted soil organic carbon, total nitrogen and available phosphorous. Blank regions within the fire perimeter correspond to unburned valley-bottom areas.

4. Conclusions

The use of remote sensing techniques for monitoring fire impact on soils is essential to determine the implementation of post-fire emergency actions aimed at mitigating soil degradation in extensive burned landscapes. This is a pioneer study evaluating the potential of L-band SAR data for this purpose. The estimation of soil organic carbon and nutrients content immediately after fire from L-band SAR backscatter featured a high performance because of the low attenuation of backscatter signal in the L-band by vegetation canopies and increased interaction with soil surface properties. The results of this study support the applicability of SAR sensors operating at long wavelength for monitoring fire effects on soil properties, reducing field data gathering costs.

Prescribed Fire, fire modeling, coupled fire/atmosphere

Abstract

Prescribed fire is increasingly being looked to as a tool that can support land and fire managers in their efforts towards ecological sustainability and wildfire risk management. As prescribed fire use is considered for treatment of more acres and in more complex settings, practitioners are having to work harder to meet their expanding treatment goals in a safe and environmentally responsible manner. In the context of a prescribed fire, the role of multiple ignitions and complex fire geometries depends heavily on feedbacks between the fire and atmosphere and accentuates the need for explicit representation of these processes in any modeling tools that are to be used to support prescribed fire managers. Computational fluid dynamics models like FIRETEC and WFDS are inherently capable of representing this interaction, but they are too computationally expensive for widespread uses by practitioners for exploration and analysis. We have developed a new simulation tool called QUIC-Fire to capture these fire/atmosphere feedbacks while being orders of magnitude less computationally expensive by coupling the fast-running 3-D rapid wind solver QUIC-URB to a physics-based cellular automata fire spread model Fire-CA. Here we describe some of the model basics and provide initial demonstration capabilities of a new fast-running modeling tool, QUIC-Fire, that can be applied to prescribed fire planning. QUIC-Fire provides a self-determining fire prediction capability that represents the critical coupled fire/atmosphere feedbacks at scales relevant for prescribed fire. Although, the development of this model is in the nascent stages, initial results show an encouraging capability to capture basic trends in fire behavior, response of fire spread to size of fire, consumption of canopy fuels in prescribed fire scenarios, interaction between multiple firelines and response to heterogeneity in vegetation. Its ability to model response to both ignition patterns and a temporally and spatially variable fire environment without computational expense of CFD solutions is encouraging.

1. Introduction

Prescribed fire is one option that land and fire managers can use in their efforts towards wildfire risk management and ecological sustainability and thus a variety of programs are working to escalate its use. Intentional ignitions are used to manage 5 million hectares annually in the US (Melvin, 2015) with several millions more burned globally (Bond and Keeley, 2005; Guyette et al., 2017; Ichoku et al., 2008). As prescribed fire use is considered for treatment of more acres and in more complex settings, practitioners are faced with the challenge of meeting their expanding treatment goals in a safe and environmentally responsible manner. Planning prescribed fire practices and defining their prescription windows to meet objectives depends on anticipating the fire's response to variation in fuels and weather conditions (Chiodi et al., 2018; O'Brien et al., 2018; Wade et al., 1989). Thus, it is desirable to have simulation tools that can be used to assist with planning and exploration of potential prescribed fire scenarios.

2. Models Applied to Prescribed Fires

Predicting prescribed fire behavior can depend on factors that are not as significant in rapidly spreading or intense wildfire, which have been the focus of much wildfire modeling to date. One factor that complicates the prediction of prescribed fire behavior compared to wildfire scenarios is the significant influence of the rates and patterns of ignition on ensuing fire behavior. The role of multiple ignitions and complex fire geometries, which are present in many prescribed fire scenarios, depends heavily on feedbacks between the fire and atmosphere, accentuates the need for explicit representation of this coupling in any such simulation tools that are to be used to support prescribed fire managers. Also, the interaction between the fire environment and practitioner-designed ignition practices depends on landscape-scale fuel, weather, and topographic conditions as well as their localized spatial and temporal variability (Canfield et al., 2014; Furman, 2018).

The absence of strong driving conditions such as strong winds, steep slopes, or extremely low fuel moistures increases the challenge of predicting prescribed fire behavior (Linn et al., 2021) In the absence of such strong drivers the three-dimensional heterogeneities of the forest structure increase in importance. Additionally, since the metrics for success of a prescribed fire often depend on meeting ecological or fuel reduction objectives without breaching safety constraints the interaction between the fire and the heterogeneities vegetation structure is important. Thus, an important characteristic for simulation tools focused on supporting prescribed fire planning is the ability to capture the interaction between three-dimensional heterogenous forest structure, and fire behavior.

Many fire behavior models have been developed to predict fire spread and energy release using a variety of approaches ranging from empirical one-dimensional spread models to three-dimensional CFD models (Sullivan, 2009a; Sullivan, 2009b), but ultimately all wildland fire models must balance representing the complexity of fire-fuel-atmospheric feedbacks and the speed of predictions (Hilton et al., 2018). Firefighter safety and rapid assessments of fire spread have dominated the objectives for much of the wildland fire modeling to date, leading to development of tools producing rapid outputs for common or dangerous wildland fire scenarios. Unfortunately, the speed of these tools is often achieved by eliminating complexity and computational cost, which can frequently means reduction of generality. Simplifications are often made to the representation of the coupling between the fire and atmosphere to fit the conceptual model of a free-burning head fire. This conceptual paradigm does not always capture phenomena associated with the complex fire geometries and multiple fires that exist in prescribed fire scenarios. These tools often do not explicitly represent the heterogeneity of the fuel or three-dimensional structure of the vegetation and thus make assumptions about the structure. Although, these simplifications are often acceptable for many intense wildfire scenarios they ignore the sensitivity of prescribed fires to subtle changes in fire environment. Computational fluid dynamics (CFD) models like FIRETEC (Linn et al., 2002 and WFDS (Mell et al., 2007) are inherently capable of representing the sensitivity of fires to their environment and important interactions at scales relevant to prescribed fires, but they are primarily research tools and are currently are too computationally expensive for widespread use by practitioners for exploration and analysis.

Tools are now being developed with more specific intent of supporting prescribed fire planning. QUIC-Fire (Linn et al., 2019) is an example of a new simulation tool designed to capture fire/atmosphere feedbacks that are pertinent to prescribed fires while being orders of magnitude less computationally expensive than CFD tools. QUIC-Fire provides a self-determining fire prediction capability that represents the critical coupled fire/atmosphere feedbacks at scales relevant for prescribed fire. This was accomplished by exploiting the capabilities of the QUIC-URB wind field solver (Pardyjak and Brown, 2003; Singh et al., 2008) coupled with a new CA-based fire spread model, referred to here as FIRE-CA. QUIC-URB is a fast-running wind field solver that was originally designed for computing flow fields around buildings in urban settings (Pardyjak and Brown, 2003). Although, the development of QUIC-Fire is in the nascent stages, initial results show an encouraging capability to capture basic trends in fire behavior, response of fire spread to size of fire, consumption of canopy fuels in prescribed fire scenarios, interaction between multiple firelines and response to heterogeneity in vegetation. Its ability to model response to both ignition patterns and a temporally and spatially variable fire environment without computational expense of CFD solutions is encouraging.

3. Looking forward

Significant efforts to refine this simulation tool are expected to improve its ability to meet the needs of prescribed fire practitioners including additional smoke and fire effects capability. It is also extremely important to continuously assess strengths and weaknesses of this tool, as with all models, through comparison against observations and the expectations of experienced prescribed fire managers. These assessments can be challenging because of the complexity of many prescribed fire scenarios and the dependence of prescribed fire behavior on heterogeneity of the fire environment, but they are crucial for identifying fire regimes warranting increased confidence or refinement in the model. When examining the behavior of models like QUIC-Fire is important to look beyond spread rate to broader context of fire and smoke behavior.

Fire Behavior, Remote Sensing, Thermal Infrared, FireFlux II, Wildfire Experiment

Abstract

The FireFlux II field experiment was conducted on January 30th, 2013 in south-east Texas, USA, under high fire danger conditions. The experiment was designed to study the behavior of a head fire progressing through a flat, tall grass prairie, and it was informed by the use of a coupled fire-atmosphere model. Vegetation properties and fuel moisture were measured shortly before the experiment. Near-surface atmospheric conditions were monitored during the experiment using an elaborate meteorological instrumentation array. Fire behavior was observed through a combination of remote and in-situ sensors. Clements et al. (2019) presented the analysis of the experiment micrometeorology and in-situ fire behavior observations acquired using a thermocouple array. In this paper, we extend the study of fire behavior during the FireFlux II experiment with the analysis of remote sensing observations. Two thermal infrared and two visible cameras were deployed during the experiment. One thermal and one visible camera were mounted on a helicopter, whereas the other two cameras were installed on a 40-m-height tower next to the burn unit. The tower infrared camera covered a reduced area of interest coincident with the thermocouple array and it allowed monitoring the fire spread as well as measuring the spatially-resolved evolution of brightness temperature. Imagery collected from the helicopter allowed extending fire behavior measurements to the complete burn unit. While airborne IR footage was saturated and did not allow estimation of emitted radiant heat, its analysis allowed tracking fire progression through the plot and therefore estimating rate of spread and fire time of arrival. The existence of in-situ temperature observations provides an outstanding opportunity to validate remote sensing methodologies. In addition, the combination of remote observations with in-situ fire and fuel measurements allows a comprehensive characterization of fire behavior, including spatially-resolved fire rate of spread and fire time of arrival, fire radiative power, Byram's fire line intensity, and air temperature during fire front passage. This paper presents preliminary results from this analysis. Such results demonstrate the usefulness of the selected datasets and the potential of the proposed methodology, encouraging further work. Possible applications of the resulting dataset include (i) the validation of existing fire behavior models that are able to predict any of the measured variables, (ii) the development of data-driven fire behavior models, and (iii) the investigation of the relative contribution of radiative and convective heat transfer mechanisms to fire spread.

1. The FireFlux II field experiment

This section summarizes the aspects of the FireFlux II experiment that are the most relevant for the present study. A complete description of the experiment design, instrumentation and measurements can be consulted in Clements et al. (2019). **Experimental site**

The FireFlux II experiment was conducted at the University of Huston Coastal Center (HCC) in Galveston County near La Marque, Texas, approximately 45 km south-east of Huston and 22 km north-west of Galveston Bay. The burn unit used in this experiment was a Texas Gulf Coast tall grass prairie, 40 ha in extension and situated 5 m above mean sea level (MSL). The last time it had been burned before FireFlux II was in 2006 during the first FireFlux experiment.

1.1. Experiment design

This fire experiment took place on 30 January 2013 under a regional burn ban and high fire danger conditions. The main goal of FireFlux II was to measure the behavior of a high-intensity head fire and monitor the corresponding near-surface atmospheric conditions. This was achieved by deploying a multifaceted set of instruments. Various platforms were used to deploy the sensors, including meteorological towers, surface fireproof sensors, and one helicopter. Figure 1 shows the experiment layout.

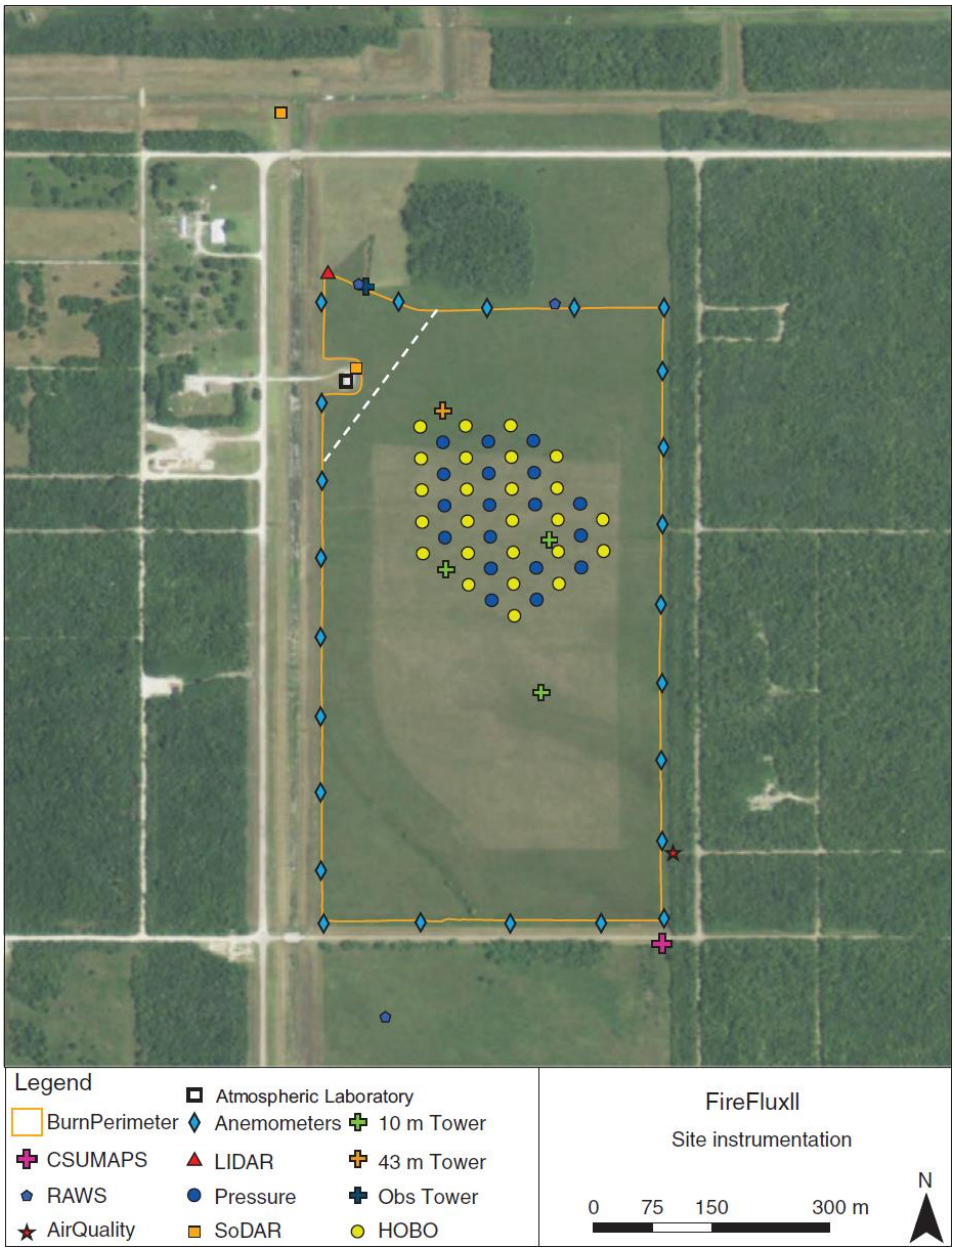

Figure 1- FireFlux II experiment layout (figure reproduced from (Clements et al. 2019)).

1.2. Atmospheric measurements

An array of towers distributed inside the burn unit constituted the primary source of meteorological data. A permanent 43-m meteorological tower is situated in the middle of the northern half of the burn unit. Additionally, three 10-m meteorological towers were installed south of the 43-m tower following a diamond pattern. Each tower was instrumented with arrays of 3D sonic anemometers, thermocouples, barometric pressure sensors, and radiometers. An additional meteorological tower was located outside the burn unit on the south-east corner and collected thermodynamic and wind profiles using 3D and 2D sonic anemometers, temperature and relative humidity probes.

Other instrumentation outside the burn unit included two Doppler sodars that provided 10-m average vertical wind profiles between 10 and 600 m above ground level (AGL), a Doppler lidar that captured radial velocities and backscatter intensities within the plume, three automated weather stations which measured wind speed and direction, air temperature and relative humidity, and an array of anemometers deployed along the burn unit perimeter to measure surface winds. Twenty-four cup-vane anemometers were installed at a height of 3.3 m AGL and spaced approximately 20 m apart from each other.

Finally, a radiosonde was launched before the ignition and recorded vertical atmospheric profiles of temperature, dew point temperature, and wind speed and direction.

1.3. Fuel sampling

Vegetation was sampled four weeks before the experiment to characterize the structure and loading of combustible material within the burn unit. Twenty destructive clip plots were established on a systematic grid within the burn unit at 25-m spacing. Fuel loading was determined from net dry vegetation weights measured after oven-drying vegetation samples at 70°C and surface-area-to-volume ratio was estimated by a detailed analysis of fuel particle geometry. Fuel loading was measured again after the experiment following a similar procedure in order to determine biomass consumption. Fuel moisture was sampled within 30 min of ignition.

2. Experimental Setup to Measure Fire Behavior

Fire behavior was monitored using a combination of in-situ and remote sensors. In-situ air temperature was measured by an array of thermocouples located at ground level and spaced 30 m apart (identified as *HOBOs* in Fig. 1). Remote instrumentation consisted of optical sensors working in the visible (VIS) and long-wave infrared (LWIR) spectral ranges. One VIS and one LWIR cameras were installed on a 40-m observation tower located at the north-west corner of the burn unit. Another VIS and another LWIR camera were installed on a helicopter that flew above the experimental site at about 450 m AGL. Figure 2 shows example frames from the different video sequences.

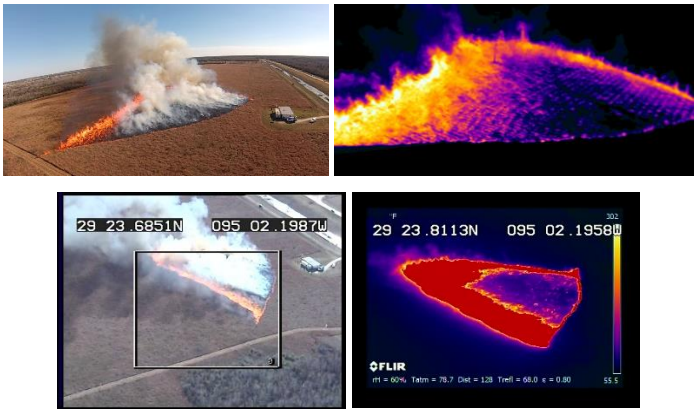

Figure 2- Example frames acquired by the four deployed cameras. Left: VIS, right: LWIR; top: tower-mounted; bottom: airborne.

3. Fire Behavior Characterization

Fire spread was monitored independently using three distinct data sources: the in-situ thermocouple array, the tower cameras, and the helicopter cameras. The observations from these three data sources overlap partially, which is leveraged in this study to accomplish a twofold objective. First, the overlapping regions are used to conduct a comparative analysis of different methodologies that are designed to yield the same result. Second, outcomes obtained from each methodology complement each other, and they are therefore combined to produce a unified dataset that contains comprehensive fire behavior metrics for the complete duration of the experiment.

3.1. In-Situ Thermocouples

Temperature profiles measured by in-situ thermocouples were used to identify the time of arrival of the fire to each sensor. Due to the lack of a unified criterion to identify fire arrival based on temperature time series, we explored three common approaches: identifying fire time of arrival as (a) the time at which the maximum temperature is reached, (b) the time at which the temperature gradient is the greatest, and (c) the time at which the temperature first exceeds a specified threshold. The three strategies produced similar results, although not identical (Fig. 3). Point estimations of fire time of arrival were interpolated to create a 2D map, as shown in Figure 4.

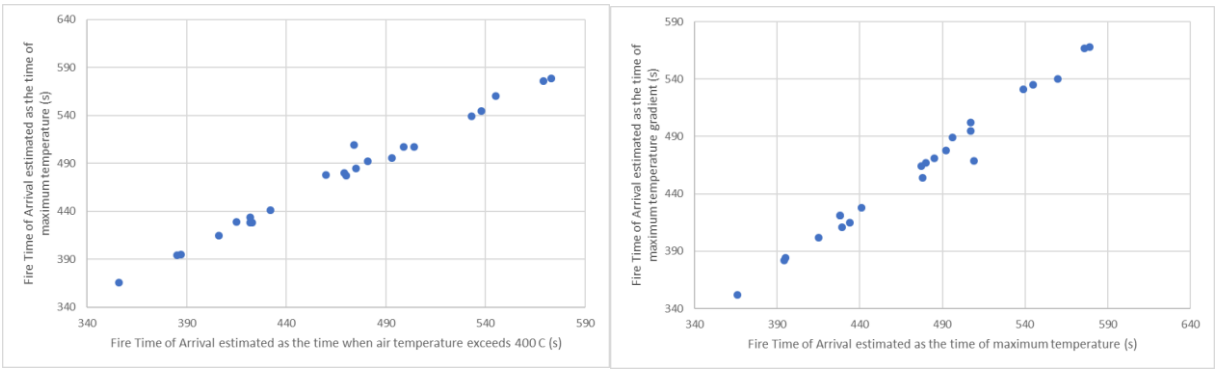

Figure 3- Comparison of different strategies to estimate fire time of arrival from in-situ air temperature measurements.

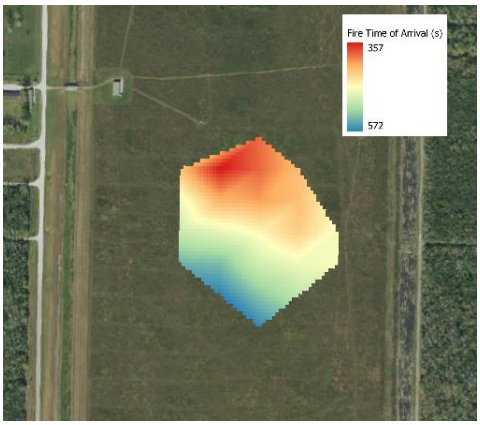

Figure 4- Fire time of arrival, relative to time of ignition, derived from in-situ air temperature measurements. Base image provided by the USDA National Agriculture Imagery Program.

3.2. Tower Remote Sensing

LWIR imagery acquired from the 40-m tower was still and provided a clear view of fire spread in a reduced area of interest, which allowed tracking the fire progression with high resolution and high positioning accuracy. The oblique imagery was geocorrected using ground control points. Resulting georeferenced brightness temperature fields were used to quantify fire progression and estimate fire time of arrival (Fig. 5). Fire progression was tracked using the methodology described in (Valero et al. 2018), whereas fire time of arrival was estimated as the time of maximum brightness temperature.

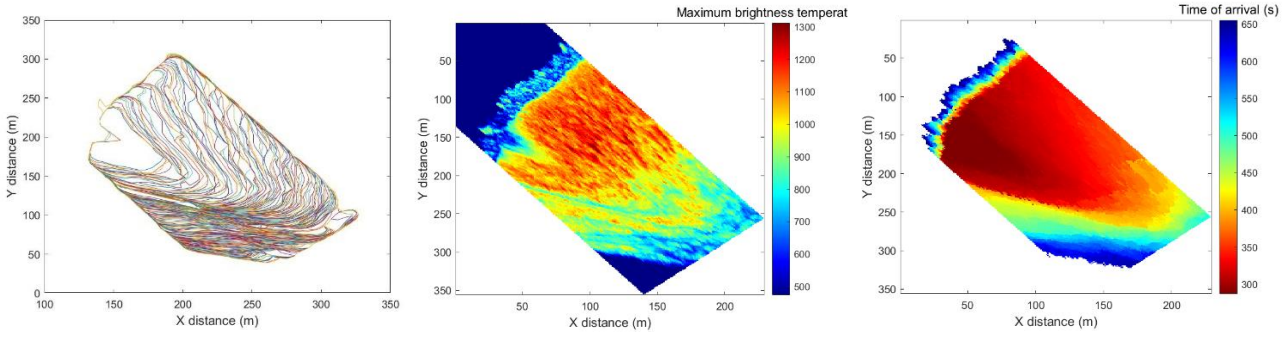

Figure 5- Fire progression (left), maximum brightness temperature registered at each location (center) and fire time of arrival relative to time of ignition (right) derived from the tower LWIR camera footage.

3.3. Airborne Remote Sensing

Airborne imagery complemented the information collected by in-situ and fixed remote sensors by covering a significantly larger area and tracking fire progression during the complete duration of the experiment. The LWIR airborne camera saturated and it therefore did not allow measuring the radiant heat emitted by the fire.

However, it was useful to track fire progression and estimate fire times of arrival for the complete burn unit (Fig. 6).

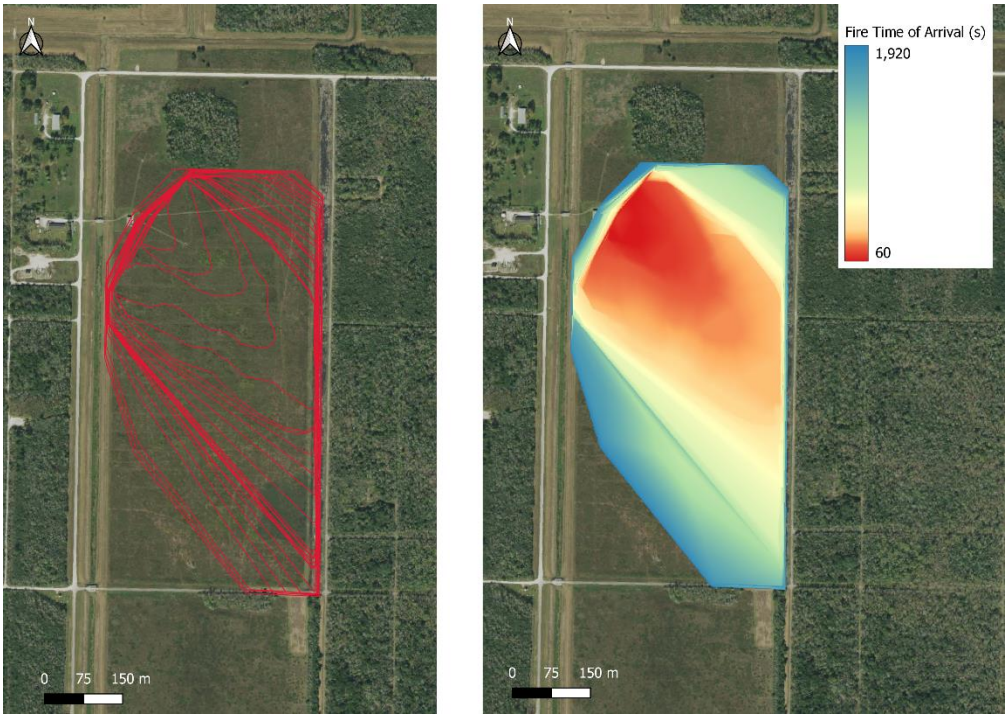

Figure 6- Fire progression derived from the airborne IR imagery. Left: fire perimeter at 60-s intervals. Right: fire time of arrival at every location in the burn unit, relative to the time of ignition. Base image provided by the USDA National Agriculture Imagery Program.

4. Conclusions and Future Work

In this paper, we present preliminary results of a detailed fire behavior analysis during the FireFlux II experiment. The results achieved so far demonstrate the utility of the three analyzed datasets and encourage further processing. Planned future work includes (i) conducting a detailed comparison of the measurements derived from each sensing technique, (ii) expanding the calculated results with additional fire behavior metrics, such as fire radiative power, rate of spread, and fire line intensity, and (iii) homogenizing the results and producing a comprehensive dataset that can be used in model validation exercises.

Fire severity, Burnt area, Spatiotemporal trends, Remote Sensing, Earth Observation

Abstract

Wildfires can pose severe threats to human lives and assets as well as to biodiversity on a global scale. Due to climate, land-use changes, and often inadequate forest management, wildfire regimes are also in transition, causing modifications in these disturbance events' spatial distribution, timing, size, frequency, and severity. In particular, increasing fire severity causes slower post-fire recovery times and a depletion in the resistance and resilience capacities which potentially trigger regime shifts in the state of ecosystems.

Satellite remote sensing (SRS) Earth Observations (EO) allow us to characterize the ecological impacts of wildfires and assess spatiotemporal trends in fire severity. The SeverusPT project is currently pursuing the objective of harnessing SRS/EO time series to characterize wildfire severity and assess its impacts on ecosystems. Our primary objectives of this exploratory research paper are two-fold: (i) assess national and regional spatiotemporal trends in fire severity and burnt area, and (ii) evaluate if fire severity regionally scales up with the total burnt area. Satellite image time series (SITS) from Terra/MODIS were obtained to calculate fire severity through the Normalized Burn Ratio (NBR) and the difference between pre- and post-fire (ΔNBR). Trend analyses were employed to quantify fire severity and burned area spatiotemporal patterns. Linear regression assessed the association between total burnt area by year/region (predictor) and fire severity (response).

Preliminary results show that at a national level, from 2001 until ca. 2008 - 2009 there was a general decrease in fire severity, followed by a reversal of this trend. This turning point has led to a general increase, with new severity highs formed in 2017 and 2020. We also found wide variation in fire severity at the regional level (NUTS-III), and trend analysis displayed that most regions increased both in burned area and severity. Linear regression showed that burned area and fire severity are correlated despite this association being highly structured at the regional level, forming a continuous spectrum from highly area-severity coupled regions (e.g., AM Porto, Médio Tejo, Viseu, Coimbra, Alto-Minho) to less coupled ones (e.g., Cávado, Trás-os-Montes, Alentejo). These results may support that the increasing amount and size of burnt area will scale up into higher fire severity for specific regions. These preliminary results from the SeverusPT project show that MODIS image time series allow assessing the spatial variation and the temporal trends of fire severity in a standardized and synoptic fashion. Future research using Landsat time series will aim to further assess these trends and profit from the data archive and the increased spatial resolution of this satellite mission. Mapping fire severity, its spatiotemporal variation and addressing its environmental drivers are now more crucial than ever to understand its dynamics and support fire management and prevention.

1. Introduction

Fire can relevantly introduce (socio-)ecological disturbances worldwide, impacting ecosystem composition, structure, functioning, and the provision of ecosystem services to humanity (Bowman et al., 2009). Modification

of fire regimes due to global environmental changes is thus at the forefront of social concerns motivating the improvement of policy and planning instruments regarding fire risk management and land tenure/use, natural resource management, and territorial governance.

Despite the vast investments in fire suppression, extreme fire events have increased across Mediterranean Europe. These extreme events, exacerbated by global climate change and fuel accumulation, often override the capacity of fire-suppression systems, putting human lives and livelihoods at risk. Assessing and predicting the effects of those events on ecosystems (i.e., fire severity), especially under a changing climate, is paramount for adequate fire prevention and fighting.

Surprisingly, there is a significant gap of publicly available, standardized and validated datasets on fire severity. Overcoming this gap is the central goal of SeverusPT, which is currently developing a framework for assessing, mapping and predicting fire severity based on satellite indicators of ecosystem functioning. A combination of metrics derived from satellite multi-spectral images (e.g. the difference Normalized Burn Ratio; ΔNBR), with data collected in-field (e.g. through the Composite Burn Index; CBI) is being exploited to assess fire severity (e.g. Cardil et al., 2019), conveying post-fire measures of environmental and ecological impacts due to fire (e.g., Koutsias et al., 2013; Tedim et al., 2017).

Our primary objectives with this exploratory research are two-fold: (i) assess national and regional spatiotemporal trends in fire severity and burned area, and (ii) evaluate if fire severity regionally scales up with total burnt area (i.e., a putative and here tentatively called "fire area – severity coupling" hypothesis).

2. Methods

2.1. Study area

This study area comprises mainland Portugal covering an area of approximately 89,100 Km^2, considered one of the countries of southern Europe with a greater incidence of forest fires in the last decades. Elevation ranges from 0 to 1993 meters, with the mountain areas occurring mainly in the north. The climate ranges from temperate Atlantic in the northwest to dry Mediterranean in southern regions. The average annual temperature varies from 4 °C in the northern mountainous interior to 18 °C in the south.

2.2. Time series data and statistical analyses

Satellite image time series (SITS) from Terra/MODIS product MOD13Q1 (version-006) containing vegetation indices at 16-day/250m were obtained to calculate fire severity through the Normalized Burn Ratio (NBR) index. NBR consists of the normalized difference between the near-infrared band #2 (NIR, 858 nm) and the shortwave-infrared band #7 (SWIR, 2130 nm), as:

$NBR = (NIR_{b2} - SWIR_{b7})/(NIR_{b2} + SWIR_{b7})$ (Eqn. 1).

A high NBR value typically characterizes normal or "healthy" vegetation, whereas low values indicate bare ground and/or recently burnt areas. Delta NBR, calculated as the difference between the pre-fire and the post-fire NBR, was used as an estimate of fire severity as:

$\Delta\text{NBR} = \text{NBR}_{pre\_fire} - NBR_{post\_fire}$ (Eqn.2).

A higher value of ΔNBR generally indicates more severe damage, whereas negative values may indicate less severely affected areas or even short-term recovery following a fire. To calculate a standardized annual time-series of ΔNBR between 2001 and 2020 for mainland Portugal, we considered the characteristic phenology of fire mostly concentrated around summer/early-fall months (Marcos et al., 2019) and defined the post-fire period from September-November and the pre-fire between March-May. Within the pre- and post-fire periods, all available NBR images were averaged through the median hence applying the following formula:

$\Delta\text{NBR} = \text{median}(\text{NBR}_{\{Mar-May\}}) - \text{median}(NBR_{\{Sep-Nov\}})$ (Eqn.3).

As a non-parametric/rank-based measure, the median is less affected by cloud cover and noise in the data. All Eqn.1-3 calculations were performed using Google's Earth Engine planetary-scale geospatial analysis platform (Gorelick et al., 2017). Based on the annual ΔNBR time series, we extracted the values only for fire perimeters (at annual time steps) identified in the National Burnt Area Database (NBAD) for mainland Portugal from

2001to 2020 (ICNF, 2022). NBAD was also employed to calculate the total burnt area and the distribution of fire perimeters at the regional NUTS-III inter-municipal level using R statistical software and the *terra* package (Hijmans, 2022). National and regional-level statistics of fire severity based on quantiles were calculated. Annual time-series plots (employing loess/moving-average smoother) were employed to assess spatiotemporal patterns of severity. Linear regression was employed to assess the relation (i.e., the degree of coupling) between total burnt area by year/region (predictor) and fire severity (response). The coefficient-of-determination (R^2) and the F-statistic p-value were estimated to convey the strength of this association and its statistical significance.

3. Results and Discussion

3.1. General trends of fire severity in the last two decades (2001 – 2020) in mainland Portugal

These preliminary results from the SeverusPT project show that MODIS image time series allow assessing the spatial variation and the temporal trends of fire severity in a standardized and synoptic fashion. Satellite data is particularly useful to assess micro- to mesoscale variation in severity (Fig.1–a) and identify slightly scorched or unburnt "islands" which hold particular relevance for post-fire biological/ecological recovery (e.g., Santos et al., 2022) across different time-frames (Torres et al., 2018) and ecosystem dimensions (Marcos et al., 2021). Such variations in fire severity can be caused by a multitude of factors such as the spatial distribution, type, state, shape, and vertical structure of fuels, as well as microclimate and weather conditions, topography, geomorphology and fire suppression efforts. These factors combine to shape the fine-scale and anisotropic variations, with fire edges typically exhibiting lower severity (Fig.1–a). SITS also excel in characterizing temporal trajectories in severity with widely different profiles from triangular patterns (potentially showing cyclical decreases and increases in biomass triggered by highly frequent fires with, respectively, less and more severity, Fig.1–b). In contrast, we also found areas with increasing fire severity where, potentially, biomass decreases caused by fire are unmatched by fast recovery times and progressive post-fire biomass accumulation coupled with fire-prone weather conditions in subsequent events.

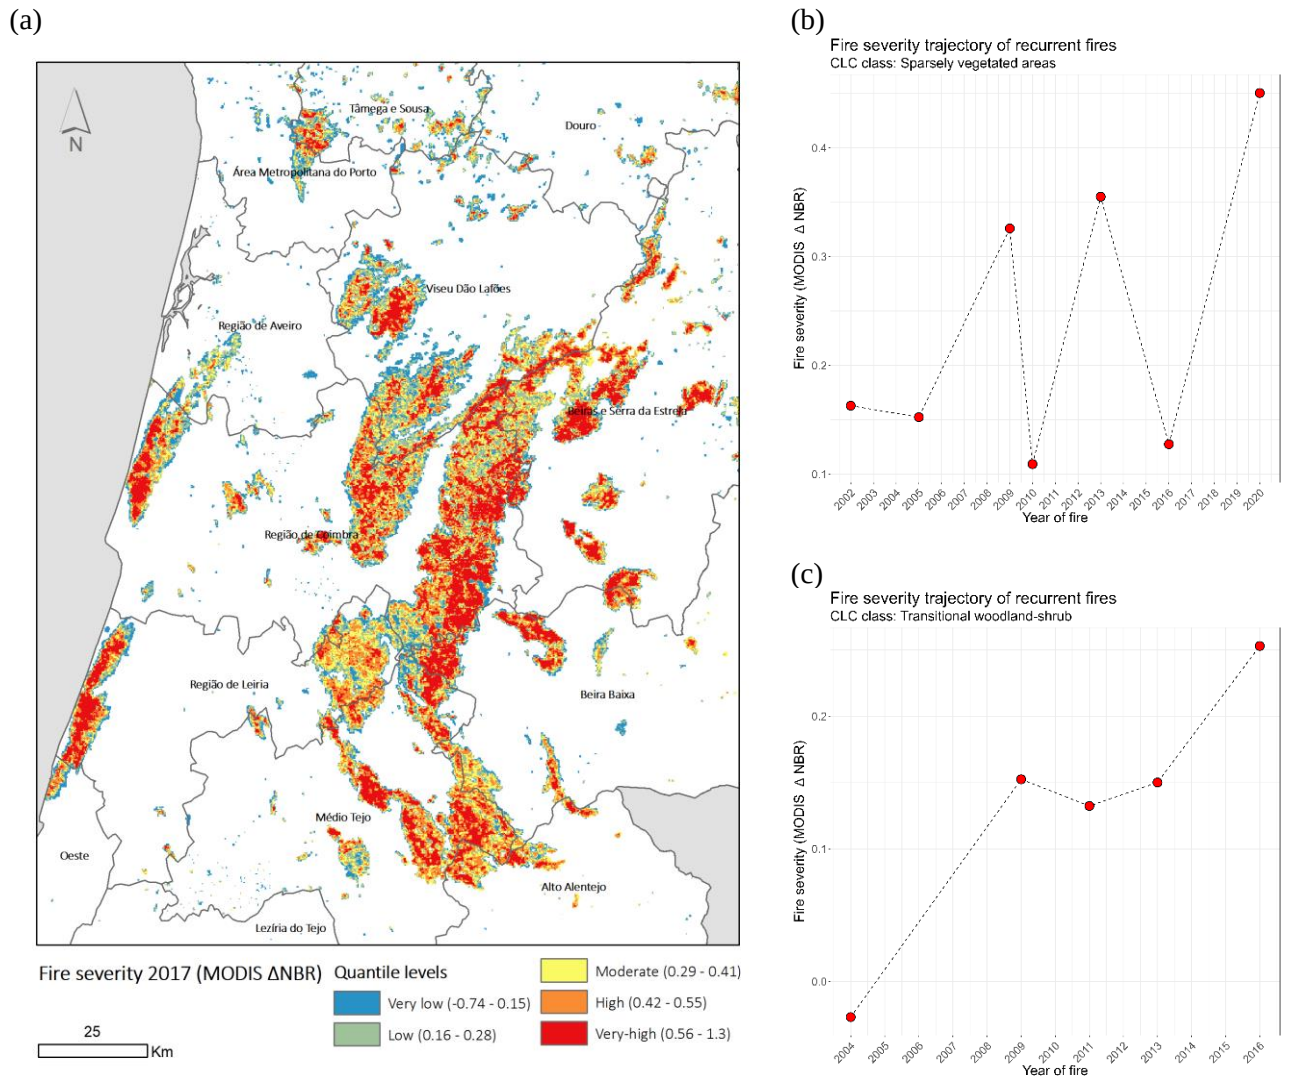

Figure 1 – (a) MODIS ΔNBR image shows the spatial variation of fire severity within and between fire perimeters of 2017. Each severity level is based on the 20% quantiles of the annual distribution. (b) and (c) comprise two illustrative severity trajectories for recurrent fires in a sparsely vegetated area following a triangular pattern (b) and transitional woodland-shrubland (c) with a monotonic linear increase trend in severity. Each point in these plots shows the severity of each fire event for a given area.

Preliminary results also show that, at a national level from 2001 until ca. 2008 - 2009 there was a general decrease in fire severity, followed by a reversal of this trend. This turning point has led to a general increase with new severity highs formed in 2017 and 2020 (Fig.2). This trend reversal also led us to separately consider this nested period of 2008 – 2020 for subsequent analyses.

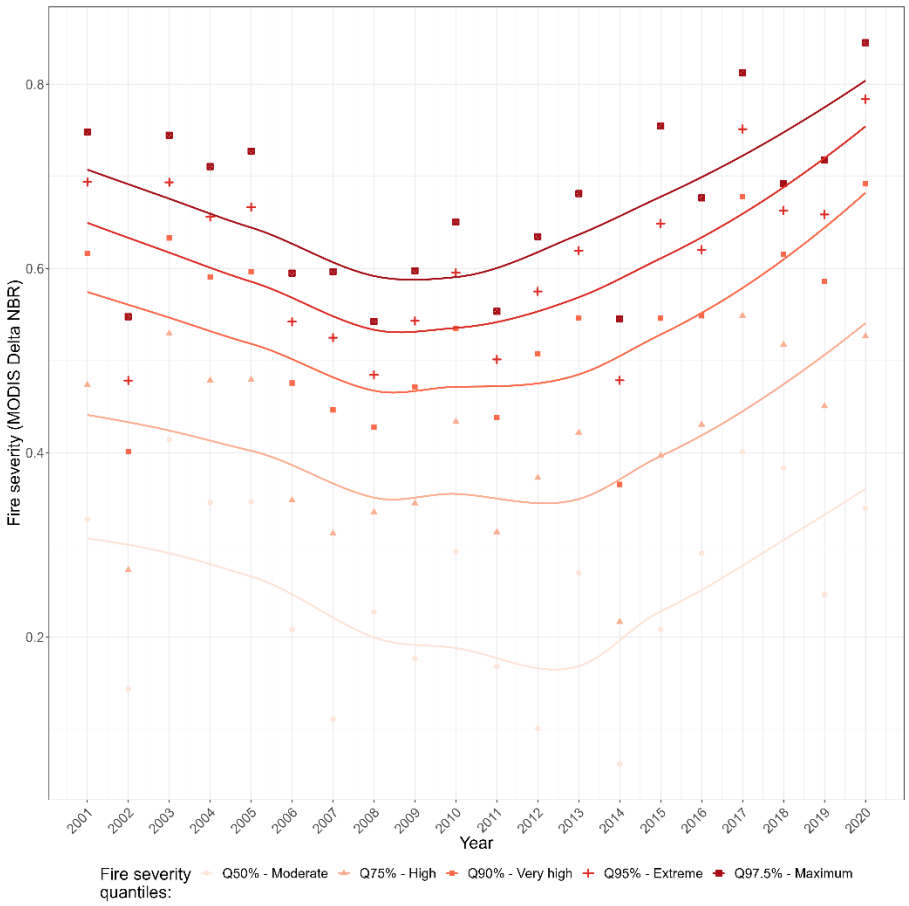

Figure 2 – Fire severity trends for mainland Portugal between 2001 and 2020 across different severity levels based on distribution quantiles (Q50% - moderate, Q75% - High, Q90% - very-high, Q95% - extreme and Q97.5% - maximum).

Moreover, preliminary results also show that there is wide variation in fire severity at the regional level (considering NUTS-III inter-municipal units; Fig.3) with the Region of Aveiro, Ave, Área Metropolitana do Porto, Médio Tejo, Terras de Trás-os-Montes and Alto-Minho recording the most significant increases since 2008 from average (50% quantile) to very high severity fires (97.5% quantile).

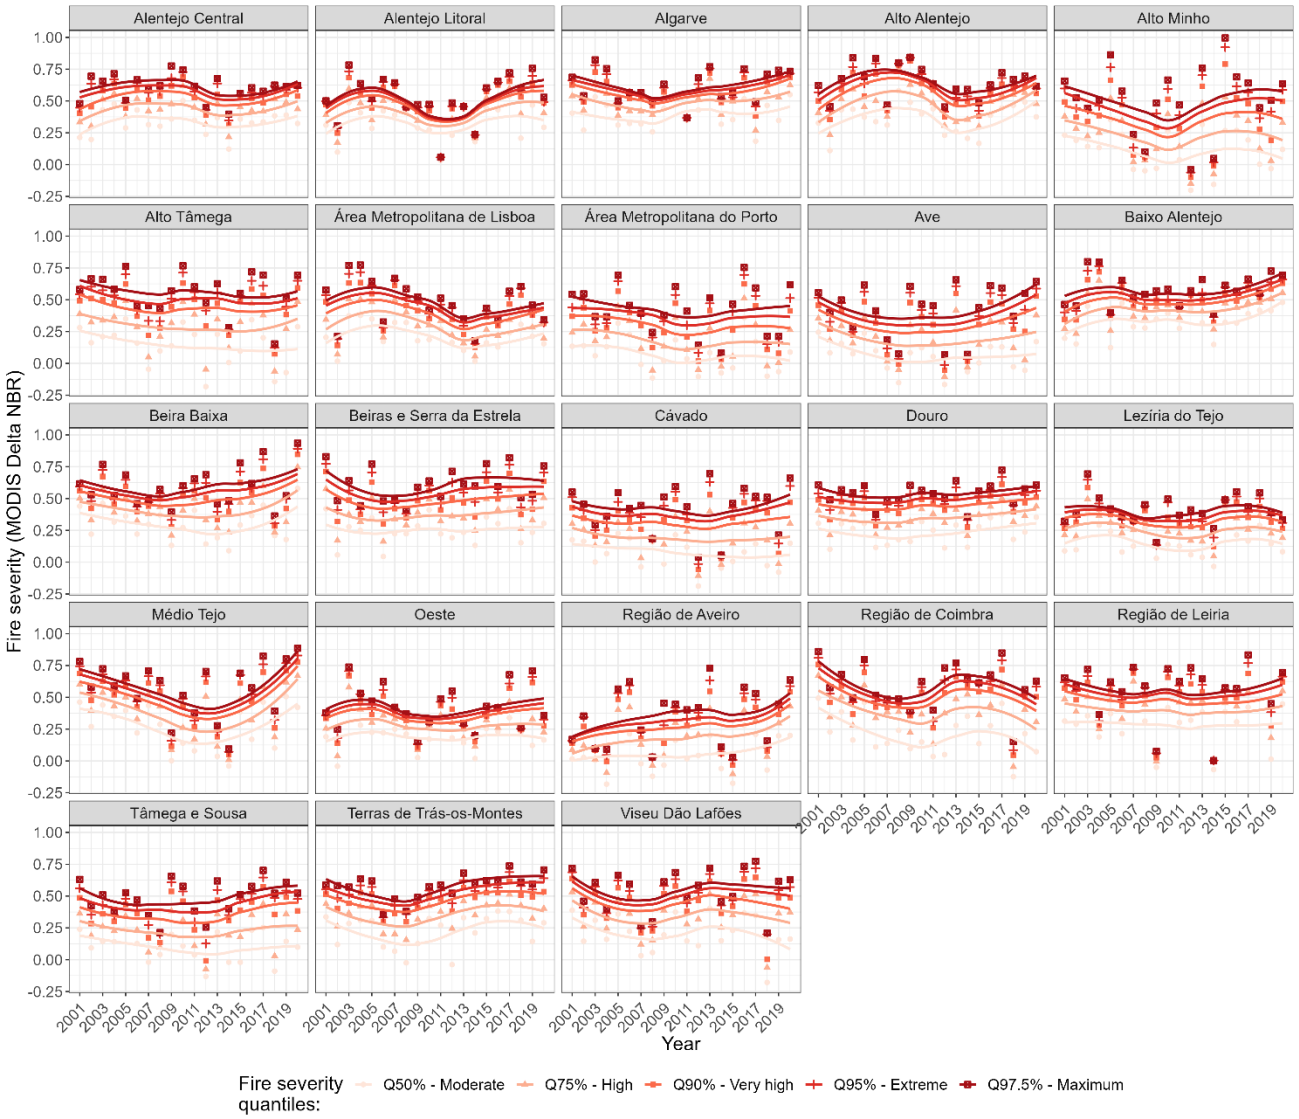

Figure 3 – Fire severity trends for mainland Portugal intermunicipal regions (NUTS-III) between 2001 and 2020 across different severity levels based on distribution quantiles (Q50% - moderate, Q75% - High, Q90% - very-high, Q95% - extreme and Q97.5% - maximum).

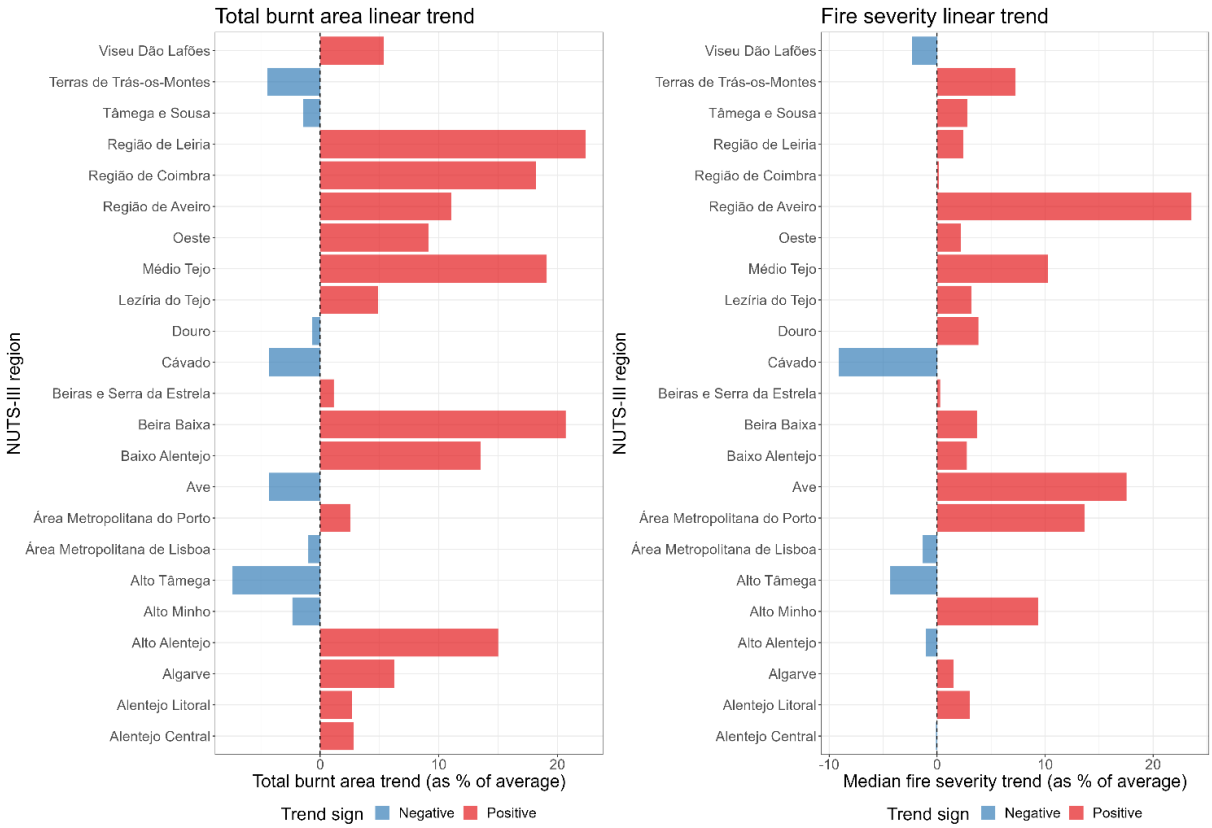
When comparing the temporal trends of burnt area *vs* median fire severity across NUTS-III regions (for 2008-2021; following the trend reversal period), preliminary results show that the most frequent class is the one combining the increase of both burnt area and severity (Fig. 4). These regions are primarily located in the country's centre portion (from AM Porto to Lezíria do Tejo) and south (Alentejo Litoral/Sul) portions. Slightly more complex combinations occur in the north with decreased trends in burnt area and severity for Cávado and Alto Tâmega regions. In contrast, a combination of burnt area decrease and severity increase is found for Alto Minho, Ave, Tâmega-Sousa, Douro and Trás-os-Montes regions. We found few regions with burnt area increase and severity increase trends, including Viseu-Dão-Lafões, and Alto/Central Alentejo.

(a)



(b)

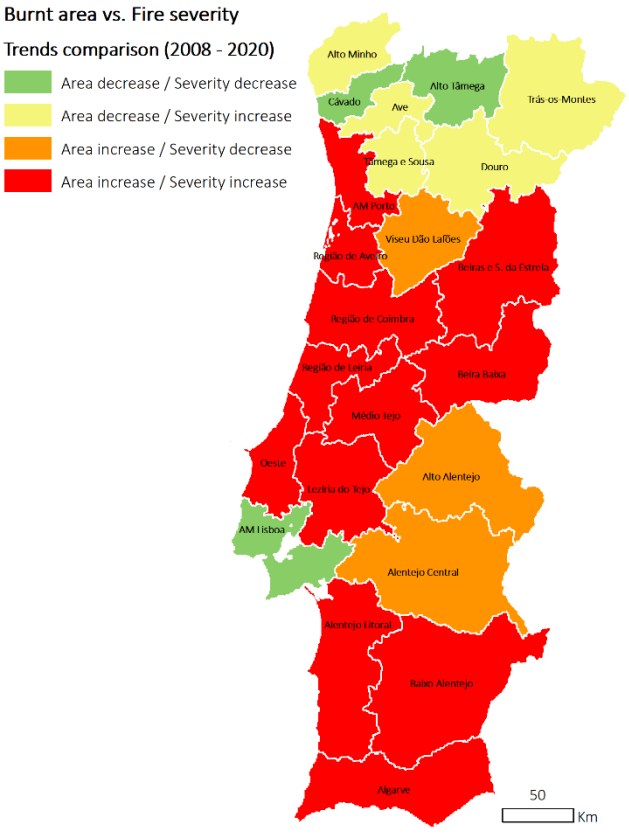


Figure 4 – Comparison of temporal trends of total burnt area vs fire severity across inter-municipal regions of mainland Portugal (NUTS-III), considering the period 2008-2021

(a) Linear trend analysis was employed and expressed as the percentage of average change. The trend sign is positive, i.e., increasing impact across time in the burnt area and/or fire severity, and negative if otherwise.

(b) Map depicting the combination of trends for the burnt area and fire severity for different NUTS-III regions.

Linear regression analyses allowed us to evaluate that burnt area and fire severity are indeed correlated. However, the nature of this relationship is highly structured at the regional level, forming a continuous spectrum of variation from highly area-severity coupled regions – with a higher coefficient of determination (R^2) values (e.g., AM Porto, Médio Tejo, Viseu, Coimbra, Alto-Minho; Fig.5) – to uncoupled regions (e.g., Cávado, Alentejo) with lower regression R^2's.

These results may support the (tentatively called) "fire area – severity coupling" hypothesis, in which, for specific regions (Fig.6), the increasing amount and size of burnt area will scale up into higher fire severity.

Overall, "coupled" regions are located in the northern and central portions of the country (exceptions to Cávado, and Trás-os-Montes; Fig.6) and the southern-most region of Algarve. For these regions, the observed fire area-severity scale-up will potentially cause a higher depletion of ecosystems functioning capacities and resilience and trigger longer recovery times (Marcos et al., 2021; Torres et al., 2018).

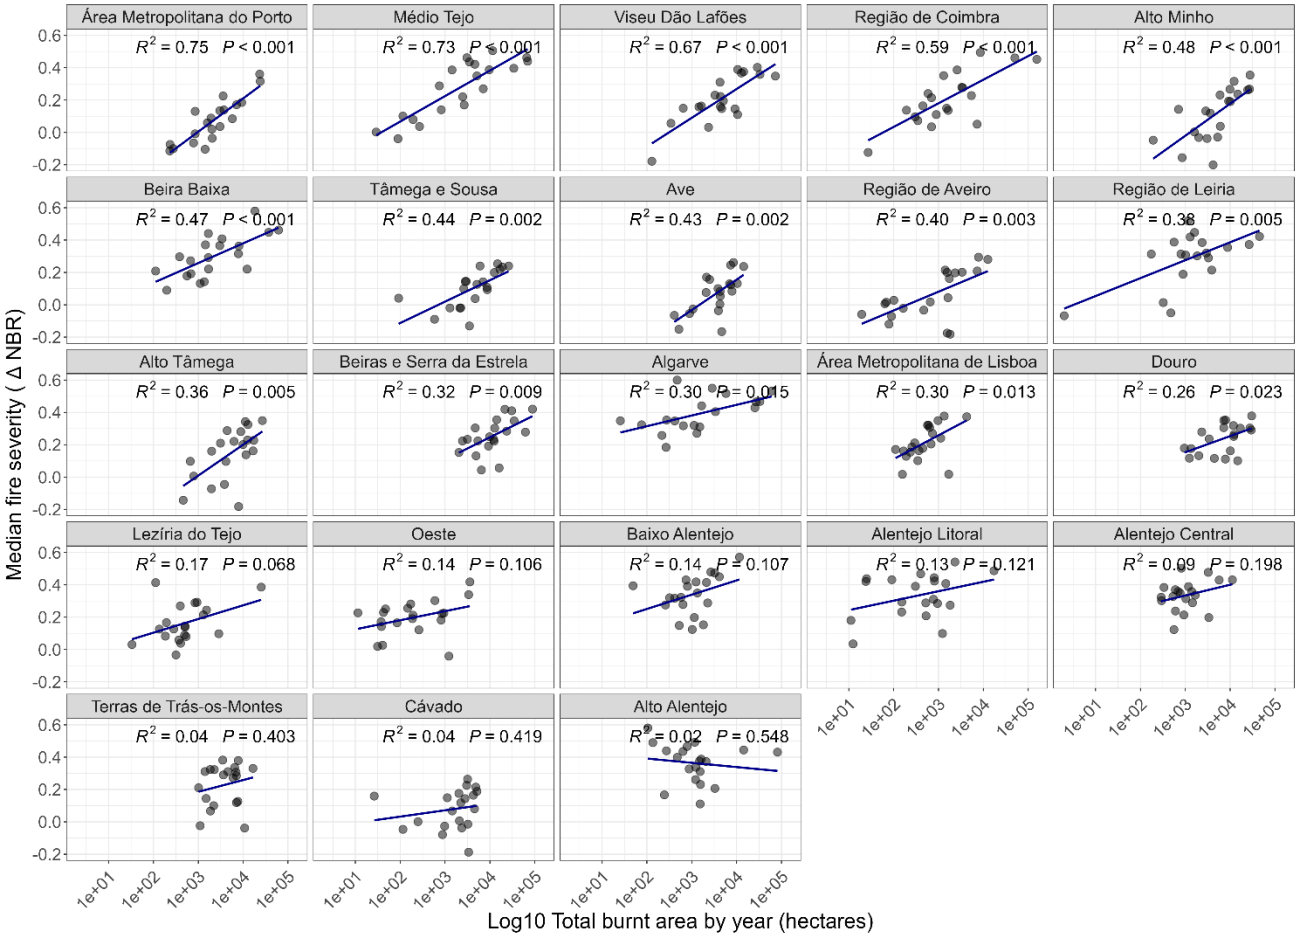

Figure 5 – Linear regression plots between total burnt area per year (2001-2020) and median fire severity (MODIS ΔNBR). Plots are shown for are all mainland NUTS-III regions and displayed by decreasing R^2 value.

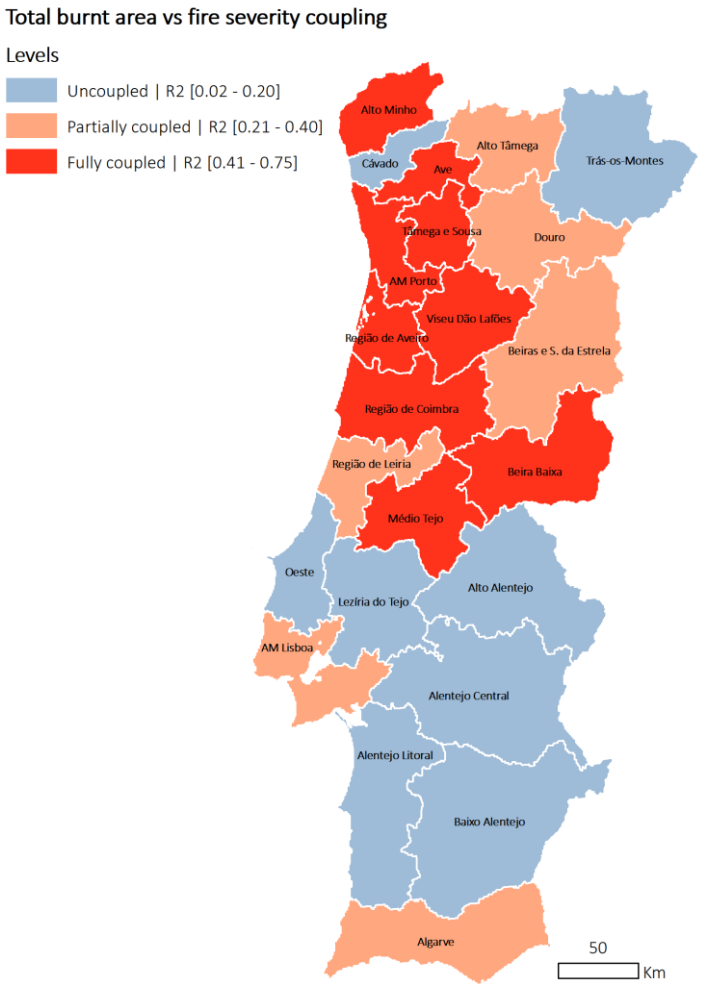

Figure 6 – Coupling between total burnt area (2001-2020) and fire severity assessed through MODIS ΔNBR.

4. Final remarks and future work

Mapping fire severity, its spatiotemporal variation and addressing its environmental drivers are now more crucial than ever to understand its dynamics and support fire management and prevention. This exploratory research shows preliminary results from the SeverusPT project addressing these goals and exploring trends and the regionally varied scaling between burned area and fire severity.

Such phenomena must be adequately addressed with different strategies across distinct regions to contain and prevent further damage from wildfires to ecosystems. Future work will examine and attempt to model the drivers of the "*fire area – severity coupling" hypothesis* and exploit finer-scale satellite image time series and improved algorithms to expand current results. In particular, Landsat time series will aim to further assess these trends and profit from the long historical data archive and the increased spatial resolution of this satellite mission.

Abstract

Computational models of wildfires are an important tool for fire managers and scientists. However, fuel inputs to wildfire models can be difficult to represent with sufficient detail to be both computationally efficient and representative of observations. Recent advances in fuel mapping with airborne and terrestrial laser scanning (LIDAR) techniques present new opportunities to capture variation in fuels within a tree canopy and on a landscape. In this paper, we develop a technique for building 3D representations of vegetation from point clouds created by Terrestrial Laser Scans (TLS). Our voxel based approach can be extended to represent heterogeneous crown fuels as collections of fuel cells in modern 3D Computational Fluid Dynamics wild fire models such as FDS, QUIC-Fire, or FIRETEC. We evaluated the effectiveness of our technique at different fuel cell resolutions by using the DAKOTA optimization toolkit to compare simulated fire behavior in FDS with observed burn data collected during a series of experiments at the Missoula Fire Sciences Laboratory. The primary finding was that within the search space of point cloud derived fuel cells, we find accurate descriptions of observed fire behavior with the FDS model. We also find that within our search space, regions of global minima are consistent across fuel cells at different resolutions. This finding suggests that while new techniques are capable of characterizing fuel models with a high degree of fidelity, high resolution 3D fuel models do not improve parity with observed fire behavior in the FDS fire model. The results of this paper offer fire modelers guidelines for translating LIDAR data to 3D fire models, and what fuel cell resolution can best capture accurate fire behavior.

1. Introduction

Wildfires are an increasingly visible natural phenomenon across the globe. In the United States, 43,371 structures were lost due to wildfires from 2016-2019 (National Interagency Fire Center 2019), and the Wildland Urban Interface (WUI), the area where houses and vegetation intersect, was the fastest growing land use type in the United States from 1990-2015 (Radeloff et al. 2018). Despite the threat to homes in the WUI, wildfires have historically been an integral part of North American forest, brush, and grassland ecosystems, and by pursuing a policy of wildfire suppression since the early 20th century, land managers have altered fire regimes in much of North America (Arno and Brown 1991). In addition to a more complicated landscape from an expanded WUI and altered fire regimes from fuel loading, fire managers also have to account for the effects of a warming climate on fire conditions. The number of areas with the potential to be adversely affected by wildfires has increased in the 21st century. Tools for mitigating the threat of wildfire to fire sensitive areas, such as the WUI, have traditionally included a combination of thinning projects and prescribed burns (Arno and Brown 1991). Unfortunately, the tools developed to evaluate the efficacy of such projects on a local scale rely on limiting assumptions, cannot be generalized across landscapes, and do not account for rapidly changing fire regimes due to climate change (Parsons et al. 2018).

Physics based Computational Fluid Dynamic (CFD) models present a possible solution to these problems by providing a mechanism to study fire behavior in heterogeneous vegetation and dynamic fire environment conditions (Linn et al. 2020). However, CFD models must be coupled with accurate models of fuel to realistically represent fire behavior (Parsons et al. 2011, Atchley et al. 2021).

Fortunately, rapid advancements in remote sensing techniques have introduced new methods capable of meeting the data requirements of physics based fire models. LIDAR is a promising remote sensing technology for the 3D characterization of vegetation and fuels (Hudak et al. 2017). Point clouds are capable of measuring vegetation height, cover, and relative density – all of which play important roles in determining fire behavior. Critically, these fuel measurements play an important role in determining the transition relationship between quasi steady-state surface fires and more extreme fire behavior such as torching and crowning, which can be crucial to understanding the fire risk of a given landscape (Parsons et al. 2017).

Despite these promising advancements in fire and fuels modeling, there are still significant gaps in the research linking fuel models to the fire modeling environment. Fire modelers must balance careful tradeoffs between computational expense, data collection, and grid resolution when deciding how to represent vegetation as 3D gridded input data. To date, no comparisons have been published between observed fire behavior and simulated fire behavior of LIDAR-derived fuel cells. This paper explores the concept of altering three-dimensional fuel cells in terms of moisture content, bulk density, and resolution to provide an algorithmic approach to translating LIDAR point clouds into a CFD based simulation environment.

Leveraging TLS and mass over time data collected in 2021 on burning saplings at the Missoula Fire Sciences Laboratory, we developed a methodology for representing complex vegetation in three-dimensional fuel cells. Then, we tested the effect of fuel cell descriptors such as fuel moisture content, bulk density, and resolution on modeled fire behavior in the FDS model. We present our methodology, which can be used to translate point cloud data to any CFD fire model with gridded fuel inputs such as FDS, FIRETEC, or QUIC-Fire. Lastly, we provide fire modelers with heuristics for making decisions on fuel cell fidelity in order to balance simulation accuracy with computational requirements using the FDS model.

2. Methods

The sapling burn experiments reported here were conducted in the Missoula Fire Sciences Laboratory burn chamber. The experiment was designed to examine the effect of drought stress on tree mortality when exposed to two controlled levels of fire intensity. We acquired 123 saplings of two species, Engelmann spruce (*Picea engelmannii*) and Ponderosa pine (*Pinus ponderosa*), from a local nursery. Saplings were acquired in May and stored in planter containers filled with soil and with the roots intact. During this storage period, half of the saplings from each species were given a low water treatment of water every one to two weeks so as to mimic conditions of a drought environment. The other half were adequately watered every three days so as to encourage normal development.

Each day of the experiment, saplings were transported to the burn chamber and ignited over a pair of concentric ring gas burners. During the ignition period, each sapling was exposed to one of three fire intensity categories: no fire treatment, low burner treatment, or high burner treatment. At the time of the fire treatment, a tree was placed through the hole such that the tree stand rested on a scale. Additionally, the weight of the sapling was recorded during the burning period with a load balance transmitting at 0.5 Hz.

For each sapling, three-dimensional scans were collected from a Leica Geosystems BLK360 Terrestrial Laser Scanner. Two scans were taken from the same location before and after the burn treatment. The TLS was run at a high density setting with a reported resolution of 5mm at 10 meters. Because the scans were taken in the same location, static references in the burn chamber were present to facilitate spatial referencing. The two scans were co-registered using Cyclone Register 360 software from Leica Geosystems in order to create a single 3D point cloud. Figure 1 shows the experimental setup with LIDAR scanner.

Figure 1- Experimental setup with LIDAR scanner at the Missoula Fire Sciences Laboratory

There are several challenges associated with correlating 3D point clouds to fine fuel mass and location without the use of destructive sampling. A higher point cloud density does not necessarily correlate to a higher density of foliage or stem biomass. A voxel based representation of the experimental saplings offers numerous advantages. Duplicated points from stitching multiple scans are represented as a single voxel, voxels represent points returned to the scanner in addition to points occluded by overlapping woody material, and voxels are one step closer to the concept of a 3D fuel cell necessary for input to a CFD fire model (Hosoi and Omasa 2006).

Our voxelization technique begins by identifying reference voxels. A reference voxel is the smallest possible voxel representation of a point cloud given the physical constraints of the TLS device and the scanning environment. Reference voxels have a Boolean value indicating the presence or absence of points within the voxel. We chose 1cm x 1cm x 1cm voxels for our reference voxel size due to the reported 5mm point density at 10 meters of the TLS device. We construct voxels at coarser resolutions by creating a voxel grid in the point cloud domain and counting the number of reference voxels that occur within the voxel at the desired resolution. When the voxel is converted to a fuel cell, biomass is distributed in proportion to the number of contained reference voxels.

We conducted a multidimensional parameter study using the DAKOTA optimization toolkit. Each n-dimensional sample generated by DAKOTA contains parameters for fuel cell resolution, fuel moisture content, and total dry foliage mass. We used the FDS lagrangian particle model to simulate the experimental burn for each sapling at five different fuel cell resolutions. FDS outputs foliage mass at 100 Hz which we used to compute a loss function between simulated and modeled fire behavior. Figure 2 shows a complement of five FDS simulations of the same sapling across five different fuel cell resolutions.

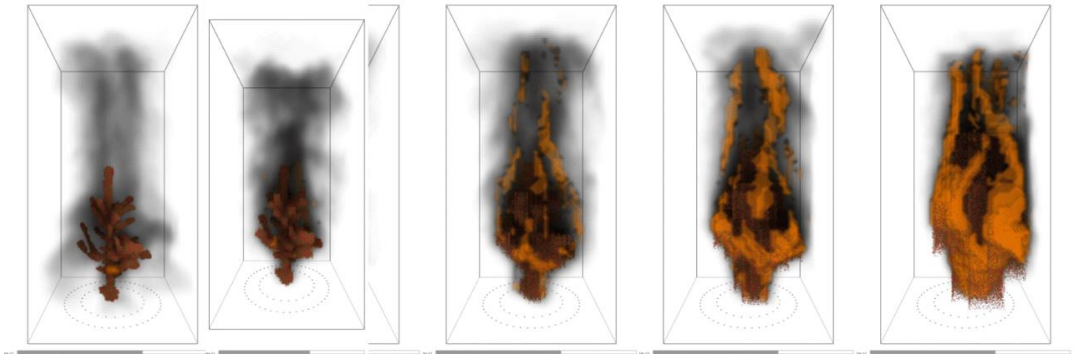

Figure 2 - FDS simulations of a burning sapling at different fuel cell resolutions

3. Results

We computed the RMSE of each simulation in the parameter sweep across sixteen saplings. For each sapling, we found the minimum RMSE determined from comparing the mass loss curves for observed and simulated burns. Figure 3 shows the minimum RMSE found in the set of simulations for Engelmann spruce sapling S63. We observe close parity between the simulated and observed mass loss in both the shape of the curves and the resulting change in mass.

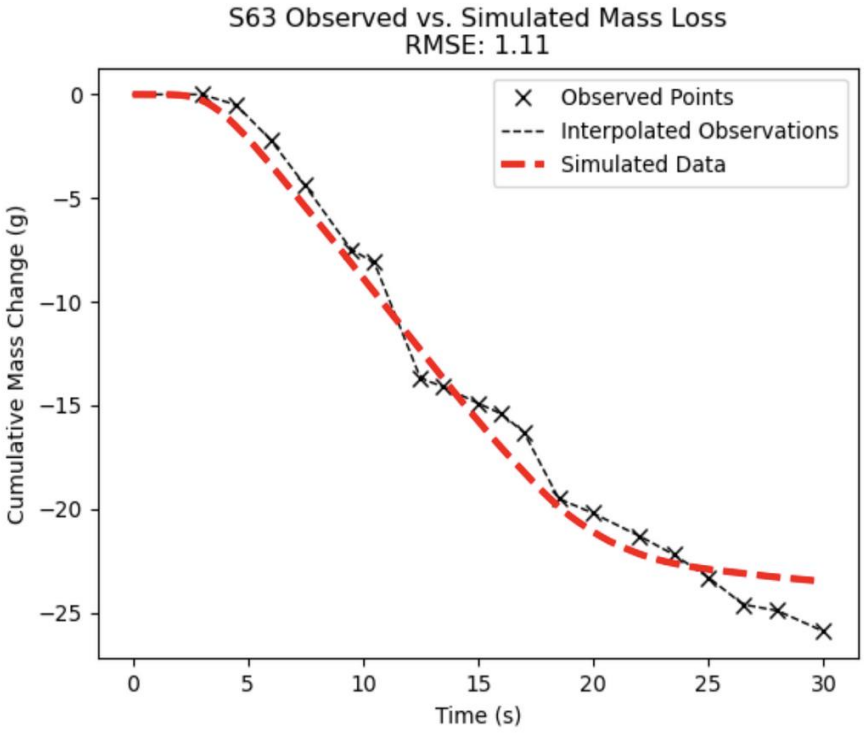

Figure 3 - Comparison between simulated and observed curves of cumulative mass change. This is the lowest RMSE value found out of the 16,384 model runs.

The correspondence between RMSE and the independent variables allows us to examine the space sampled by DAKOTA in our multidimensional parameter study. Figure 4 shows the results of the numerical experiment as described above for one Engelmann spruce sapling. Each pane in the image represents a parameter sweep across 2D points for a given fuel cell resolution. Each pixel has a value for fuel moisture content and dry foliage mass. Fuel moisture content was sampled uniformly in the range [20, 350]%, and dry foliage mass was sampled in the range [10, 80]g for a total of 256 points for each sampled fuel cell resolution.

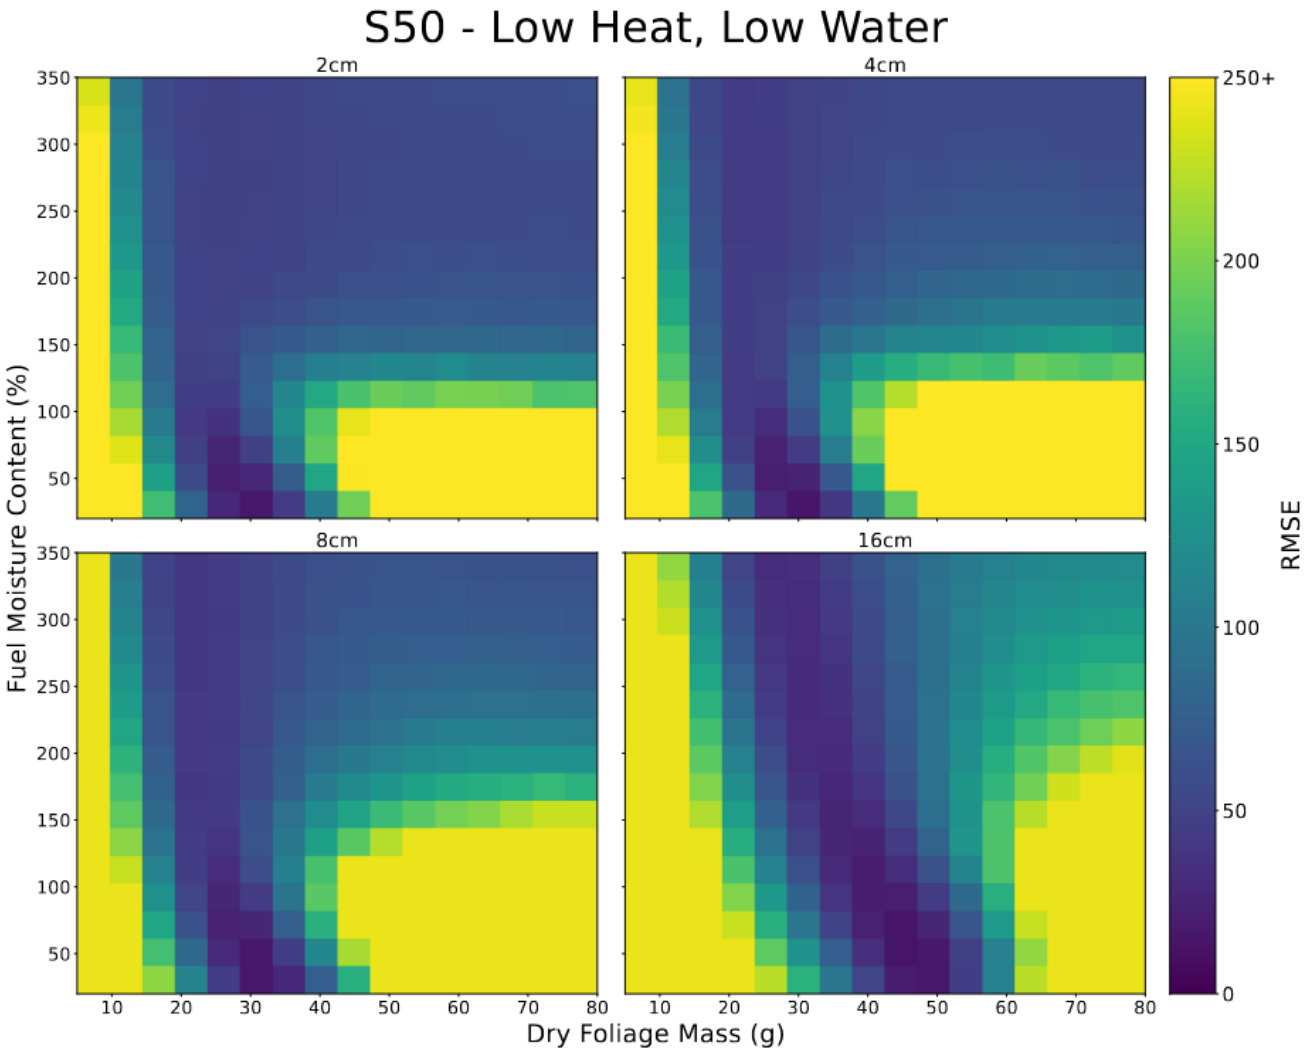

Figure 4 - Distribution of RMSE values for the full 1,024 samples in the parameter sweep for sapling S50. The upper left pane is for simulations with a fuel cell resolution of 2cm, upper right for 4cm, bottom left for 8cm, and bottom right for 16cm. The x and y axis of each pane correspond to the sampled range of dry foliage mass and fuel moisture content. Each pixel is colored according to the RMSE resulting from the comparison between the simulated model output and the observed data for sapling S50.

The multidimensional parameter study identifies a region of consistent minima across all fuel cell resolutions. The model is sensitive to dry foliage mass values as evidenced by the areas of high RMSE below 25g and above 50g along the x-axis in figure 4. Minimum RMSE values occur at higher dry foliage mass values for the coarsest fuel cell resolution of 16cm x 16cm x 16cm. Additionally, the model shows sensitivity to fuel moisture content. This effect is more pronounced when dry foliage mass is high, and the model appears less sensitive to fuel moisture content when the dry foliage mass is low. The parameter sweep identifies a consistent region of minima across all fuel cell resolutions. We find that the coarsest fuel cell resolution expands the area of RMSE minima across a larger range of dry foliage mass values.

In addition to the parameter space plots for individual saplings, we also analyze the effects of independent variables on RMSE. We compute the Pearson correlation coefficients between dry foliage mass, fuel moisture content, and fuel cell resolution on the logarithm of RMSE for each of the sixteen multidimensional parameter studies. The distribution of correlation coefficients are displayed in Figure 6. This result suggests that fuel cell resolution has a significantly lower ability to predict RMSE than dry foliage mass or fuel moisture content.

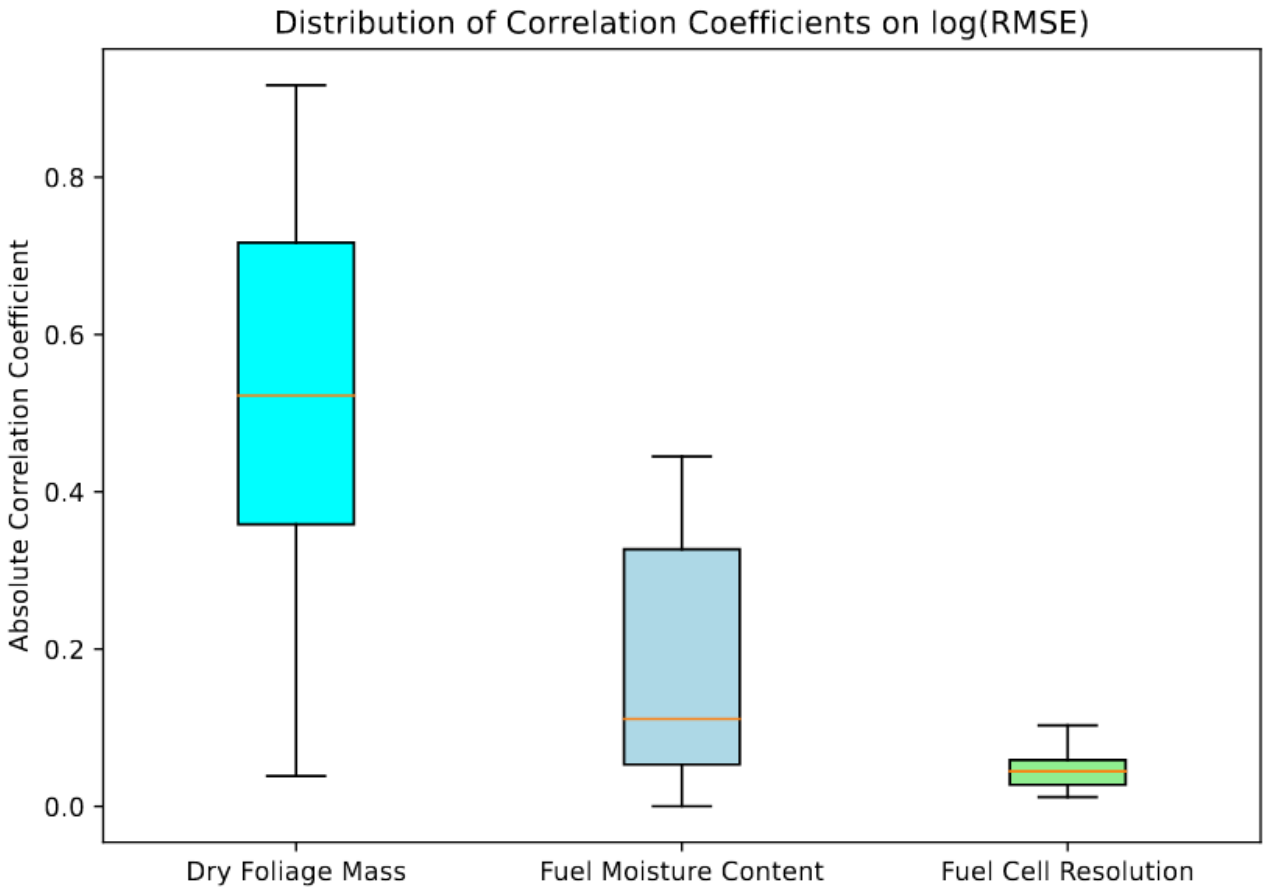

Figure 6 - Box and whisker plot of the distribution of correlation coefficients between log(RMSE) and three independent variables: Dry Foliage Mass, Fuel Moisture Content, and Fuel Cell Resolution for n=16 saplings. The box extends from the first quartile (Q1) to the third quartile (Q3) of the data, with a line at the median. Whiskers extend from the lowest correlation coefficient to the highest correlation coefficient in the data. We take the absolute value of the correlation coefficient in order to capture the magnitude, but not the direction, of the correlation.

4. Discussion

In this study we developed a methodology for describing heterogeneous canopy fuel loads using LIDAR point clouds. Next, we conducted a series of numerical experiments examining the effectiveness of this technique by comparing FDS model output with observed load balance data taken from a series of experimental tree burns. We used DAKOTA to conduct a parameter sweep on fuel moisture content and dry foliage mass and identified physically plausible local minima. Additionally, we found that our sampling technique identified an area of RMSE minima for all fuel cell resolutions, and that the area was consistent for 2-8cm resolution fuel cells.

Our fuel cell methodology represents a first step at achieving this goal of linking data from LIDAR points clouds and coupled fire-atmospheric models. While we found close parity between our fire simulations in FDS and observational data using our 3D fuel models, many opportunities for further research and refinement exist. For example, our technique tends to over-sample reference voxels associated with the stem of the saplings. The result of this phenomenon is the over-weighting of combustible thermally thin foliage concentrated in the middle of the 3D fuel model. This phenomenon likely results in an overestimation of mass loss when the vegetation is exposed to a heat source in a fire effects model. Future research can expand on previous work segmenting foliage from woody material in LIDAR point clouds (Seielstad *et al.* 2011) in order to improve our methodology by characterizing reference voxels by vegetative return type.

Both fine and coarse fuel cell grids were capable of accurately characterizing observed mass loss in a simulation environment. Based on these results, we conclude that if the primary goal of a simulation is to reproduce the burning behavior of a 3D fuel model, then a coarse fuel cell grid can successfully balance tradeoffs between

computational complexity and representative heterogeneity. While high resolution LIDAR data can improve the representative heterogeneity of 3D fuel models, we find that high resolution fuel descriptions do not improve model results.

Additionally, the importance of dry foliage mass and fuel moisture content suggest that fire modelers should have a high level of confidence in their fuel attributes in order to have confidence in model results. Non-destructive biomass estimates of vegetation are an active area of research. Our study suggests that obtaining accurate biomass estimates is crucial for achieving model accuracy. More work is needed to examine the relationship between biomass measurements from traditional field techniques or derived from LIDAR data, and fuel inputs to couple fire-atmospheric models.

One major shortcoming of our study is that we were unable to evaluate the relationship between numerically identified fuel attributes from RMSE minima and actual fuel attributes measured from vegetation samples. While the majority of parameter spaces resulted in physically plausible fuel attributes, regions of RMSE minima also contained physically implausible minima. For example, our numerical experiments consistently identified regions of high dry foliage mass and low fuel moisture content as minima. This often contradicted known high water treatments applied to the sapling.

Future research can examine the role of branchwood in thermal degradation, velocity fields, and moisture content. The role of DAKOTA can expand to include additional parameters, simulation designs, and more advanced analysis techniques. Additional investigations into the effects of more detailed 3D fuel models on fire behavior models will help us better understand how to apply coupled fire-atmospheric fire models to real world problems like prescribed burn planning.

forest fire, fire suppression, firefighting demand, fuel management

Abstract

The island of Kythira, in Greece, suffered a devastating forest fire that started on August 4, 2017. After that, it became evident that the location of the island, away from aerial fire suppression resources bases and with limited capacity for quick arrival of significant ground firefighting reinforcements, necessitates careful fire prevention and presuppression planning to avoid repetition of the disaster. The study presented here aimed to examine the adequacy of the available 13 firetrucks on the island to successfully carry out initial attack under similar conditions to those of 2017, and to evaluate what could be the effect of four alternative fuel treatment scenarios on reducing the potential of a future disaster. A map of the forest fuels on the island, a weather scenario similar to the conditions at the start of the 2017 fire, and the Digital Elevation Model (DEM) of the island were used with a fire spread simulator (G-FMIS) first to simulate the actual fire and to examine if it matches the observed fire spread in 2017. Once good agreement was verified, four fuel treatment scenarios were applied on the fuels. The accordingly adjusted fuel map was used for further simulations. The resulting fire perimeter growth, taking flame length into consideration, was examined against the capacity of ground forces (firetrucks) to control lengths of the perimeter using a simple but effective fire suppression model, that is based on an equation developed earlier for assessment of the effectiveness of such forces in Greece. The results showed that under broadcast grazing on the island the risk of escaped fires can be minimized, reducing the need for heavy aerial support in case of a fire.

1. Introduction

In Greece, the island of Kythira, which lies south of Peloponnese, suffered a devastating forest fire that started on August 4, 2017, and spread actively for three days. It finally burned 2,471 ha (8.91% of the island) creating significant problems to the environment and the economy of Kythira including its important tourism sector. In the frame of a post-fire effort to reduce the chance of repetition of such a disaster (Xanthopoulos et al. 2022) it was needed to estimate the requirement of firefighting resources for suppression of potential fires and compare it with those currently available on the island. The island's location, away from the bases of aerial resources, and with a long time requirement (4-6 hours) before significant ground reinforcements can arrive by boat, means that the initial attack must be handled by the locally stationed 13 firetrucks with their crews. An analysis of the firefighting requirement was identified as important for highlighting the need for effective fire prevention to the local authorities and population, both in regard to mitigation of fire starts and to fuel treatment for biomass reduction. Furthermore, it can demonstrate the importance of quick and strong mobilization of resources in case of a fire start under weather conditions that could lead to a failure of initial attack and repetition of the 2017 disaster. The effort for estimation of the firefighting requirement, using fire spread simulation both with the actual fuels and those under different fuel management scenarios, is described here. The study uses the area of the August 4, 2017 burn as an example, because it spans the most typical fuel types on the island.

2. Methodology

In the frame of the post-fire fire prevention effort on Kythira, a forest fuels map was developed for the island (Xanthopoulos et al. 2022). The fire behavior and the growth of the August 2017 fire was documented in detail and it was possible to reconstruct fire evolution with good accuracy. Next, the G-FMIS fire spread simulator, was used for simulating fire spread (Xanthopoulos et al. 2022). Inputs included a weather scenario similar to the conditions at the start of the 2017 fire, the forest fuels map and the DEM of Kythira. The outcome was a realistic simulation, matching well the true evolution of the fire (Xanthopoulos et al. 2022). Once good agreement was verified, G-FMIS was used to examine the effect on fire spread, that four potential fuel treatments could have if they had been applied, prior to the fire event, to the area that burned. The four scenarios were:

- Scenario 1: Mechanical treatment (tractor) only in agricultural areas
- Scenario 2: Mechanical treatment (hand tools) only in agricultural areas
- Scenario 3: Grazing everywhere (in all types of vegetation)
- Scenario 4: Intense grazing everywhere (in all types of vegetation)

Modified post-treatment fuel models were estimated for the four scenarios, based on scientific literature review, the forest fuel map was adapted accordingly, and new fire spread simulations, using the same weather conditions as those at the time of the 2017 fire, tested the effect of the fuel treatment on fire perimeter growth and flame length under the four scenarios. Fire spread was simulated for six hours in time steps of 1 hour. The fire perimeter of the simulated fires under the four scenarios, for each time step, were traced manually and the perimeter length for each of five classes of flame length (m) was calculated. The classes were a) 0-1.5 m, b) 1.5-2.5 m, c) 2.5-3.5 m d) 3.5-10 m e) >10 m.

The effect of the fuel treatments on the firefighting demand (firetrucks) was assessed using a published formula for calculating the length of the flank of a fire that can be extinguished by a firetruck having a water carrying capacity of 2500 l, as a function of flame length (Simos and Xanthopoulos 2014). The formula is as follows:

$$EXT2500L\_Flank = 20.756 + 57.493 / FLflank$$

Where the extinction length EXT2500L_Flank and the flank flame length FLflank are expressed in meters. Table 1 is based on the equation above.

Table 1- Length of the fire perimeter of a fire (EXT2500L_Flank) that can be extinguished by a 2500 l firetruck, as a function of flame length

Flame length class	**FL value used in simulation**	**Extinction of perimeter (m) per 2500l firetruck load**
1: up to 1.5 m	1.2	68.7
2: up to 2.5 m	2.2	46.9
3. up to 3.5 m	3.5	37.2
4. up to 10 m	10.0	26.5
5. more than 10m	20.0	23.6

In order to develop a more realistic firefighting requirement estimation, the reduction in the effectiveness of the firetrucks due to the need for refilling with water needs to be taken into consideration, as well as the average time for emptying the load of a firetruck to the fire (Joerscke 1999). Assuming a typical average distance of 4 km to water sources at Kythera, a fire truck travel speed of 50 km h^{-1} on the winding and narrow road network of the island, and a time of 15 minutes for using-up one water load on the fireline, the truckloads that can be achieved by a firetruck per hour were calculated as shown in Table 2.

Table 2- Estimated fight and reload rounds per hour (LOADS_PER_HOUR) that can be achieved by a firetruck with a 2500 l water carrying capacity on Kythira island.

Average distance (km)	ADIST	4.00
Firetruck speed (km/h)	SPEED	50.00
Water loading time with delays	WLT	5.00
Travel time (min)	TRAVEL=WLT+((2*ADIST/SPEED)*60)	14.60
Time for using-up one water load (min)	WUT	15.00
Total time needed per truckload for each round (min)	TT=TRAVEL+WUT	29.60
Fight & reload rounds per hour	LOADS_PER_HOUR=60/TT	2.03

The required firetruck loads for extinguishing a length of the perimeter of each flame length class at each time step, was estimated by dividing the length of the perimeter by the corresponding EXT2500L_Flank for that flame length. The number of hours for each time step (1 to 6 hours), divided by the LOADS_PER_HOUR, provided an estimate of the truckloads that can be delivered by a firetruck in this step's hours. Thus, the required number of firetrucks to deliver the needed truckloads at each time step was calculated by dividing the required firetruck loads for extinguishing the perimeter until then, with the truckloads that can be delivered by a firetruck.

3. Results

Figure 1 shows the simulated growth of the August 4, 2017 fire, in hourly steps, indicating through different colours the flame length along the perimeter. The flame length classes correspond to the broadly accepted limits for firefighting (Tedim et al. 2018). It is noted that at no point across the perimeter, a flame length over 10 m is predicted. Figure 2 illustrates the effect that the four fuel treatment scenarios would have on the burned area and flame length along the perimeter

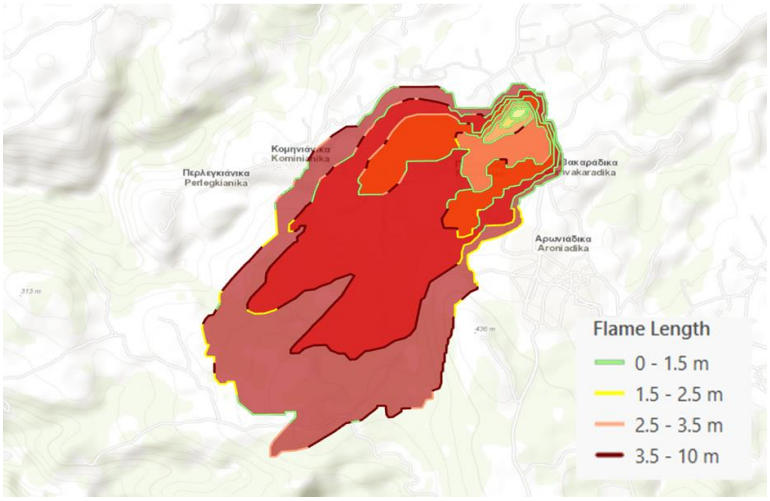

Figure 1- Simulation of the August 4, 2017 fire on Kythira based on the existing fuels at the time, showing the flame length classes along the perimeter at each (hourly) simulation step.

Figure 3 presents the growth of the perimeter with time along the 6-hour simulation, including the simulation with the "real" fuel situation (i.e. the fuels that actually burned in the 2017 fire) and the simulations with the four fuel treatment scenarios. The significant effect of grazing (treatments 3 and 4) is obvious. On the other hand, treatments 1 and 2 seemingly have little effect. This is explained by the relatively small percentage (7.19%) that agricultural areas that receive these treatments, occupy within the specific burned area.

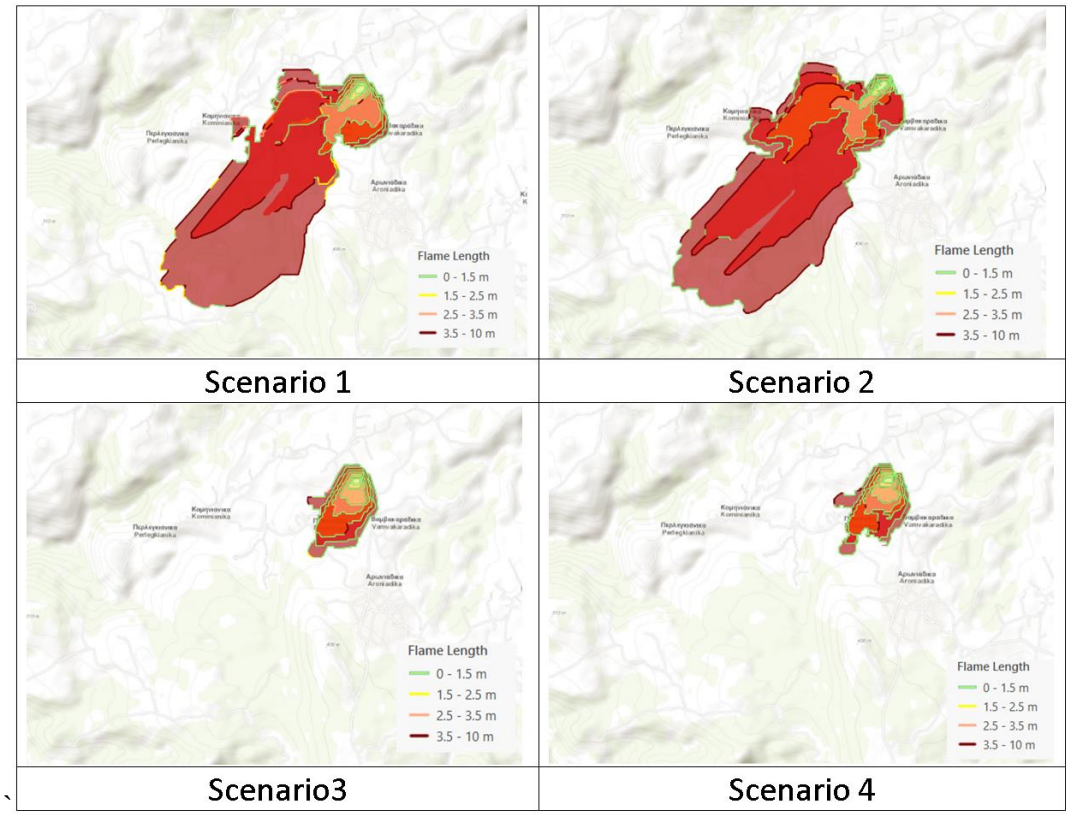

Figure 2- Influence of the four fuel treatment scenarios on burned area and flame length along the perimeter (simulation of 6 hours)

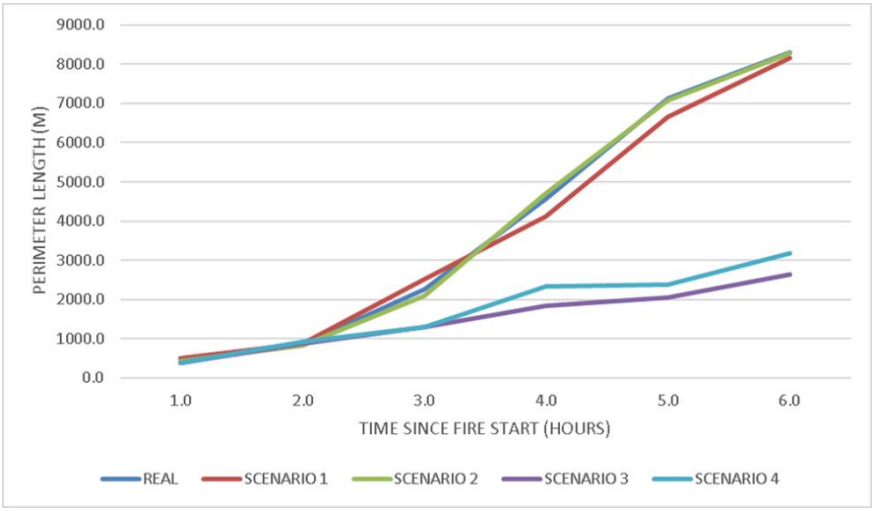

Figure 3- Fire perimeter length growth with time for the simulations with the real fuels and under four fuel treatment scenarios

The treatments also have an effect on flame length along the perimeter, which influences the firefighting requirements, as shown in table 4 which presents the required of firetruck loads (T) with time. As an example, the perimeter length after 3 hours of simulation with the real fuels, indicated as PL_3 in table 4, is 2271.4 m. It consists of 1924.5 m of FL class 1 (i.e. 1.2 m), 85.5 of FL class 2 (2.2 m), 121.2 m of FL class 3 (3.5 m) and 140.2 of FL class 4 (10.0 m). Taking table 1 into consideration, the 1924.5 m of FL class 1 require 1924.5/68.7= 28.0 truckloads. The other parts of the perimeter require 1.8, 3.3, and 5.3 truckloads respectively for a total requirement of 38.4 truckloads in 3 hours.

Table 4- Estimated requirement of 2500 l firetruck loads (T) for extinguishing the fire Perimeter at each time step (i=1-6), taking the Flame Length of all the parts of the perimeter (in classes) into consideration (PL_i)(m)

Fuels	PL_1	T	PL_2	T	PL_3	T	PL_4	T	PL_5	T	PL_6	T
Kythira fire fuels	505.8	7.4	864.3	14.2	2271.4	38.4	4572.6	88.2	7117.3	204.0	8302.3	202.4
Scenario 1	504.3	7.3	867.4	14.1	2516.8	40.8	4118.6	76.7	6654.9	162.3	8153.4	175.9
Scenario 2	438.1	6.4	841.2	12.3	2093.8	36.2	4703.6	102.8	7084.1	183.5	8275.3	189.6
Scenario 3	394.0	5.7	875.9	12.8	1292.2	19.3	1839.0	29.0	2060.6	30.0	2629.0	41.4
Scenario 4	388.6	5.7	917.7	13.4	1292.7	19.7	2328.8	36.2	2379.6	34.7	3190.1	51.2

Continuing on the previous example, using LOADS_PER_HOUR = 2.03 from table 2, it is calculated that a firetruck can transport and use 3 x 2.03= 6.1 truckloads in 3 hours. The number of firetrucks that can achieve the required 38.4 truckloads, are 38.4/6.1 = 6.3 firetrucks. Figures 4 and 5, present the estimated evolution of required truckloads as the fire spreads, and ultimately the number of the required firetrucks for the 6 hours of the simulation.

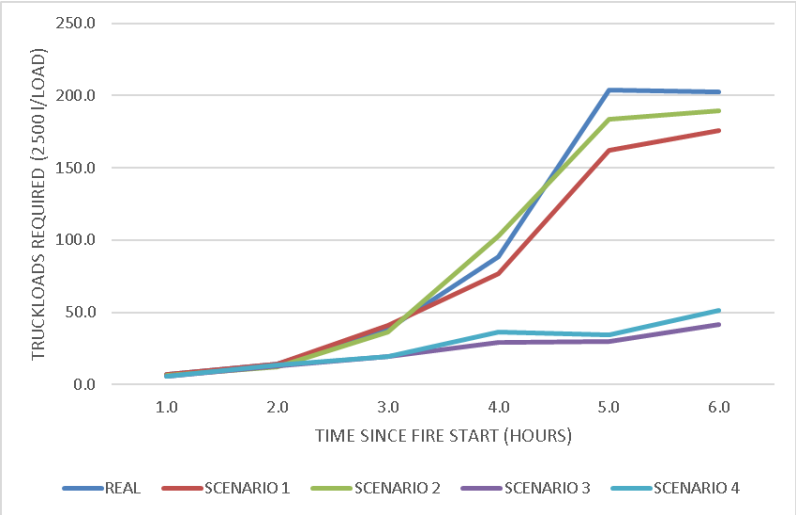

Figure 4- Number of required truckloads of 2500 l for extinguishing the fire perimeter with time, for the five simulations

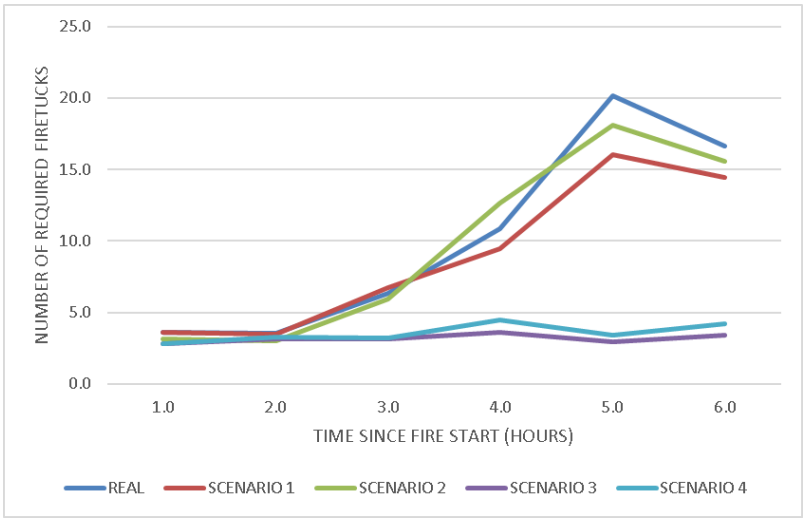

Figure 5- Evolution of the required number of firetrucks for controlling the perimeter of the fire as a function of time, for the five simulations

4. Conclusions

In conclusion, the simple method developed here for estimating ground firefighting demand has produced some very interesting results. It demonstrated the need for increased prevention and better presuppression planning and the value of systematic broadcast grazing as a fuel treatment across the island. Under such fuel treatment the 13 available firetrucks could be able to control starting fires even under difficult conditions. Aerial resources, if dispatched, could have an auxiliary role. The concept presented here can be used for similar analyses elsewhere.

Abstract

The recent upsurge in the incidence of extreme wildfire events, the expected impact of climate change on the frequency and severity of fires, and the progressive expansion of wildland-urban interface areas highlight the tangible need for improvement in our ability to predict, mitigate and manage the growing risk to which communities are exposed. The aim of this research is to contribute to deepen the knowledge on the spatial simulation of the complex dynamics of wildland surface fire behaviour through the development and application of a spatially distributed predictive model for the simulation of wildland surface fire spread intended for operational purposes. Given the position of one or more ignition points, the developed model allows to (i) obtain near real time dynamic estimates of the geo-environmental parameters that control the fire spread, (ii) compute the direction and intensity of the maximum rate of fire spread in heterogeneous environments, and (iii) simulate the surface fire spread using agent-based models. The final aim is to provide competent authorities with timely information on the expected evolution of the flame front to optimise decision-making processes. The model, developed under synthetic conditions, is then applied to case studies recorded in the territory of the Autonomous Region of Sardinia, that offers institutional information on the ignition location, the evolution of the flame front, and the completed fire suppression activities, which are implemented in the model as well. Overall, the model showed a promising predictive capacity evaluated in quantitative terms of morphological matching between the observed and predicted fire spread patterns, returning more accurate results in areas with less complex morphologies and dominated by herbaceous rather than shrubby fuels. The model also made it possible to obtain simulations with processing times compatible with its operational application as a tool for optimising and planning fire risk prevention and mitigation strategies and policies as well as fire management activities. Future research will be aimed at estimating the propagation of the parametric uncertainty through the model and applying the model to fire events occurred across different Mediterranean-type climate regions to consistently evaluate its predictive capacity.

1. Introduction

Wildland fires are a global and pervasive phenomenon whose incidence and intensity are expected to further increase in the next decades in response to the complex interactions between climatic and anthropogenic factors (Jolly et al. 2015; Flannigan et al. 2016; Williams and Abatzoglou 2016; Turco et al. 2018; Forkel et al. 2019; Dupuy et al. 2020; Jones et al. 2020). Mediterranean-type climate regions appear to be particularly prone to suffer for such an exacerbated fire activity (Turco et al. 2016; Bowman et al. 2017; Kelley et al. 2019; Salis et al. 2019; Mantero et al. 2020). Contextually, recent studies have highlighted that wildfire management policies in Mediterranean-type climate regions are predominantly focused on reactive fire suppression strategies, while struggling with proactive preparation and mitigation actions (Moreira et al. 2020; Ganteaume et al. 2021). Hence, the latest report by the European Commission's Directorate-General for Research and Innovation, which was aimed at providing evidence-based scientific support to the European policymaking process, warned about the emerging risk of a disproportionate increase in uncontrolled extreme wildfire events and the consequent urgent need for a reassessment of wildland fire management policies and strategies at the European level (Rego et al. 2018). An integrated wildfire risk management requires contribution from multiple disciplines, ranging

from susceptibility mapping to early active fire detection and fire spread simulation modelling. Accurate predictions of the spatiotemporal evolution of both predicted and ongoing events are of crucial importance for planning and optimising emergency response strategies, which are essential to control the fire spread before it could overwhelm suppression capabilities (Tedim et al. 2018).

The development of a comprehensive model for simulating the spread of surface fires includes (i) a method for converting a multi-dimensional set of geo-environmental data into a set of parameters describing the spread of wildland surface fires and (ii) a method for extending these one-dimensional measurements in space and time and simulate the evolution of the flame front. Sullivan (2009a, 2009b, 2009c) and then Papadopoulos and Pavlidou (2011) conducted exhaustive comparative reviews of the strategies adopted and developed to model the fire spread, (i.e., physical and quasi-physical or empirical and quasi-empirical models), and to simulate the fire growth, (i.e., raster and vector implementations). Modelling fire spread and growth is a complex task due to multiple factors including the spatiotemporal heterogeneity and variability of geo-environmental conditions as well as the uncertain effect of fire suppression interventions (Alexander and Cruz 2013). Especially in the last decades, the increasing computational resources and the growing availability of remotely sensed datasets have fuelled the development of a considerable number of wildland surface fire behaviour models (Szpakowski and Jensen 2019; Jain et al. 2020). However, the optimisation of near real-time simulation of fire spread and growth in operational environments remains an open issue.

The objective of this study is to support the optimisation of the decision-making processes of wildland surface fire risk management in the island of Sardinia, Italy, which is preliminary assumed as representative of Mediterranean-type climate regions. This project intends to pursue the main objective of developing and validating a spatially distributed predictive model for the simulation of wildland surface fire spread intended to be implemented as a geospatial decision support system aimed at providing strategies and tools for an integrated wildfire risk management.

2. Methods

2.1. Model development

When considering models that can be used as decision support tools for operational fire management, some constraints become evident: (i) short decision time frame; (ii) fine-scale spatiotemporal resolution; (iii) input data retrievability in operational environment; (iv) low complexity of laboratory and field experiments; (v) minimum computational requirements at the desired spatiotemporal resolution. The simulation model design and implementation are aimed at providing competent authorities with near real-time multi-temporal maps of the expected evolution of the surface fire spread and growth capable of accurately and dynamically capturing the spatiotemporal variability of the geo-environmental drivers of fire spread.

The quasi-empirical mathematical model defined by Rothermel (1972), one of the most extensively employed method for simulating fire behaviour in operational environments, has been adopted for the prediction of the maximum rate of fire spread. In fact, despite their site-specificity and their tight dependence on local geo-environmental conditions, the empirical and quasi-empirical models boast calculation promptness and usability compared to physical and quasi-physical models. To obtain more flexibility in handling the model equations (Rothermel 1972; Albini 1976; Andrews 2012, 2018), an independent algorithm capable of estimating the same parameters defined by the model has been implemented. The algorithm takes as input combinations of the drivers of fire spread, including geo-morphometrical parameters, horizontal wind speed and direction, fuel types, and their characterisation in terms of live and dead fuel moisture contents, and performs pixel-based evaluations of the magnitude and direction of the maximum rate of spread relative to upslope, the flame length, the intensity of the flame front, and the eccentricity of the ellipse which represents the analytical approximation of the spatial pattern produced by a wildland fire spreading under ideal homogeneous conditions. The algorithm has been then integrated into a spatial simulation model which adopts a hybrid raster-vector approach to simulate the spatiotemporal growth of the flame front. Indeed, while vector implementations for simulating fire growth generally offer greater accuracy, the advantages of raster implementations include simplicity, better portability to parallel computing environments, and higher computational efficiency. Therefore, an agent-based model has been implemented to simulate fire growth with discrete time intervals of 1-minute length and discrete spatial

units with a modular area. Spatial units are represented by hexagonal cells, each of which can host at most one and only one agent. An agent instantiated in a cell might represent both the actual ignition point of an active fire or a simulated ignition originating from the elliptical vector simulation propagated from one of the adjacent cells (Figure 1).

2.2. Model application to case studies

The model has been developed under synthetic conditions to verify its conceptual validity and then, applied to case studies referring to historical wildland fire events recorded in the fire database of the Autonomous Region of Sardinia to evaluate its accuracy and predictive capacity.

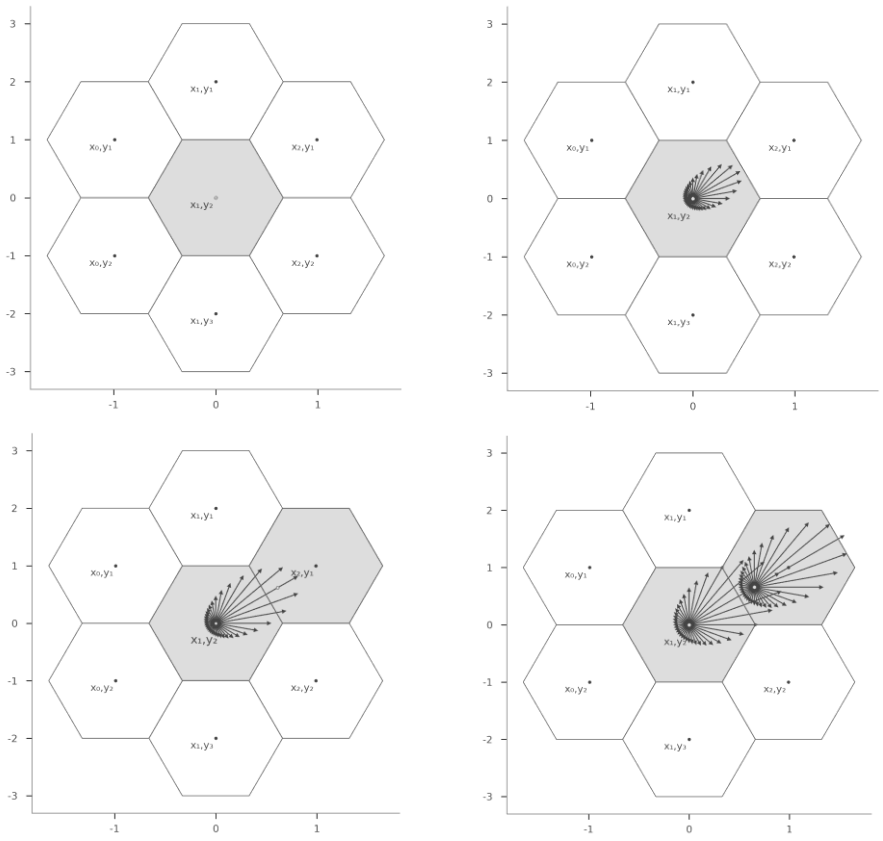

Figure 1- Agent-based model behaviour. A single ignition agent is instantiated in the centroid of the grey hexagonal cell at time t0 (a). After a time t1, an elliptic vector simulation has started from that agent spreading according to the rate and direction of fire spread calculated for that cell by the Rothermel's model (b). After a time t2, the elliptical vector simulation has generated a new agent in one of the white adjacent hexagonal cells (c). After a time t3 a new elliptical vector simulation has started from the new agent (d).

Obtaining dynamic estimates of the geo-environmental parameters that control the fire spread and growth, is essential for the model to compute the direction and intensity of the maximum rate of spread and to simulate the spatiotemporal patterns of fire growth. The near real-time simulation of the evolution of expected and ongoing fire events requires a continuous monitoring of the spatiotemporal variability of the geo-environmental drivers, including wind speed and direction and fuel moisture content. Remote sensing methodologies, making use of either airborne or spaceborne active and passive sensors, provide exceptional advantages over traditional methods for the estimation of geo-environmental parameters, especially in an operational context. Dynamic estimates of the drivers of fire spread have been derived from remotely sensed datasets and global reanalysis with suitable spatial and temporal resolutions. Information on the spatiotemporal variability of live and dead fuel moisture fractions have been derived by adopting empirical relationships already defined in literature for plant communities in Mediterranean-type climate regions (Chuvieco et al. 2004; García et al. 2008; Frey et al. 2012; Nolan et al. 2016), which relate vegetation indices (MODIS Terra NDVI; Vermote and Wolfe 2015) with

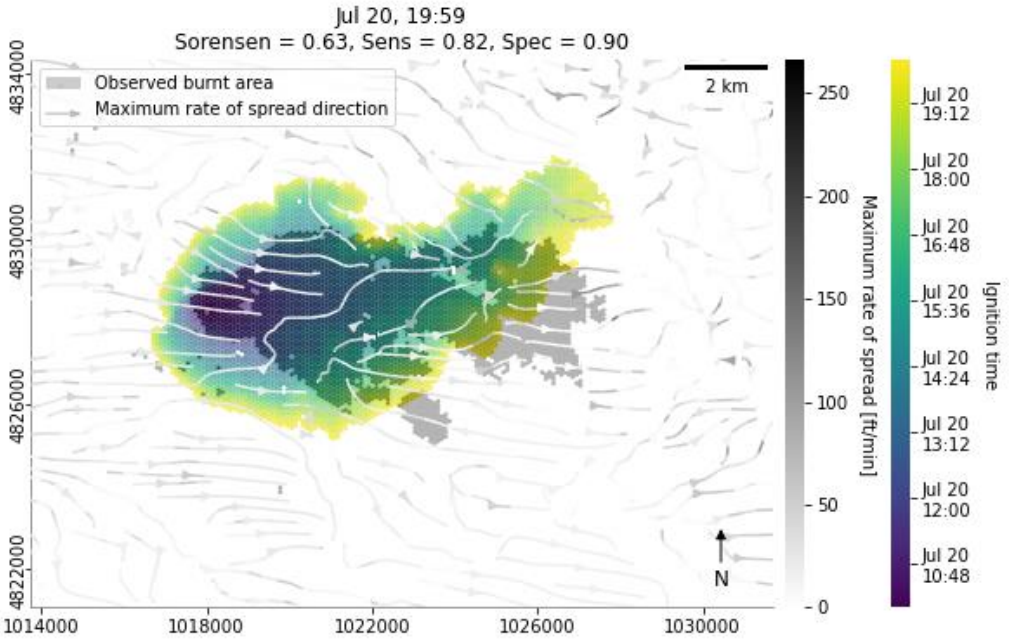
land surface temperature estimates (MODIS Terra LST; Wan et al. 2015). Horizontal wind speed and direction have been obtained from the ERA5-Land climatic reanalysis, produced by ECMWF, which provides measurements at 10 m above the ground with a spatial resolution of 9 km and a temporal resolution of 3 hours (Muñoz Sabater 2019). Both standard and custom fuel models for Sardinia (Duce et al. 2012) have been assigned to land cover units (Autonomous Region of Sardinia, 2008) according to the literature (Salis et al. 2013).

The availability of accurate institutional information regarding the evolution of the fire spread and growth as well as of successful fire suppression activities, such as control lines, have been also simulated. Finally, standard quantitative indices such as the Sørensen similarity coefficient or sensitivity and specificity measures, have been computed to estimate the model performance in terms of spatiotemporal agreement between the observed and simulated fire spread and growth patterns.

The procedure for estimating the drivers of fire spread has been automated by means of the Google Earth Engine platform (Gorelick et al. 2017) and the spatial model simulating fire spread and growth is entirely developed in Python (Kluyver et al. 2016).

3. Results and Discussion

The predictive patterns resulting from fire growth simulations exhibited a satisfying level of agreement with theoretical knowledge on fire behaviour modelling. It has been observed that wind speed and direction play a decisive role in determining the speed and direction of maximum spread of the flame front. Similarly, fuel continuity and its vertical structure have shown a significative impact on the predicted patterns of fire growth.



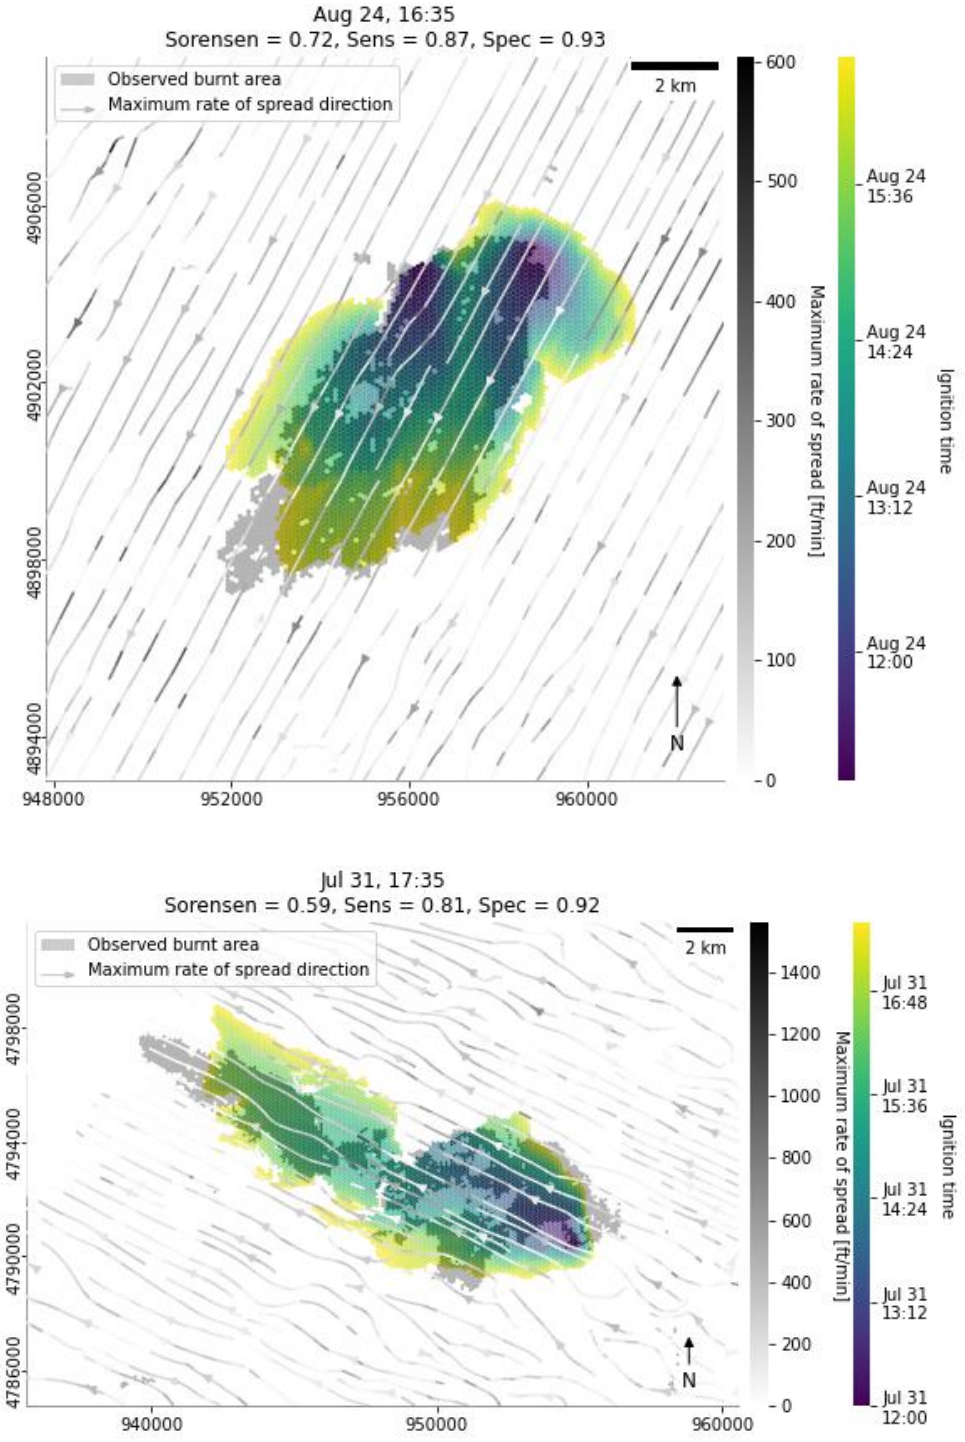


Figure 2- Predicted patterns of fire growth for the case studies of Isili (CA), July 20th, 2016 (a), Sagama (OR), August 24th, 2016 (b), and Gonnosfanadiga (VS), July 31st, 2017 (c). Grey shadows indicate the observed burnt area while the predicted patterns of fire growth are represented with a colormap referring to the hexagonal cell ignition time. Sensitivity and specificity measures and the Sørensen similarity coefficient are reported. Grey arrows indicate the magnitude and direction of the maximum rate of spread according to the Rothermel's model.

Although not fully representative of the complexity and diversity of the geo-environmental conditions in the study area, the selection of case studies for the model application strived to capture heterogeneous geo-environmental conditions. Predicted patterns of fire growth exhibited probability of omission or commission errors lower than 20% (Figure 2), even without the simulation of active fire suppression interventions, which

played a significant role in reducing commission errors. A greater model predictive capacity has been observed in the absence of complex morphologies (Figure 2b), reflecting intrinsic limitations of the Rothermel's model and the complexity of properly simulating wind fields, found to be critical for the estimation of both the magnitude and direction of maximum surface fire spread. A higher predictive capacity also emerged in the presence of herbaceous fuels (Figure 2a-b) compared to fuels characterized by sclerophyllous shrubs typical of the Mediterranean maquis and garrigue (Figure 2c), hence, highlighting the need to obtain more accurate estimates of the horizontal and vertical fuel continuity. Omission errors might be attributable to (i) uncertainties connected with the estimation of geo-environmental parameters and their propagation within the model, but also to (ii) ground fire spread phenomena or secondary outbreaks triggered by embers carried by the wind.

Comprehensively, the model developed for the simulation of the propagation of surface forest fires showed a satisfactory predictive capacity in terms of morphological correspondence between the observed and simulated perimeter. Results of the model application to case studies recorded by the Autonomous Region of Sardinia suggest the model suitability for operational use as a tool for the near real-time forecast of the magnitude and direction of the maximum rate of surface fire spread.

Future studies will aim to: (i) calibrate and validate the methodology for the estimation of the geo-environmental parameters; (ii) propagate the parametric uncertainty through the model; (iii) simulate the occurrence of secondary outbreaks due to reignitions or spotting events; (iv) implement a wider range of fire suppression activities and techniques; (v) apply the model to fire event occurred across different locations in Mediterranean-type climate regions to consistently evaluate its predictive capacity.

Abstract

Using the fully physical model FireStar3D, numerical simulations of grassland fires were carried out on a sloping terrain (10°, 25°, and 40° inclinations) for a 10 m-open wind speed of 1, 2, and 3 m/s. To reproduce the behaviour of a quasi-infinite fire front, periodic conditions were considered in the fireline direction. The simulations highlight the role played by the additional wind induced by the fire (that reaches about 10 m/s at 10 m above ground) and its feedback action on fire behaviour. This interaction results in the transition of the fire behaviour to induced-wind-dominated fire, and this goes along with a substantial increase of the fireline heat release rate that reaches 20 MW/m. In addition, the simulations highlight the acceleration of the fire spread resulting from flame attachment observed for the inclinations of 25° and 40°. The fire regime was characterized by Byram's convection number, based on the effective crosswind speed, that drops by two orders of magnitude once fire-induced wind takes effect on fire behaviour.

1. Introduction

Fire blow-up or flare-up (Viegas, 2005) is considered a very dangerous aspect of wildfire events, and is characterized by a sudden change in its behavior within a very short lapse of time. Therefore, this phenomenon presents a significant threat and one of the main causes of human losses, because of its unpredictable behavior that surprises firefighters and engulfs them with flames. There have been too many accidents imputed to blow-up fires, for instance: Mann Gulch fire in the USA, 1949 (13 victims), Storm King fire in the USA, 1994 (14 victims), Palasca in France, 2000 (2 victims), Guadalajara in Spain, 2005 (11 victims), Kornati in Craotia, 2007 (11 victims) … Many explanations have been proposed for this phenomenon (Viegas & Simeoni, 2011; Werth, 2016) and the first kind of interpretations is based on the external conditions related to stability in the atmosphere and change in the wind velocity or direction. However, real fires showed that fire blow-up could occur in the presence of contrary wind (Countryman, 1968), and laboratory experiments showed flare-up behaviors under no wind conditions (Viegas & Pita, 2004; Dold & Zinoviev, 2009). The second kind of interpretations proposed the interaction between the spreading fire and other factors like wind and topography. Indeed, the majority of blow-up fires have been observed to occur in connection with canyons or steep slopes. Thus, many models have taken into account the topographic effects in order to study flare-up behavior (Viegas, 2005; Viegas & Pita, 2004; Dold & Zinoviev, 2009; Viegas, 2006; Wu et al., 2000; Drysdale & Macmillan, 1992) and many have highlighted the role played by flame attachment to explain this fire behavior. For instance, Wu et al., 2000, carried out laboratory scale experiments on inclined surfaces and obtained a critical inclination angle of 24° for flame attachment, that separates fire spread dominated by radiative heat transfer and convective one (Dold & Zinoviev, 2009), while Drysdale & Macmillan, 1992, had noticed a change in fire behavior around 15° inclination angle. The role played by induced wind and its feed-back action on fire propagation is still an open question, but it is sure that this indraft provides oxygen to the combustion zone and contributes to fire propagation. At field scale, the accident of Freixo de Espada-a-Cinta reported by Viegas, 2005 is a good example of the presence of induced wind in a canyon. Moreover, Viegas & Pita, 2004, showed clearly the presence of

the induced wind and its effect on the fire behavior during laboratory experiments of fires spreading in canyons. In order to better understand the role played by induced wind on the behavior of fire on sloping terrain, a 3D Large Eddy Simulation (LES) was conducted using a complete physical model, namely FireStar3D (Morvan et al., 2020; Frangieh el al., 2018). The configuration was set up to allow for fire-induced wind to take place and interact consequently with the fire that induced it.

2. Modelling and Numerical Method

The mathematical model used in FireStar3D is based on a multiphase formulation (Grishin, 1997). The model consists of two parts that are solved on two distinct grids. The first part consists of the equations governing the reacting and turbulent flow of the gas mixture of fresh air and the gaseous products resulting from the degradation of the solid fuel (by drying, pyrolysis, and heterogeneous combustion) and the homogeneous combustion in the flaming zone. The second part consists of the equations governing the thermal degradation, the state and the composition, of the solid phase subjected to an intense heat flux coming from the flaming zone. The interaction between the gaseous and the solid phases, is obtained through coupling terms that appear in both parts of the model. The reader is invited to consult references (Morvan et al., 2020; Frangieh el al., 2018; Morvan & Dupuy, 2004) for more information about FireStar3D model. To avoid border effects induced by a finite-length ignition line on the fire behaviour, the simulation was carried out using periodic boundary conditions along the two lateral sides of the computational domain, as shown by Fig. 1. The homogeneous vegetation layer, of height δ = 0.6 m and whose physical properties are given in Tab. 1, is located at 30 m from the domain inlet. Domain inclination (α = 10°, 25°, or 30°) was specified through two non-zero gravity components: $g_x = -g\sin(\alpha)$ and $g_z = -g\cos(\alpha)$, where $g = 9.81$ m/s^2 is Earth gravity.

Table* 1. *Main physical properties of the vegetation

Particle density, ρ_v (kg/m^3)	1000
Volume fraction, β	0.003
Fuel moisture content, FMC (%)	60
Fuel bed depth, e (m)	0.6
Fuel load, σ (kg/m^2)	1.8
Surface-area to volume ratio, s (m^{-1})	3000
Thermal emissivity, ε	1
Fuel particles shape	Cylindrical

Initially (i.e., at t = 0), a one-seventh power horizontal velocity profile was imposed in the entire computational domain with a 10-m open wind speed U_{10} = 1, 2, or 3 m/s, and the hydrodynamic module of the code was run long enough until reaching a statistically-steady state. During this purely dynamic phase, the one-seventh power velocity profile was imposed at the domain inlet and a homogeneous Neumann outlet conditions were imposed for all primary variables of the problem. At the top boundary, a constant wind speed $U_{Top} = 1.43 \times U_{10}$ (obtained from the one-seventh power wind velocity profile) was imposed during the entire simulation time. Once the flow had reached a statistically-steady state, a 2 m wide burner was activated along the entire fuelbed width by injecting CO gas at 1600 K from the bottom boundary of the domain. The burner was activated during 10 s (at most) or until the consumption of a solid-fuel mass equal to that available above the burning area.

For the solid phase, a uniform grid with (Δx,Δy, Δz) = (0.2m, 0.2 m, 0.03 m) was used, while for the fluid phase, a uniform grid with (Δx, Δy, Δz) = (0.4 m, 0.4 m, 0.015 m) was used within the vegetation before being gradually coarsened both in the x and in the z directions. Both these grids are characterized by cells sizes below the radiation extinction length scale (Morvan, 2011) within the vegetation, given by $4/s\beta$, where s is the surface to volume ratio of the vegetation (m^{-1}) and β is the volume fraction of the solid phase (see Tab. 1); this characteristic length is equal to 0.445 m in present case. A variable time stepping strategy was used, based on a truncation-error control, with time step values varying between 0.001 s and 0.01 s. At each time step, the solution is assumed to be obtained when the residuals of all conservation equations had reached 10^{-4} in normalized form.

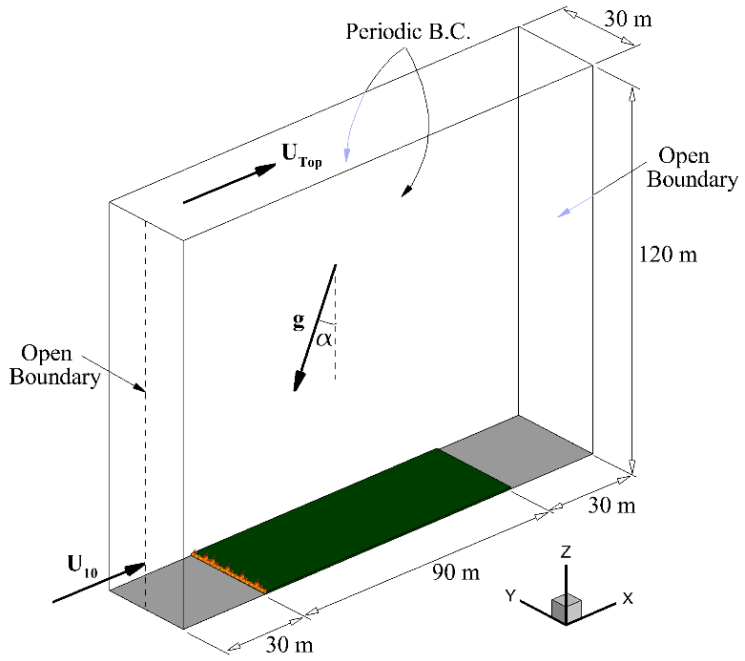

Figure 1- Computational domain and boundary conditions used to simulate an induced-wind-dominated fire on a sloping terrain.

3. Results and discussion

Figure 2 shows the time evolution of the pyrolysis front position (average at the vegetation surface), as well as the fireline heat release rate (HRR) obtained for two cases. For $\alpha = 10°$ and $U_{10} = 1$ m/s, we notice that a quasi-constant rate of spread (ROS) (the curve slope) of about 0.45 m/s is obtained, while the fireline HRR increases from about 6 to 12 MW/m after steady state of fire propagation was reached. For $\alpha = 40°$ and $U_{10} = 3$ m/s, in addition to the substantial increase of the HRR that reaches 20 MW/m, we notice a transitional phase in fire propagation where the ROS increases between 60 and 80 s after ignition from 0.5 m/s to 0.7 m/s.

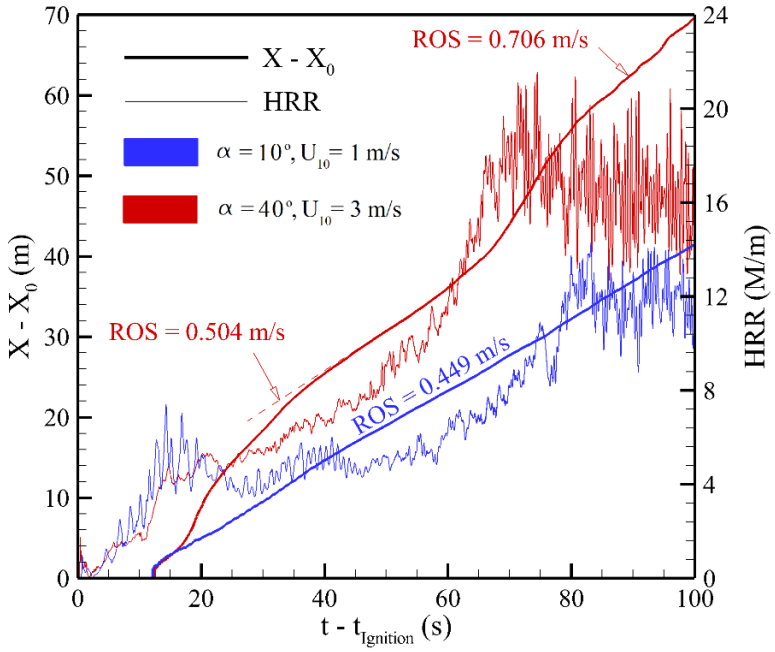

Figure 2- Time evolution of the pyrolysis front distance from burner position ($X-X_0$) and of the fireline HRR obtained for the two extreme considered cases.

To better understand the substantial increase in the HRR, figure 3(a) shows the time evolution of the 10-m open wind speed, shown in Fig. 1 at the domain inlet, for three different cases. We notice that U_{10} starts at the value imposed by the initial conditions, then it increases continuously during the simulation. This additional wind speed is induced the fire itself, it provides fresh air to the combustion zone, pushes the flames onto the unburned vegetation, and increases substantially the extend of the flaming zone, as shown in Fig. 4, and consequently the fireline HRR. Figure 3(b) shows the time evolution of the wind velocity profile along the vertical dashed-line shown in Fig. 1 at the domain inlet for $\alpha = 25°$ and $U_{10} = 2$ m/s; similar results were obtained for the other two cases. We notice how the shape of the velocity profile changes over time, with a maximum wind speed located at about 10 m above ground.

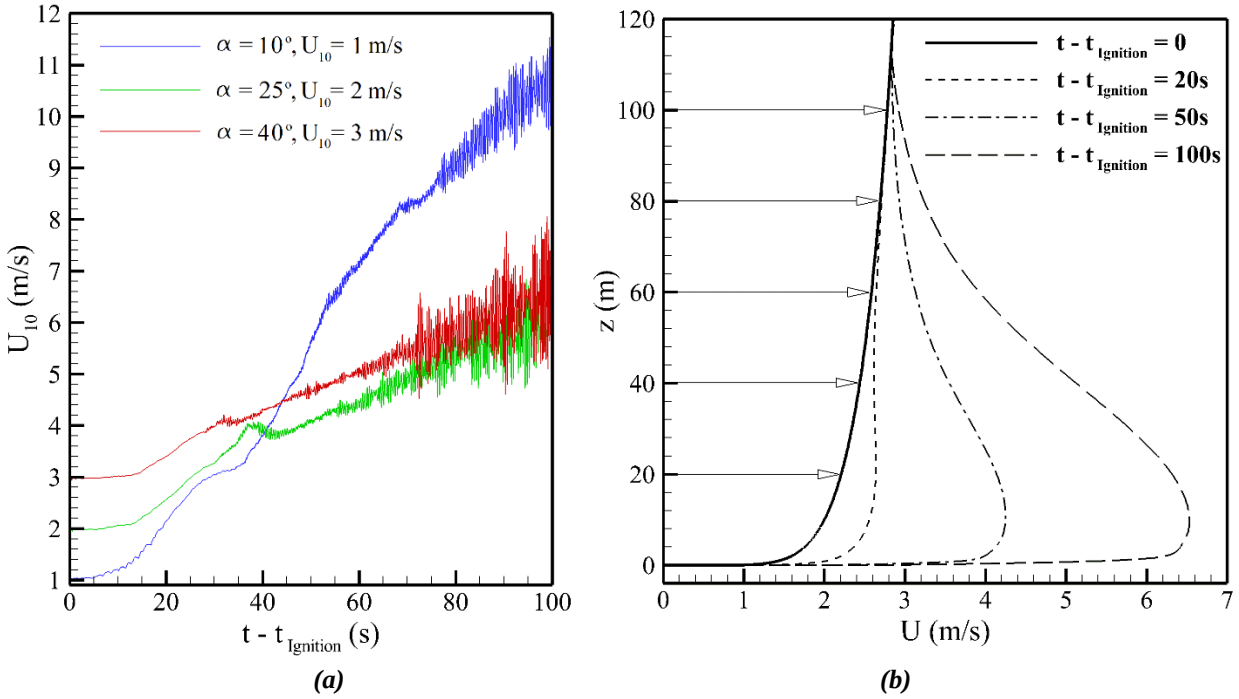

Figure 3- (a) Time evolution of the 10-m open wind speed, U_{10}, at the inlet (x = 0, y = 15 m, z = 10 m) for different simulated cases. (b) Inlet wind profile along the vertical dashed line shown in Fig. 1 at different simulation times for $\alpha = 25°$ and $U_{10} = 2$ m/s.

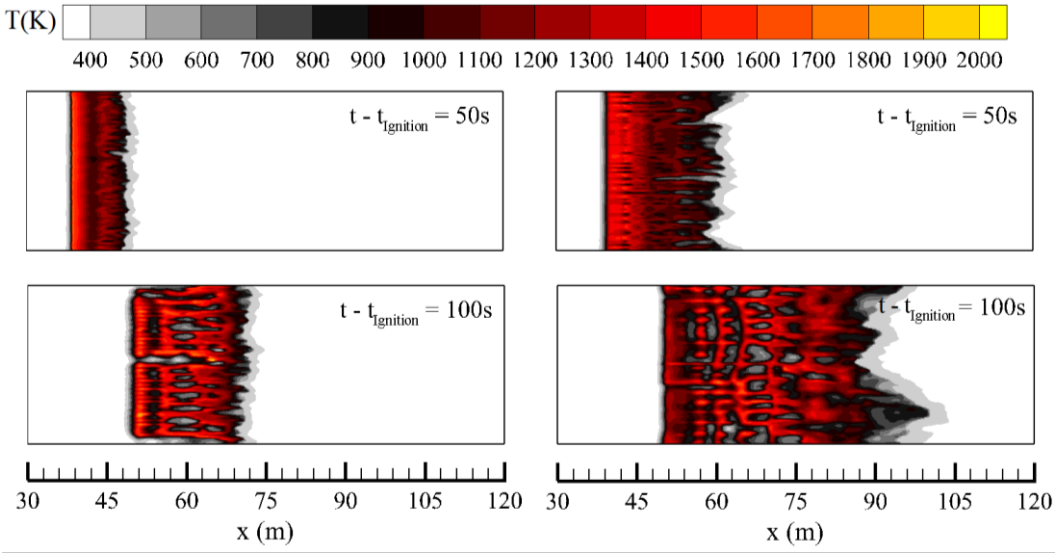

Figure 4- Distribution of the fuel particles temperature at the fuel-bed surface and for two simulation times. Left: $\alpha = 10°$ and $U_{10} = 1$ m/s, right: $\alpha = 40°$ and $U_{10} = 3$ m/s.

The transitional phase in fire propagation observed in Fig. 2 for α = 40° and U_{10} = 3 m/s (also obtained with less intensity for α = 25° and U_{10} = 2 m/s) seems to result mainly from flame attachment, as shown in Fig. 5, while it was not observed for α = 10° and U_{10} = 1 m/s, which is consistent with literature (Wu et al., 2000).

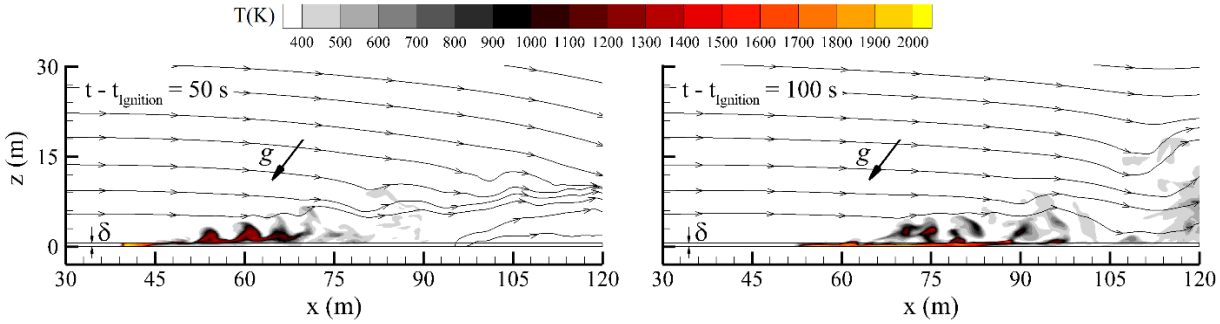

Figure 5- Temperature field and streamlines in the vertical median plane (y = 15 m) obtained for α = 40° and U_{10} = 3 m/s before ($t - t_{Ignition}$ = 50 s) and after ($t - t_{Ignition}$ = 100 s) flame attachment.

The transition between plume-dominated and wind-dominated regimes is piloted by the ratio between the two forces governing flames trajectory: buoyancy contributing to maintain the flames more or less vertical and the wind inertial force pushing the flames towards the unburned vegetation. The ratio between the power of these two forces defines a dimensionless parameter, Byram's convective number (Nelson, 2015), defined by Eq. (1).

$$N_C = \frac{2\, g\, I\, cos^3\alpha}{\rho_0\, C_{P0}\, T_0\, (U_{10}^e - ROS)^3} \tag{1}$$

where, ρ_0 and C_{P0} represent the density and the specific heat of air in standard conditions at temperature T_0, g is the acceleration of gravity, I is the fireline intensity (aberage value of the HRR), and U_{10}^e is the effective 10 m-open wind speed (accounting for the fire-induced wind). The thresholds for the transition between the two regimes of propagation are: $N_C < 2$ (wind-driven fire) and $N_C > 10$ (plume-dominated fire) (Morvan & Frangieh, 2018; Byram, 1959). Figure 6 shows the evolution time of Byram's number, obtained from Eq. (1), for the three considered cases. We notice that Byram's number decreases by the action of the additional wind induced by the fire itself and eventually corresponds to wind-driven fires for all considered cases. Also, the signature of flame attachement is visible between 60 and 80 s after ignition on the evoluation of Byram's number.

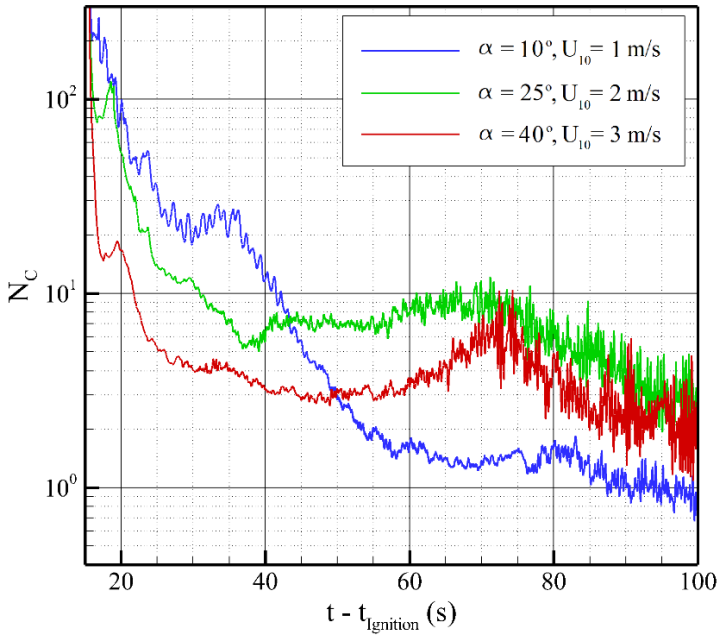

Figure 6- Time evolution of Byram's number obtained from Eq. (1) for the different simulated cases.

4. Conclusion

Induced-wind-dominated fire has been simulation numerically on a sloping terrain using FireStar3D. The action of the induced wind results within few seconds in a substantial increase of the HRR. This is coupled to the flare-up effect of flame attachment that was observed for an inclination angle higher than 25°. This study is, to our knowledge, the first to numerically demonstrate the feed-back action of fire-induced wind. This pioneering work paves the way to other numerical studies that could address open questions related to the role played by induced wind, such as: What are the conditions that favour the development of this mechanism? Does it develop in the case of a finite fireline? Answering these questions will certainly improve our understanding this type of fires and its triggering mechanisms.

Burned soil rehabilitation, Spectral monitoring, handheld spectrometer, multispectral, unoccupied aerial system (UAV), remote sensing

Abstract

Inocula containing photosynthetic microorganisms such as cyanobacteria and microalgae can promote the formation of biocrusts, improving the soil properties and allowing ecosystem recovery. The GreenRehab project aims to develop a low-cost, eco-friendly, and easy-to-implement system to rehabilitate burned soils and protocols to evaluate the success of an ecosystem after-fire recovery. For this purpose, native cyanobacteria and microalgae were isolated from soil/biocrusts and tested, with selected strains being cultivated on a large scale. To evaluate the performance of the proposed rehabilitation system (based on the inoculation of native cyanobacteria and microalgae), we analyzed spectral data scanned from a portable visible/near-infrared spectrometer that indirectly estimates top-soil photosynthetic activity. Several spectral indices based on the normalized difference combination of spectral bands were calculated and compared for their ability to assess photosynthetic activity over time. Results showed that treatments with microalgae and cyanobacteria effectively enhanced photosynthetic activity, with Trichocoleus stimulating soil rehabilitation the most. Moreover, the best performing normalized difference index was the one combining the 660 nm and 860 nm wavelengths. Parallelly, very-high resolution imagery obtained from a UAV equipped with a multispectral camera is currently being tested to assess the performance of different inocula previously selected from microcosm experiments in environmental conditions closer to real ones in post-fire scenarios. Preliminary results led us to develop an integrated protocol for image acquisition, radiometric calibration and photogrammetric post-processing. This allowed us to characterize baseline conditions in the test area, including geomorphology, vegetation and portray fine-scale patterns in greenness and photosynthetic activity. Overall, spectral measurements from portable spectrometers and UAVs open the possibility of assessing which treatments exploited in the GreenRehab project effectively enhance soil rehabilitation and recovery from frequent fires. Such innovation may translate into other "real-world" applications in ecology, forestry, and agronomy.

1. Introduction and context

The GreenRehab project aims to develop a system for rehabilitating burned soils by applying inocula composed of native and locally-harvested cyanobacteria and microalgae. These photosynthetic microorganisms promote

the formation of biocrusts improving the soil properties and allowing the re-establishment of the ecosystem (Rossi et al. (2012), Colina et al. (2014), Büdel et al. (2016), Lababpour et al. (2016)). For this purpose, native cyanobacteria and microalgae were isolated from soil/biocrusts and tested in microcosm experiments to select soil conditioners and plant growth enhancers. Selected strains will be cultivated on a large scale, and different microbial consortia and distinct dispersion methods will be tested in restricted burned areas. Finally, the soil properties, microbial community, edaphic fauna and vegetation recovery will be assessed before and after re-inoculation. By the end of the project, we intend to have a low-cost, eco-friendly, and easy-to-implement system to rehabilitate burned soils and a protocol to evaluate the success of an ecosystem after-fire recovery.

2. Approach

(I) A microcosm experiment was developed to select which native cyanobacteria and algae performed best for enhancing soil activity. This experiment was divided into controls (soil not inoculated) and four different inoculation treatments with soil, perlite and photosynthetic organisms isolated from biological soil crusts – one microalga: *Klebsormidium*; and three cyanobacteria: *Oscillatoria*, *Trichocoleus* and, *Nodosilinea*.

We evaluated the implementation and performance of rehabilitation of these treatments by analyzing the spectral data scanned from a portable visible/near-infrared (VNIR) spectrometer (LinkSquare-1, URL: https://linksquare.io, hereafter LS1, covering the VNIR region from 350 nm to 1100 nm) that indirectly estimates the top-soil photosynthetic activity.

Several spectral indices based on the normalized difference combination of spectral bands were calculated and compared in R statistical software (R Core-Team, 2019) for their ability to assess photosynthetic activity over time. Measures were collected weekly and systematically based on a predefined mesh placed over each soil tray. Ten spectral measurements per tray were collected weekly using LS1 handheld spectrometer.

(II) Mesocosm experiments are also being performed in GreenRehab to assess the effectiveness of each cyanobacteria and microalgae inocula in environmental conditions closer to real ones found in post-fire scenarios. This effort involves developing a detailed framework to support post-fire severity and recovery monitoring (e.g., Torres et al. 2017), characterizing baseline conditions in the field site selected for the in-situ, and designing a tailored experimental setup (e.g., Gonçalves et al., 2016). In particular, very-high resolution imagery obtained from an unoccupied aerial vehicle (UAV, DJI Phantom-4) equipped with a multispectral camera (Parrot Sequoia+) is being tested to assess the performance of different inocula previously selected from microcosm experiments. Predefined semi-automated flights were used to collect images from the study area and later used for 3D photogrammetric assembly. Ground control points were collected with a centimetre-precision GNSS station to improve the accuracy of 3D reconstructions using Agisoft Metashape Pro software (Agisoft, 2021). Radiometric corrections were applied for multispectral VNIR images. A dense point cloud, orthomosaic, digital surface model (DSM) and spectral indices were obtained to characterize reference conditions.

3. Preliminary results

3.1. Microcosm experiments – hyperspectral monitoring

The results showed that the portable spectrometer LinkSquare-1 could provide reliable and relevant information for detecting VNIR spectral data. Treatments with microalgae and cyanobacteria effectively enhanced photosynthetic activity. When comparing the different treatments and their performances with spectral indices, *Trichocoleus* (T3) seemed to stimulate soil rehabilitation the most. Although *Nodosilinea* (T4) and *Klebsormidium* (T1) treatments showed an inferior performance to *Trichocoleus*, they still increased over time. *Oscillatoria* (T2) obtained the lowest results in stimulating top-soil photosynthetic activity based on spectral data. The best performing normalized difference index was the one combining the 660 nm (red) and 860 nm (NIR) using the infrared light source of the LS1 device.

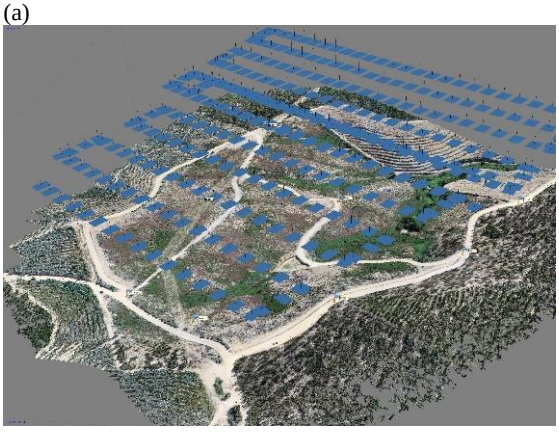
(c)

Figure 1 – Growth of the different microorganisms on the microcosm experiment monitored using a handheld LinkSquare-1 spectrometer for the collection of hyperspectral measurements for treatments (T): (a) T1 – Klebsormidium (microalga) and T2 – Oscillatoria (cyanobacterium); (b) T3 – Trichocoleus and T4 – Nodosilinea (cyanobacteria). CTL1A/CTL1B – burned soil moistened with BG11 medium; CTL2A/CTL2B – burned soil covered with perlite soaked in BG11 medium. (c) Spectral data collected with LS1 handheld spectrometer using a mesh over the soil surface.

3.2. Mesocosm experiments – UAV multispectral monitoring

Results from GreenRehab project have allowed us to devise a conceptual and analytical framework for fire severity assessment and post-fire recovery monitoring based on remote Earth observations (Marcos et al. 2021). Furthermore, field tests with the UAV/multispectral imagery have allowed us to detail the protocol for image acquisition, radiometric calibration and photogrammetric post-processing. Initial results point out that UAV imagery and DSM can be used to characterize baseline conditions in the test area, contributing to understanding geomorphology and vegetation patterns as well as dominant plant species (Fig.2 a–c). In addition, Normalized Difference Indices based on radiometrically calibrated images (Fig.2 d) can portray fine-scale patterns in greenness and photosynthetic activity.

(a)



(b)

(c) (d)

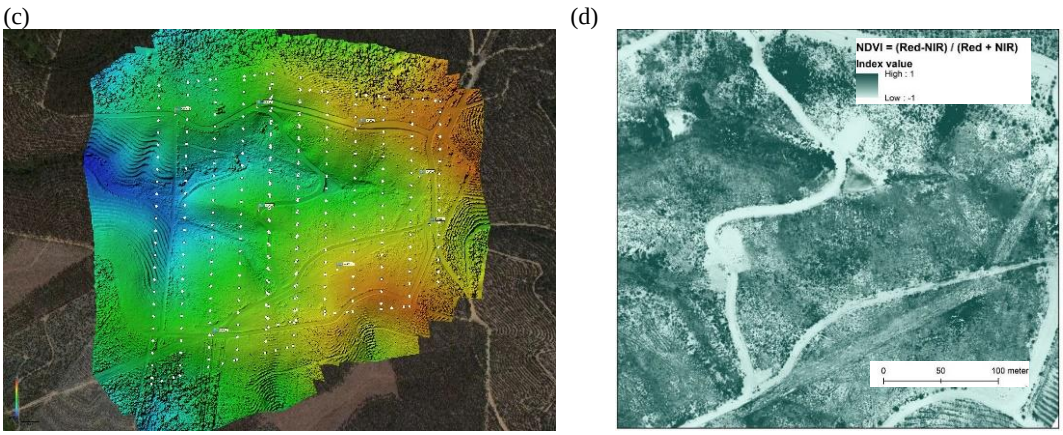


Figure 2 – Outputs from UAV surveys obtained for monitoring the macrocosm experiments in the field: (a) densified point-cloud, (b) orthomosaics with ultra-high resolution (2.5 cm), (c) digital surface model (blue and 'colder' colors indicate lower altitudes whereas reds and warmer ones indicate higher elevations), and (d) image depicting the normalized difference vegetation index (calculate from red and near-infrared spectral bands). Darker greens show higher amounts of vegetation in the test/experimental site.

4. Final remarks and future research

Spectral measurements and indices from portable spectrometers and UAVs open the possibility of assessing which treatments exploited in GreenRehab project enhance soil rehabilitation and recovery from frequent fires. Such innovation may translate into other "real-world" applications in ecology, forestry, and agronomy.

Future research will continue to expand these results and explore how image time series, collected at regular time steps, can aid in monitoring the effectiveness and velocity of different treatments to provide a low-cost and easy-to-implement system to rehabilitate burned soils.

Abstract

The definition of the structural parameters of forest stands and its vertical and horizontal continuity is relevant for a number of environmental applications, such as carbon dynamics studies, sustainable forest management, ecological studies, and fire risk mitigation and management.

Obtaining detailed information on tree structures and canopy variables requires extensive and time- consuming field campaigns. Recently, proximal sensing techniques as Terrestrial Laser Scanning (TLS) have been used for forest monitoring studies and have demonstrated their potential to overcome the limitations of conventional ground-based forest inventory techniques. However, accuracy and applicability of TLS techniques for canopy characterization of broadleaf evergreen forests still require further investigation. In particular, a proper separation between points representing woody material, leaves and small branches is fundamental for the estimation of tree attributes and crown characterization.

In this work, we developed and tested an automatic procedure based on the DBSCAN point density algorithm to accurately separate points derived from terrestrial Lidar measurements at plot level. The objective was to identify volume of woody material, tree density, and canopy cover of a forest stand.

The study was conducted in an area located in southeastern Sardinia (Italy) covered by evergreen forests dominated by holm oaks, with different types of understorey (sparse and dense). Destructive and non-destructive measurements were carried out within three circular plots of 20 m, 25 m and 30 m diameter, respectively. TLS data were collected in field by multiple scans of the three plots. 3D point clouds were processed to isolate trees, soil and understorey. The point clouds were then transformed into voxel clouds (cubic volumes) that were used as input to classify woody and non-woody components by applying both DBSCAN point density clustering algorithms and principal component analysis.

The results show that the proposed method enables the correct identification of crown, trunk, and main branches through an automatic procedure that requires the setting of only a few parameters. Moreover, the procedure does not need excessive computing power and takes only a few minutes to complete the process. Our approach represents a step forward in improving the procedure for measuring forest structure from three-dimensional point clouds. However, further studies are needed to test the capabilities of this method in forest stands characterized by higher and denser understorey and with different tree species (e.g. mixed forests).

1. Introduction

Information on forest canopy structure and reconstruction of tree geometry is required at a wide range of spatial scales for several environmental applications such as carbon dynamic and ecological studies, ecological and forest management, ecosystem productivity model, forest fuel studies and fire risk management.

In particular, an accurate description of fuel is crucial for fire hazard mitigation planning by predicting potential fire behaviour and effects of fuel treatment. Obtaining landscape-level fuel maps, allows the description of the parameters needed to interpret the fire behaviour models, increasingly used to support fire management processes. A correct characterization and classification of fuel needs accurate estimates of vegetation structure

and crown attributes. However, many fuel characteristics are often operationally hard to be measured requiring manual field measurements and cutting.

Because to obtain detailed information on forest stand and canopy variables estimation, extensive, difficult and laborious field campaigns are required, remote and proximal sensing techniques for forest monitoring have become popular in recent decades. Specifically, Terrestrial Laser Scanner (TLS) has demonstrated its potentials to overcome the limitations of the conventional ground-based forest inventory techniques. TLS is a LiDAR system from which detailed 3D information called point clouds can be collected. Using a laser beam, TLS provide a high-resolution 3D view on vegetation structure right down to branch and leaf scales, making it superior to data obtained through traditional field work. Using the intensity of the returned laser pulses, TLS can be used to estimate the water content and photosynthetic capacity of the vegetation. TLS allows accurate estimation of traditional structural metrics used in forest monitoring and management, such as basal area per hectare, tree height, and diameter at breast height-DBH, and also offers a non-destructive approach to estimate quantify canopy and stem volume with high accuracy, thus allowing estimation of AGB parameters with reduced uncertainties, as well as development and improvement of reliable allometric equations.

Although several studies highlight the effectiveness of TLS in describing forest parameters, the accuracy and applicability of TLS techniques for canopy characterization of broadleaf evergreen forests needs further investigations. In particular, estimation of tree attributes such as canopy density, crown bulk density, branch size distribution, etc., in evergreen plants presupposes a correct separation between points representing shrubs, woody material, leaves and small branches. Separation of photosynthetically active material (leaves) from non-photosynthetically active material (wood) is particularly challenging in the case of non-deciduous broadleaf trees, which are characterized by complex crown architecture and where measurements must be performed under foliage conditions.

In a previous work (Ferrara et al., 2018) we proposed an approach based on the point density algorithm DBSCAN for wood-leaf separation from terrestrial LIDAR point clouds of single trees. The TLS data set collected in field by multiple scanning on single trees were partitioned in cubic volumes (voxels) that were used as input to generate clusters through DBSCAN. The most highly populated cluster, due to continuous bark shape versus chaotic leaf distribution, represented wood voxels. So that process led to the identification of wood and non-wood voxels.

In this work we applied the previous DBSCAN based approach at plot level in order to evaluate performance of the proposed procedure in estimating woody material volumes, tree density and canopy cover in holm oak forest stand.

2. Materials and methods

The study was carried out in an area located in South-East Sardinia, Italy. The area was covered by evergreen forests dominated by holm oaks with associated species consisting of Arbutus unedo, Erica arborea, etc. Destructive and non-destructive measurements were done inside three circular plots of 20 m, 25 m and 30 m diameter, respectively. Data sets were collected in field by multiple scanning of the three plots using a Leica HDS6100 laser scanner in super high-resolution mode, it means 3.1 x 3.1mm point spacing at 10 m range. The TLS data set collected in field were processed as reported in figure 1 with the purpose of isolating trees from understorey and separating wood from foliage. The whole process was carried out by algorithms in the opensource R platform.

The first step of the process is the discretization of the point cloud, going from scattered points to voxels ordered in a grid. A voxel is a cubic element, that we choose of 2 cm edge, that contains n points. This step allows to reduce the amount of data in the further computation and also to reduce the noise characteristic of laser scanner acquisition.

The second step is to classify voxels as ground or above ground biomass. Ground voxels will be useful to determinate the height in each point of the plot, needed for example in DBH determination, but are not useful in the following process to determinate wood, leaf and understorey biomass.

Third step; with respect to the single tree approach which used DBSCAN cluster algorithm, in this case the identification of wood voxel clusters was made by applying the principal component analysis and setting a minimum threshold of number of voxels per cluster.

3. Results and Discussion

Due to significant advances in technology and refinement of analysis methods over the past decade, several approaches have been proposed to separate leaf and wood points in a TLS point cloud. These separation methods can be divided into: 1) methods based on the geometric characteristics of point clouds; 2) methods based on the radiometric characteristics of point clouds; 3) methods with machine learning algorithms. Most of the methods developed focus on the geometric attributes of the point clouds.

The results obtained show that the separation method which uses density-based spatial clustering of application with noise (DBSCAN) algorithm proposed, allows the discrimination of the woody groups from the foliar ones and consequently to correctly identify foliage, trunk and main branches at plot level. It is a fully automated procedure that requires the choice and setting of few parameters in order to work properly. Unlike other developed methods, it does not require excessive computational power and takes only a few minutes to complete a good classification. Not being bound to the use of a specific instrument and requiring open source software, it can easily be replicated and applied to any point cloud.

The approach used represents a further step in the improvement of the measurement procedure of the forest structure from clouds of 3D points, in particular as regards the estimation of the woody material, the density of the trees and the projection area of the foliage, especially when the underlying layer is dominated by a not high herbaceous vegetation.

However, further studies are needed to assess the ability of this method in forest stands characterized by high and dense understorey and with different species of trees.

Abstract

The California Fire Dynamics Experiment (CalFiDE) is a 6-week study of wildfire behavior and its response to spatially and temporally evolving wind fields in California, USA. It is the result of a partnership between the Chemical Sciences Laboratory (CSL) at the National Oceanic and Atmospheric Administration (NOAA), the Wildfire Interdisciplinary Research Center (WIRC) at San Jose State University (SJSU) and University of Nevada, Reno. A Twin Otter aircraft will be instrumented and flown over landscape-scale wildfires in California between August 14 and September 30, 2022. Onboard instrumentation includes (i) a scanning Doppler lidar system capable of measuring vertical profiles of 3D wind speed and turbulence, (ii) a multispectral infrared imaging system designed to remotely sense fire behavior, (iii) NightFox fire radiative power sensors (iv) AIMMS probe to measure flight-level winds, temperature, and water vapor content, and (v) Chemistry instruments to sample flight level NOX , NOY, O3, CO and GHG. Airborne measurements will be complemented with ground-based mobile scanning radars and lidars, which will be positioned around the fire to characterize the spatial structure and internal dynamics of the smoke plume. This combination of sensors will provide a unique opportunity to characterize landscape-scale wildfire behavior, fire weather and fire atmospheric chemistry in a synchronized manner. We expect that the datasets resulting from this experiment will have a broad applicability in fundamental fire dynamics studies, fire model validation exercises and the calibration of spaceborne remote sensing fire observations.

1. Introduction

Rigorous observation of fire behavior and fire meteorology during landscape-scale wildfires is essential to develop and validate wildfire models. Validation of coupled fire-atmosphere models, for example, poses unique data challenges that have so far limited rigorous model assessment. In order to validate coupled fire models, observational data must be comprehensive enough to validate all of the model components. For fire spread focused implementations, coupled fire models involve an atmospheric component, a fuel moisture component, and a fire spread component, while air quality applications require additional emission, aerosol and chemical transport modules. As these model components are interlinked, an error in one module can impact the final fire simulation results beyond the specific physical processes modeled by that module. For example, model inaccuracies in the rate of spread may be a result of the deficiencies of the fire spread component itself, but also due to the model's inability to resolve ambient weather conditions, or limitations in representing the local fire-induced circulation. An example of the fire-induced circulation simulated by a coupled fire-atmosphere model (WRF-SFIRE) is presented in Figure 1.

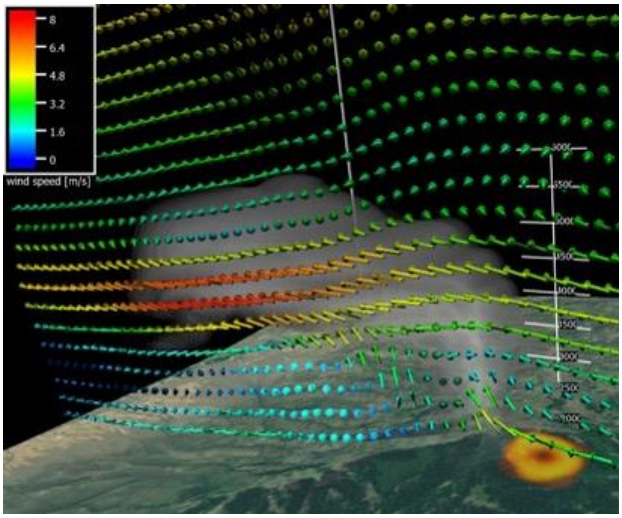

Figure 1. Example of a fire-induced circulation simulated by WRF-SFIRE, a coupled fire-atmosphere model, for Langdon Burn in Utah National Forest, November 7th 2019.

At present, no suitable datasets exist for validating and improving current and future coupled fire-atmosphere models that predict the spread and impact of landscape-scale wildfires (i.e., 1000s of acres). While validation datasets exist for small-scale fires (e.g., Craig B Clements et al. 2007; C B Clements et al. 2014; Craig B. Clements et al. 2019; Ottmar et al. 2016), the physics of landscape-scale fires are different, with processes such as long-range spotting, strong fire-induced winds, large vortex formation, and pyrocumulonimbus (pyroCB) development impacting fire processes.

CalFiDE has been designed to address this problem by integrating airborne and terrestrial remote sensing systems to simultaneously characterize fire behavior, plume dynamics and local circulations near the fireline. Data will be acquired using a rapid deployment strategy during active fires with a combination of airborne infrared (IR) camera systems, airborne Doppler lidar, truck-mounted scanning Doppler radar, and a suite of truck/trailer mounted scanning Doppler lidars. These observations will resolve process-level details of the fire (rate of spread, fire radiative power, etc.), fire-induced winds, plume rise dynamics, and pyroCb development. This sampling approach will provide the necessary data to validate model forecasts and diagnose deficiencies in model physics.

2. Sensor description

The primary objective of CalFiDE is the spatially and temporally resolved observation of fire dynamics and micrometeorology in the fire environment. Consequently, the main sensing packages designed to be deployed during this experiment include (a) an airborne Doppler lidar to characterize the wind field around the fire and plume, (b) an infrared multispectral imaging system to track fire progression and measure fire behavior, and (c) a set of ground-based mobile radar and lidar sensors to characterize vertical winds, smoke plume dynamics and boundary layer evolution. In addition, a number of physical and chemistry sensors will be installed on the aircraft to make in-situ measurements of flight-level thermodynamic conditions as well as air chemical composition. Table 1 summarizes CalFiDE's sensing capabilities, whereas the rest of this section provides additional detail on the main instrumentation.

Table 1: Summary of CalFiDE's sensing capabilities.

Sensor	Deployment strategy	Measuring capabilities	Resulting data products
Airborne Doppler Lidar	Airborne	Partial hemispheric scans of wind speed and direction	Horizontal wind profiles and vertical motion in the fire area
Visible camera	Airborne	3-band color images	Contextual visual information about the fire scene
Mid-wave IR camera	Airborne	Broad-band irradiance in the midwave infrared range	Fire Radiative Power, Brightness Temperature, identification of flaming vs. smoldering areas
Long-wave IR camera	Airborne	Broad-band irradiance in the longwave infrared range	Fire geometry, fire line location, fire rate of spread, identification of flaming vs. smoldering areas
NightFox	Airborne	Scanning radiometers @ 1.6μm & 4μm (± 30°)	Spatially resolved Fire Radiative Power
NOxCaRD & PICARRO	Airborne	NO_x , NO_Y, O_3, CO and GHG	Ozone Photochemistry and Fire Impacted Urban O_3
Ka-Band Polarimetric Doppler Radar	Ground-based, mobile	Radar reflectivity, radial velocity, and polarization	Fine-scale kinematics and microphysical properties of active wildfire smoke plumes
Scanning Doppler Lidars	Ground-based, mobile	Lidar backscatter intensity and radial velocity	Smoke plume dynamics, kinematics, horizontal wind fields and turbulent properties

2.1. Airborne Doppler Lidar

Dynamics of the plume and wind fields surrounding the fires will be measured using a Doppler lidar installed on board the NOAA Twin Otter aircraft. Combined with a partial hemispheric scanner that allows for measurements both below and above the aircraft, the lidar will provide profiles of the horizontal wind field, vertical motions, and aerosol backscatter intensity throughout the boundary layer. Figure 2 shows the morphology (a) and vertical motions (b) of a fire plume emanating from a fire shown as a red hot spot in the ground track. The horizontal wind profile, shown as colored arrows pointing in the direction of flow in the foreground, indicates 5 m/s flow with a strong directional shear layer at 1000m. In Figure 2b upward motions in the plume are shown in warm colors.

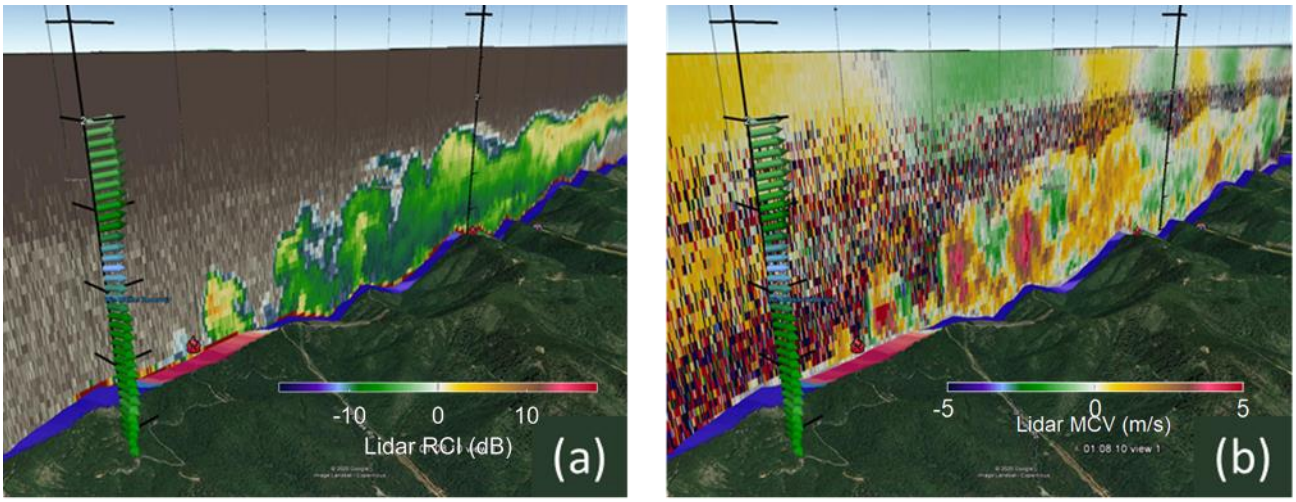

Figure 2: Doppler lidar data from a wildland fire during a previous NOAA field campaign on the Twin Otter. The red area at the surface indicates the fire area. Arrows on the left axis of each figure indicate horizontal wind speed and direction. The colored fields indicate; (a) aerosol backscatter intensity, and (b) vertical velocity.

2.2. Airborne Infrared Imaging System

Fire behavior will be monitored using a combination of optical sensors operating in the visible, medium-infrared (3.9 μm), and thermal-infrared (8-14 μm) spectral ranges. This selection of bands will allow measuring fire

location, fireline geometry, rate of spread, and fire radiative power with a spatial resolution of about 3m for a nominal flight altitude of 11,000 ft. The across-track swath sampled by the camera system will be ~2 km. All optical sensors will be mechanically coupled to an inertial navigation system (INS) which will provide geolocation and attitude information for image direct georeferencing. Raw inertial navigation measurements taken in real time will be corrected after the mission using Post-Processing Kinematics (PPK). Furthermore, direct georeferencing outcomes will be refined using image processing algorithms like those described in (Valero, Jimenez, et al. 2018; Valero et al. 2021). The resulting georeferenced imagery will be analyzed using the methodology developed by (Valero, Rios, et al. 2018) and it will also be used for the identification of spot fires. Figure 3 shows an example of observations collected using this methodology in a previous small-scale experiment.

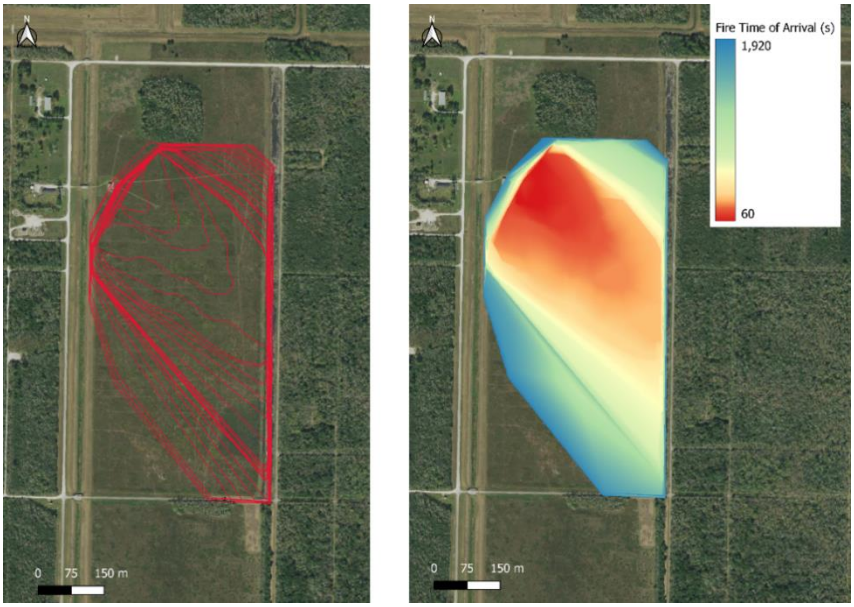

Figure 3. Fire progression during the FireFlux II experiment (Clements et al., 2019) derived from airborne IR imagery. Left: fire perimeter at 60-s intervals. Right: fire time of arrival at every location in the burn unit, relative to the time of ignition. Base image provided by the USDA National Agriculture Imagery Program.

2.3. Ground-Based Mobile Radar

Time-and-space resolved observations of wildfire plume structure will be generated with SJSU's truck-mounted scanning Ka-band (35 GHz, 8-mm) fully polarimetric Doppler radar (SKAR). These data will quantify plume volume, plume injection height, and pyroCu/Cb initiation. SKAR has a narrow beam width (0.33°), 15 km range, and range gate resolution of up to 5 m, and scans the full upper hemisphere in ~ 2 minutes. The SKAR's capabilities in probing wildfire plumes is well-established (Aydell and Clements 2021). Figure 4 shows SJSU's truck mounted Doppler radar (a) and Doppler lidar (b).

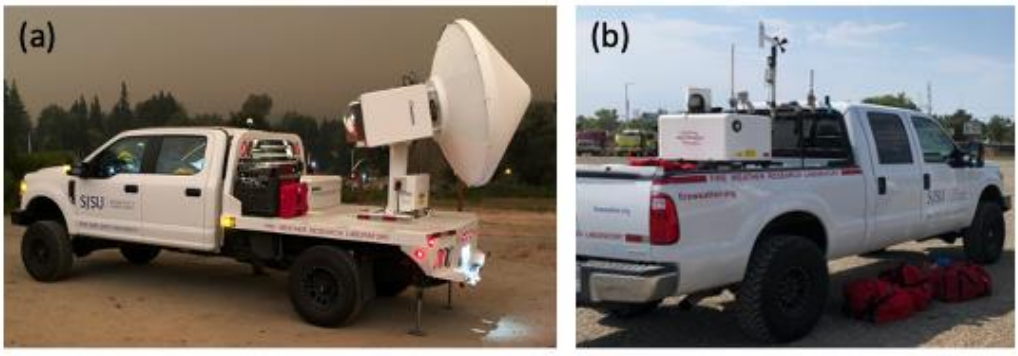

Figure 4. SJSU's Doppler Ka-band radar (a) and Doppler lidar (b).

2.4. Ground-Based Mobile Lidars

Two scanning Doppler lidars (SJSU, UNR) will be deployed within 1-2 km of the fire front to characterize plume structures and dynamics and atmospheric vertical wind profiles and boundary layer evolution. These data are critical for understanding the coupling of fire and atmospheric processes that can drive rapid fire spread and intensification.

Additionally, a NOAA motion-stabilized truck-based lidar will measure convective boundary layer (CBL) depth, vertical velocity variance, and horizontal wind profiles proximal to the fire, but away from the fire front.

3. Experiment design

The project will be headquartered in San Jose, CA between August 14 and September 30, 2022. Ground-based instruments will be staged on the SJSU campus. The research aircraft will be staged at the San Jose International Airport (KSJC), or other ad-hoc flight bases as necessary. Instruments and crews will deploy to wildfires on a day-to-day basis within intensive observing periods (IOPs).

IOPs will be declared one to three days in advance. Five IOPs are planned, each up to 3 days, yielding a total of 15 research days for the ground assets. Observations will typically occur from 12 AM to 8 PM (local time) in order to capture peak fire behavior. The aircraft will make two afternoon flights, separated by refueling. Operations meetings will be held each morning and evening to examine weather and fire conditions, research objectives, and instrument sitting.

Potential “blow-up” fires will be identified through a combined examination of weather, fire and plume development, fuels, topography, and simulated fire growth. UNR and SJSU forecasters will provide daily weather briefings to monitor conditions conducive for “blow up” fires. Satellite IR and NIROPS fire perimeters will be used to track day-to-day fire growth. NEXRAD radar, visible satellite, and webcam networks will be used to track plume development. Maps of topography, fuel type, fuel load, and fire history will be used to estimate growth potential for active fires. Finally, once a fire of interest is identified, an existing “point-and-click” web interface for the WRF-SFIRE simulator (WRFXPY) will be used to predict the expected mesoscale weather evolution and fire growth for a 54-hour window.

Aircraft flight paths will typically follow a “lawn mower” crosswind pattern just upwind of the plume core. An emphasis will be placed on keeping the head fire within the 2 km scan swath of the IR instrumentation. Flight altitudes will be confined between the Temporary Flight Restriction (TFR, ~10,000 ft) and 16,000 ft, which is the flight ceiling. Truck-mounted radars and lidars will deploy to safe locations within 5 km of the head fire. Where possible the locations will be distributed to provide view angles with >30° of separation to measure different components of the wind. Previous deployments have used scenic overlooks, rest stops, reservoirs, ski areas, helipads and airports, and open meadows as safe locations with good field of view.

Abstract

The FireLoc system aims to allow the reporting of forest fires observed by citizens using a dedicated app developed for mobile devices. The collected data includes the observer's geolocation, a photograph of the observed event, and the orientation of the observer towards the fire. These data are integrated into the FireLoc system, which also includes other types of georeferenced data about the terrain, including, e.g., land cover and slope information. The system processes the collected data and identifies the geolocation of the observed events in near real-time. This may enable a fast geolocation of fire events and also assist in monitoring the progress of the fire. This short paper briefly describes the FireLoc System that comprises three components: 1) a data collection component developed for mobile platforms; 2) a data integration and processing component, in charge of processing the collected data and assessing the most probable location of the fire event considering the reliability of the contributed data; and 3) a component for providing information to relevant institutions and the general public, which is developed for both mobile and desktop platforms and allows to monitor the progress of the reported events.

1. Introduction

Due to climatic changes and human intervention in the environment, the frequency and severity of forest fires are increasing in several regions, a phenomena that is likely to increase even further in the next few years (e.g., Cleetus & Mulik, 2014). As these events may become uncontrollable over the right atmospheric, land cover and topographic conditions (e.g., Liu et al., 2015; Viegas, 2012; Rossa, 2015), as occurred in Portugal in 2017, it is very important to be able to geolocate ignitions as soon as possible. Several types of systems are used for this purpose, including human observers at observation towers or complex systems using digital cameras and Unmanned Aerial Vehicles (UAV). However, these systems have limitations and do not cover all locations. In some cases, they are not able to collect data near the event or, such as the UAV systems, are only able to monitor a relatively limited region and therefore may only be used when a given event has already been detected. On the other hand, many regions include villages and roads crossing forested areas, which means there may be citizens in the proximity that may help to geolocate fires at an early stage by sending data in real time, should a system be available to facilitate those contributions. This is the aim of the FireLoc system (https://fireloc.org), currently under development in the context of a project funded by the Portuguese Foundation for Science and Technology (Fundação para a Ciência e Tecnologia - FCT). This paper briefly describes the components of the FireLoc system, with emphasis on the ones that enable the interaction with users.

Other approaches based on crowdsourced data have been proposed, using, e.g., data extracted from social media (e.g., Al-Salehi et al., 2021; Tavra et al., 2021; Arapostathis & Karantzia, 2019) or dedicated apps, such as the CITISENS project in Greece (Bogdos & Manolakos, 2019). However, the geolocation with data collection from social media has many limitations, including the data and metadata obtained using the available social media

APIs (Fontes et al., 2017). Regarding projects using dedicated apps, to the best of the authors knowledge, none is available for general use. Also, none uses the FireLoc methodology to geolocate the observed events, which is based on the intersection of estimated lines of sight. For example, the CITISENS project uses a methodology that geolocates the events using additional data collected from the smartphone, such as gyroscope and accelerometer data, to identify the observer's line of sight and geolocates the observed fire events by intersecting the estimated line of sight with a Digital Elevation Model. The authors stated that the geolocation estimated following such methodology provided accurate results (Bogdos & Manolakos, 2019), even though it assumes that the observer has a direct line of sight to the fire (i.e., it would not work in case the observer is just seeing a column of smoke). Therefore, it would be interesting, in a subsequent stage, to compare the geolocation accuracy obtained with both approaches and determine if the fusion of both methodologies is able to increase the accuracy of the geolocation of observed events.

2. The FireLoc System

The FireLoc system is composed by three main components that include several modules (Fonte et al., 2021), namely: 1) a data collection component, which includes a mobile app enabling citizens to upload data, and modules to collect other types of geospatial data, such as satellite imagery, meteorological data, or data from the OpenStreetMap project (https://www.openstreetmap.org/); 2) the data processing and validation component, containing a central core module complemented by modules to: a) geolocate the observed events using data uploaded by citizens, b) assess the reliability of citizen contributions and classify the uploaded photographs as showing fire or smoke, and c) estimate the risk associated to the computed location of the observed events and its neighbourhood; 3) the interfaces component, which includes a graphical user interface to be used by end-users, and a back-office interface for system administrators. Further details on the components that enable the interaction with the citizens are given in section 3, for the FireLoc app, and section 4, for the FireLoc portal.

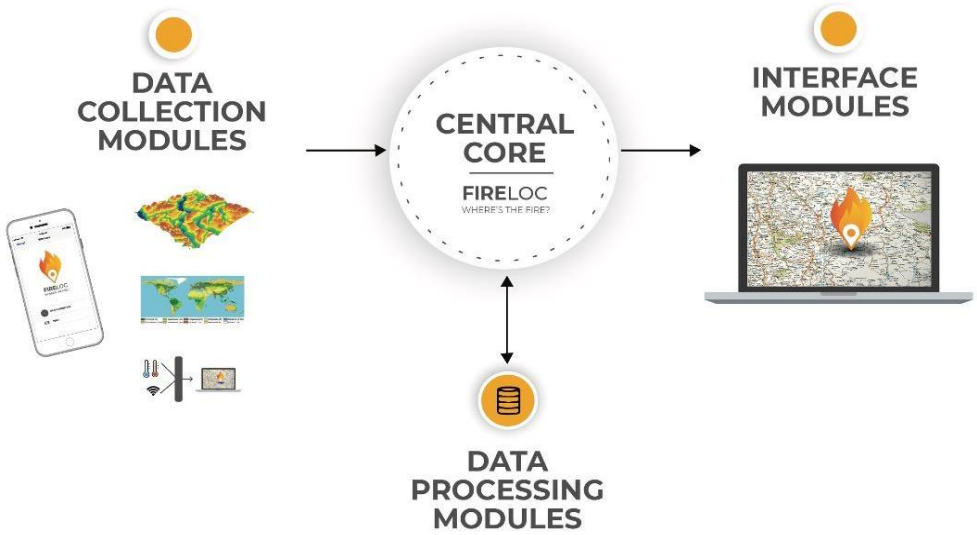

Figure 1- The FireLoc system.

3. The FireLoc app

The FireLoc app was developed to collect the data contributed by citizens. So far it is only available in Portuguese. Figure 2 shows the interfaces of some of the steps related to the data collection process, namely the geolocation, the orientation towards the fire, and the photograph collection steps.

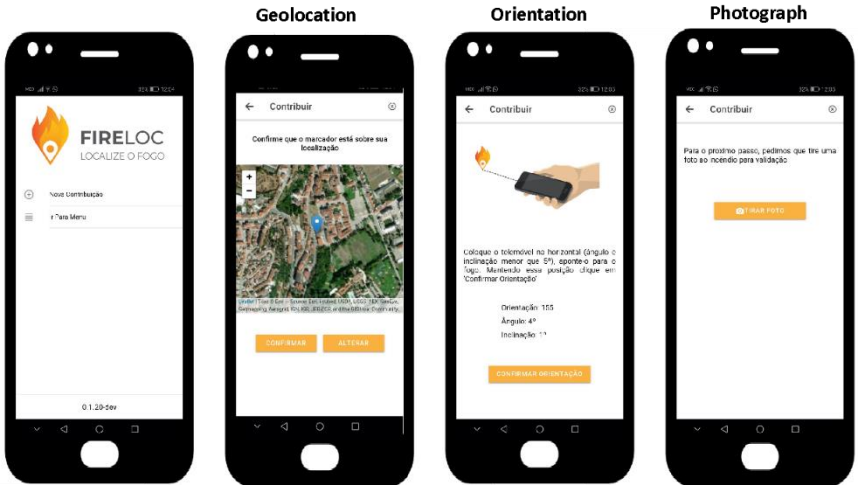

Figure 2- The FireLoc app

Part of the data required by the system are collected automatically by the app using the mobile device sensors when the volunteer starts a contribution, such as the observer geolocation (even though the volunteer may correct it over a map), the date and the time of observation. To collect other necessary data, the volunteer needs to follow a set of steps, indicated by the app, which include:

1. Orientation towards the observed fire and recording of the magnetic azimuth;
2. Orientation towards the fire and taking a photograph of the observed event.

The collection of the above-mentioned data is mandatory, and the contribution can only be uploaded if these steps are followed. However, the volunteer may also upload additional data, which will be useful to assess the quality and validity of the contribution. As in any projects involving citizen participation, a crucial aspect is related to their willingness to contribute. Therefore, there has to be a balance between the data that system administrators would like to collect and the data the volunteers are willing to provide. Due to this constraint, even though potentially useful, the contribution of additional data was considered to be optional at the current version, to avoid overloading the volunteer with too many mandatory steps. These additional data include:

1. Orientation towards the volunteer's shadow and measurement of the magnetic azimuth;
2. Additional geolocation after the volunteer moves backward or forward in the direction of the fire;
3. The indication of the approximate distance to the fire;
4. A short text message with any information the volunteer may consider useful.

The measurement of the magnetic azimuth in the direction of the volunteer's shadow is useful to compare the bearing measured by the mobile device with the known bearing of the shadow at the observation location, date and time. This will provide information about the order of magnitude that can be expected in the orientation measured by the mobile device, which can help avoiding large errors usually associated with the bearings measured by mobile devices (Fonte et al. 2022). The repeated geolocation after the volunteer's movement in the direction of the fire provides additional data to estimate the orientation towards the event. The estimate distance to the fire, even though difficult to provide by a volunteer, may be a useful insight to determine if the fire is in the close proximity of the observer's position (i.e., a few hundreds of metres) or farther away (i.e., several kilometres away). Finally, text messages may provide additional information about, for example, the stage, severity or level of dangerousness of the event.

4. The FireLoc portal

The FireLoc portal (see Figure 3) includes a webpage where information about the project is available, and a Geoportal where several types of data may be visualized (Figure 4). The data available for visualization depends upon the type of user. Four types of users were considered:

1. Common users, not registered in the system;
2. Registered users with the "volunteer profile";
3. Registered users with privileged permissions (e.g., civil protection agents or firefighters)
4. System administrators.

Among the data available for visualization are:

- The events geolocation and evolution identified with the data provided by the citizens, within a specific interval of time or a selected region. When the user has the required permissions, these may be visualized in real time, or only in the aftermath of the event;
- Citizen contributions (different data are available depending on the type of user);
- Statistical analyses and graphs about the reported events and contributions;
- Several types of ancillary geospatial data, including land-use/land-cover maps, digital elevation models, slope maps, cartography of built-up areas, or maps of the burnt areas obtained, e.g., from satellite imagery classification.

Data available in the portal may be used in real-time to geolocate events reported by citizens. The analysis of these data may help to geolocate the event and provide a better insight about the fire, e.g., through the observation of collected photographs, which may offer useful details about the event to decision makers (e.g., the dimension or spread at the time of the contribution, or the characteristics of the landscape). Other geospatial datasets available in the system may provide additional useful information, such as the proximity to inhabited areas or the regions vulnerability to fire propagation.

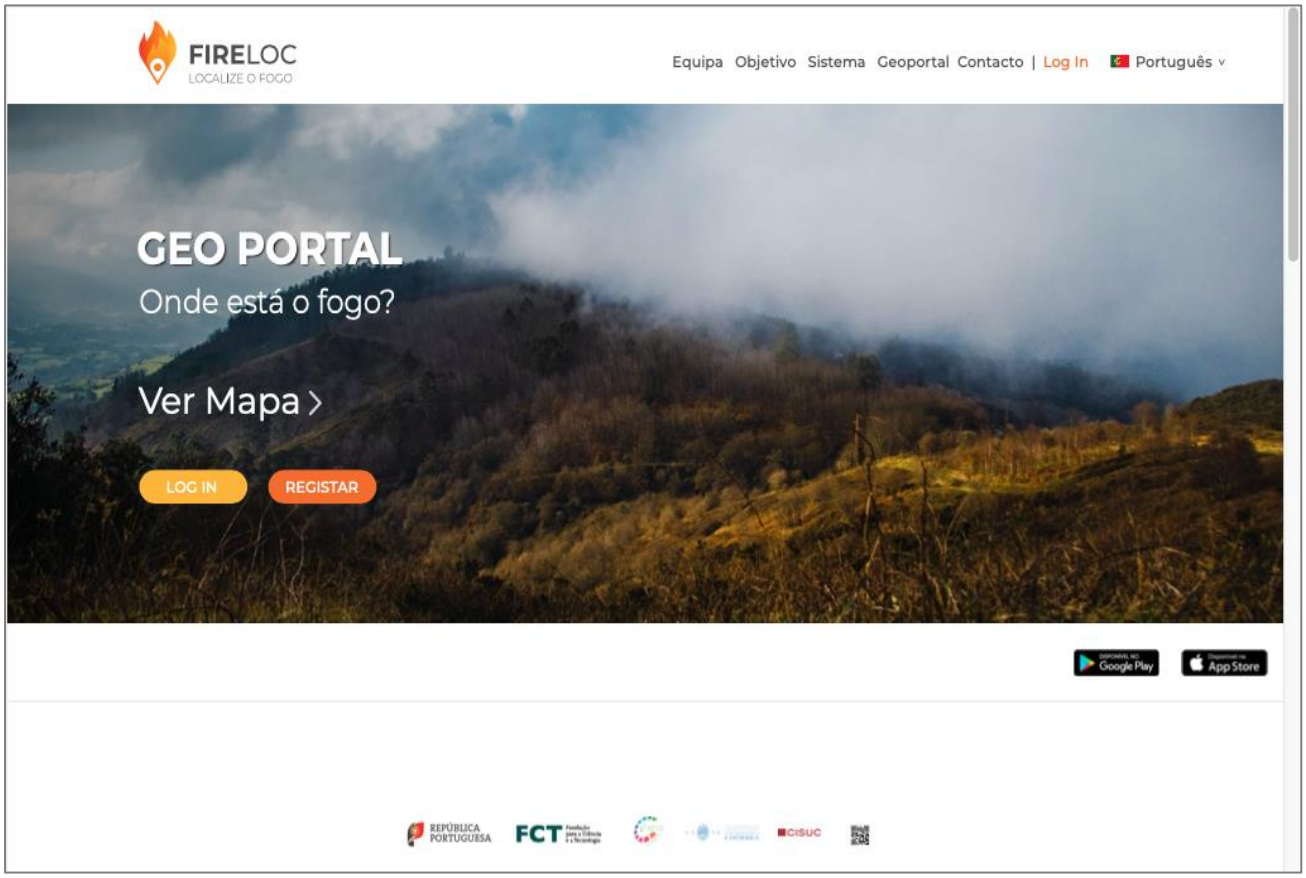

Figure 3- The FireLoc portal initial page.

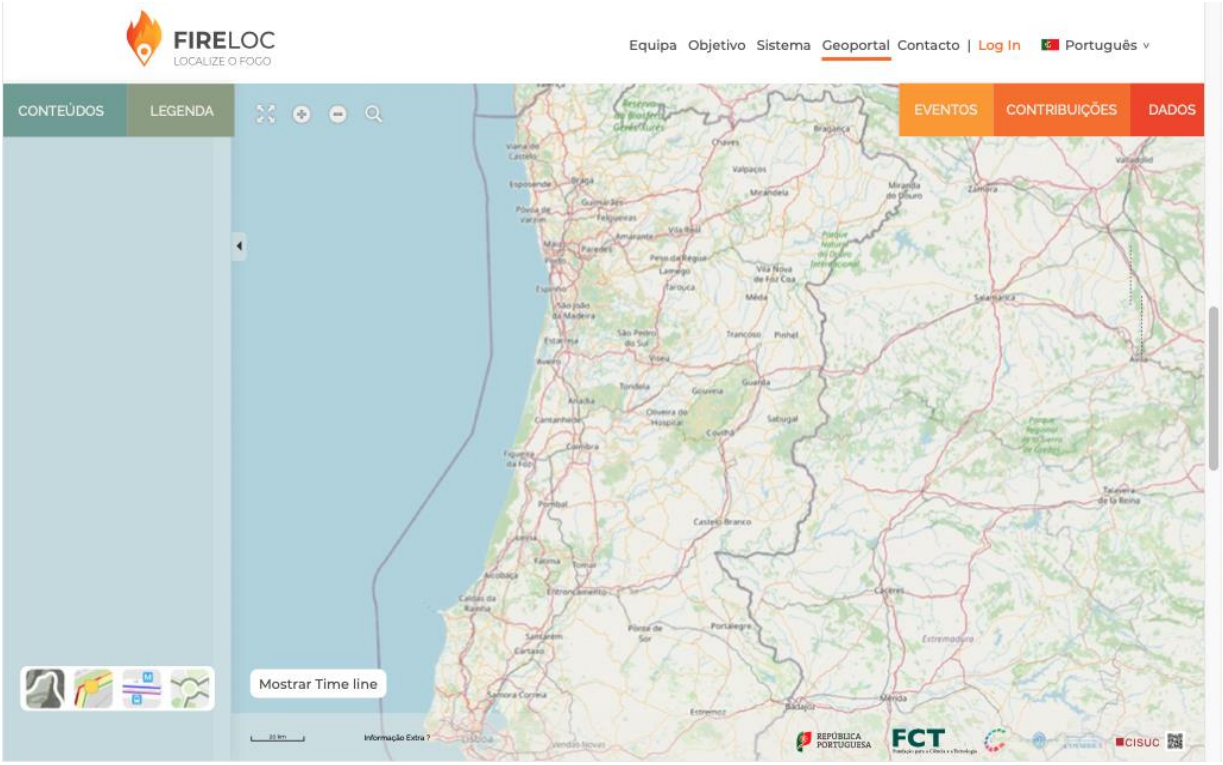

Figure 4- The FireLoc geoportal.

5. Conclusions

The FireLoc system will enable the collection of geospatial data provided by citizens that may assist in fire detection and monitoring. The uploaded photographs will enable the early visualization of the event by authorities, which proved to be crucial in previous experiments (Albuquerque et al. 2016). The geolocation of both the observer and the event may provide key information, especially in cases where reported events are not spotted by official personnel in observation towers or more complex systems, but only through a phone call to the emergency number 112 (where the geolocation of the event is made only based on the observer's oral description). Moreover, the processing of the collected data will provide additional information about the fires, that may be very useful both in real time analysis but also when analysing past events.

Abstract

The FireLoc system aims at geolocating forest fires observed by the citizens using data uploaded by them through a dedicated app developed for mobile devices. The collected data includes the location of the observer (determined with the Global Navigation Satellite System receiver embedded in the device), the magnetic bearing registered by the mobile device when facing the fire and the approximate distance to the fire. However, due to the errors that may be associated with the measurement of the magnetic bearing an additional measurement is collected with the app, which is the magnetic bearing measured when the volunteer is facing his/her shadow. Even though the collection of this data is not mandatory to upload a contribution at the current version of the app, it may be very useful to estimate the error associated with the measurement of the magnetic bearing. This short paper describes the process to determine the location of the observed fire with the collected data, without considering the error associated with the measurement of the orientation and when this error is considered by using a fuzzy approach to identify the region where the fire is more likely to be located.

1. Introduction

The FireLoc project aims to provide to the citizens a tool that can be used to upload data about forest fires. This data is collected using a dedicated app, and includes the geolocation of the observer, computed with the Global Navigation Satellite System (GNSS) receiver embedded in the mobile device, the magnetic bearing measured when facing the fire, the approximate distance to the fire and the magnetic bearing measured when facing the observer's shadow. This last two values are not mandatory in the present version of the app, so that the process to contribute does not include too many steps, which may demotivate the volunteer. However, this last data may turn out to be very useful to estimate the orientation errors, which may be very large (e.g., Kuhlmann et al., 2021; Fonte et al., 2022, Novakova, 2017). In this short paper we present the procedure used to geolocate the fires using these data.

2. Base strategies for fire positioning

The fire positioning is based upon the following approaches:

1. Positioning with the observer's geolocation and the distance between the observer and the fire.
2. Positioning considering the intersection of at least two contributions.
3. Positioning considering the intersection of at least two contributions and the estimated error in the orientation extracted from the orientation to the observer's shadow.

The first two approaches are further explained in the next subsections, while the third is explained in section 3.

2.1. Positioning with the observer's location and the distance

If only one observation is uploaded, it is possible to know in which direction the event was observed but not to position it exactly unless the observer indicates the distance to the fire. In this case the coordinates of the fire location are obtained with equations (1) and (2), where (X_{Fire}, Y_{Fire}) are the coordinates of the fire in a projected reference systems, $(X_{Observer}, Y_{Observer})$ are the coordinates of the observer in the same reference system, *D* is the distance between both and CB_{Fire} is the cartographic bearing, computed using the measured magnetic bearing and the cartographic declination.

$$X_{Fire} = X_{Observer} + D\ sin\ (CB_{Fire}) \quad (1)$$

$$Y_{Fire} = Y_{Observer} + D\ cos\ (CB_{Fire}) \quad (2)$$

2.2. Positioning with the intersection of at least two contributions

This positioning approach requires the contribution of at least two volunteers. Figure 1 illustrates the process when four volunteers send data corresponding to the same event. Angles MB_i $(i = 1, \ldots 4)$ represent the magnetic bearings measured with the mobile device when the observers are oriented towards the fire. They are measured in the clockwise direction and vary between 0° and 360°. The intersection of each set of two observations identifies a point. If the time interval between the contributions is below a specified value (selected by the system administrator) the event location is the convex bounding box containing the points obtained with all intersections (orange polygon in Figure 1).

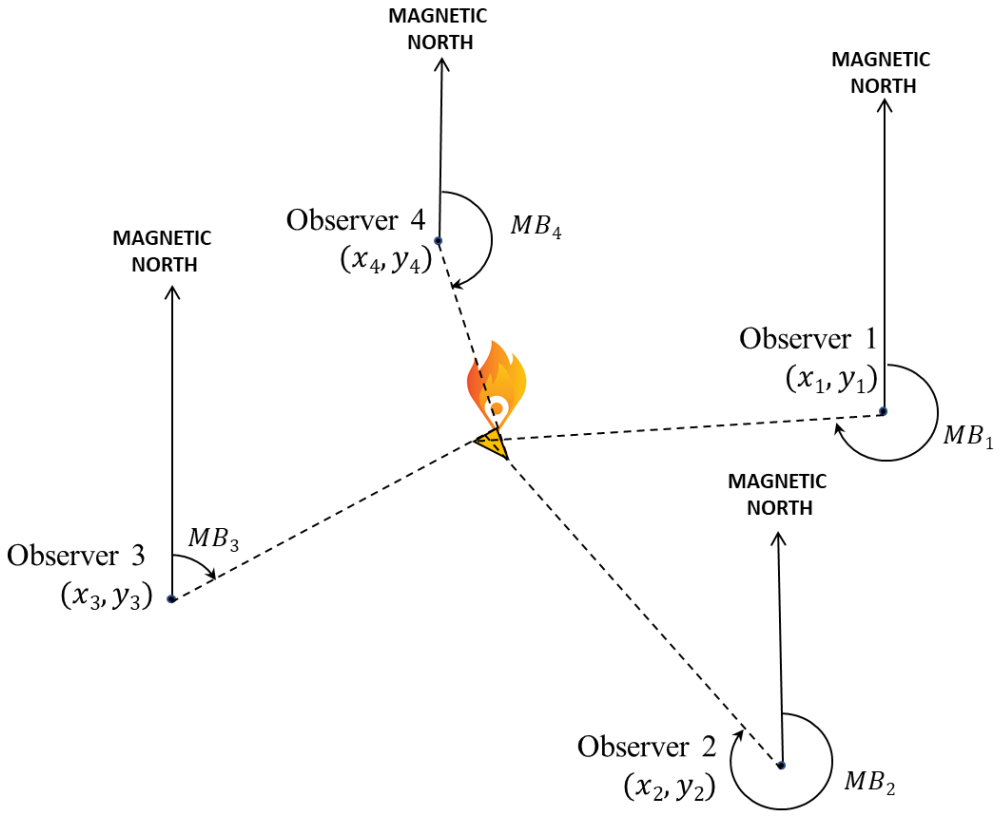

Figure 1- Event geolocation principle with the volunteers' contributions

3. Strategies for minimizing errors in the fire positioning

The positioning strategy presented in section 2.1 has always low accuracy due to the difficulty in estimating the distance to the event. Therefore, it is only used in solo if no other contributions are available. Strategy 2.2

enables the geolocation of the observed events if the observations correspond to the same event and if no significant errors are associated with both the observer's geolocation and the measure magnetic bearing. However, there are errors associated with these measurements. There may be also a time interval between the contributions, which means that the event may have moved between them. In this short paper only the first two sources of error will be addressed.

3.1. Errors associated with the measurements

The observer's positioning errors may be due to several factors, such as multipath, number and position over the horizon of the satellites used to compute the location, and the GNSS receiver characteristics. These errors are usually lower than a few hundreds of meters, even though outliers may occur (e.g., Fonte et al., 2022; Zhang et al., 2018). The errors associated with the orientation measurement may be due to, e.g., the lack of calibration of the mobile device compass, the influence of external objects with magnetic fields, the quality of the mobile device and its handling by the user. Tests have shown that these errors may have large magnitudes, which may reach a few tens of degrees. Even though these two sources of error influence the quality of the fire's geolocation, the influence of the observer's location error only generates a translation of the fire position with the same magnitude. Therefore, the effect of these errors over the fire geolocation is not important due to the level of accuracy required for this type of application, where a geolocation with an accuracy of a few hundred of meters is enough. On the other hand, the influence of the orientation errors increases with the distance between the observer and the observed fire (Fonte et al., 2021). For example, an error of 10° corresponds to a displacement perpendicular to the observation direction of 174 m if the fire is 500 m away from the observer, but it is already 3,5 km if it is 10 km away. Therefore, a strategy was developed to estimate the order of magnitude that may be associated with the measured magnetic bearing in each contribution, based on its measurement towards a known direction: the observer's shadow.

3.2. Observation strategies used to minimize the effect of observation errors

Even though the errors associated with the observer's geolocation are not critical due to the reasons explained above, the app keeps registering the geolocation during the whole time the volunteer is contributing. This enables the FireLoc system to perform a statistical analysis of its variation, including the mean location and the associated standard deviation, which is an indicator of the expected quality of the coordinates. Moreover, the volunteer can see the computed geolocation over a map and correct it if it is incorrect.

Regarding the orientation, the FireLoc app asks the user to orient himself/herself towards his/her shadow, so that the magnetic bearing can be registered. As the magnetic bearing of the shadow is known at any location over the Earth at any time, this enables the comparison of the measured value with the known value. Figure 2 illustrates this procedure, where δ represents the magnetic declination (its value is computed by the magnetic observatories and is regularly updated), AZ_{Sun} is the Sun's azimuth, MB_{SHADOW} is the shadow magnetic bearing $MB_{SHADOW}^{MEASURED}$ is the measured shadow magnetic bearing, $MB_{FIRE}^{MEASURED}$ is the magnetic bearing measured towards the fire, and ε is the estimated error in the magnetic bearing. Equation (3) shows how the magnetic bearing of the shadow is computed. Depending on the location on Earth the magnetic declination may have to be added or subtracted to the Sun's Azimuth, and, as the magnetic bearing varies between 0° and 360°, 180° needs to be added or subtracted if the Sun's azimuth is, respectively, lower or larger than 180°. Equation (4) shows how the magnetic bearing measurement error ε is computed and equation (5) how the corrected magnetic bearing towards the fire (MB_{Fire}) is obtained.

$$MB_{SHADOW} = AZ_{Sun} \mp \delta \mp 180° \quad (3)$$

$$\varepsilon = MB_{SHADOW} - MB_{SHADOW}^{MEASURED} \quad (4)$$

$$MB_{Fire} = MB_{FIRE}^{MEASURED} + \varepsilon \quad (5)$$

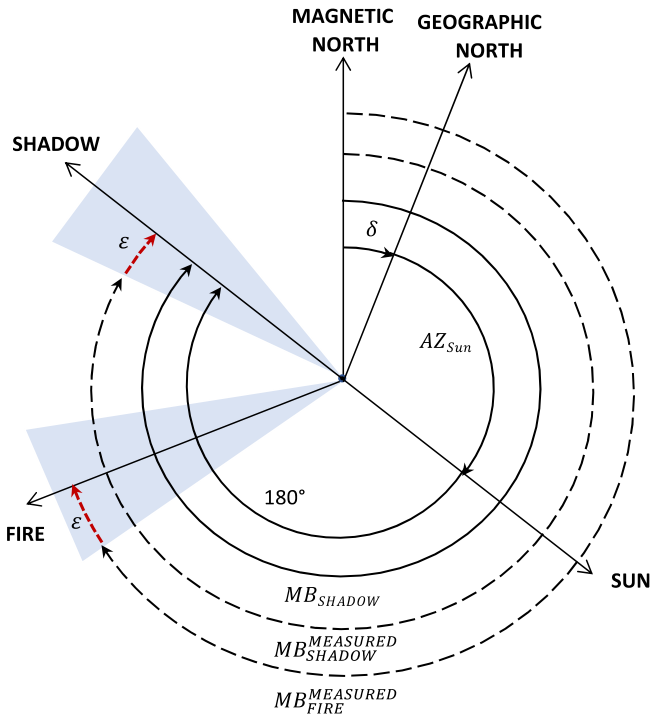

Figure 2 – Relation between the measured and computed orientations

A procedure was implemented to compute the Sun's Azimuth (AZ_{Sun}) given the observer's coordinates (latitude and longitude), the date and the time of observation. Other necessary parameters are considered constant, namely the distance between the centre of the Earth and the Sun, and the ecliptic obliquity. The algorithm requires the computation of the sideral time corresponding to the Gregorian date in the Julian calendar. Then, the Geocentric Sun's right ascension and declination is computed using the NREL's Solar Position Algorithm (SPA) (https://midcdmz.nrel.gov/solpos/spa.html) and the hour angle is computed. These data enable the computation of the altitude and azimuth of the Sun and the given location and time. The Sun's apparent position is then computed using the atmospheric refraction and geocentric parallax, and the Sun's azimuth is corrected with the diurnal aberration, computed with the observer's location (e.g., Green, 1985).

3.3. Strategies to geolocate the fire with the available data

Given the impact of the orientation errors over the fire geolocation, an approach was developed that considers the orientation towards the fire not as a line but as a region, centered at the MB_{Fire} direction and with a maximum amplitude of ε to both sides, as shown in Figure 3. A fuzzy approach was applied to express the variability of the likelihood of the fire location, considering trapezoidal fuzzy sets perpendicular to the line of sight, having a support with an amplitude of 2ε and the core an amplitude of ε as shown in Figure 3. The intersection of these fuzzy regions enables the identification of the expected fire location, where the most likely region corresponds to the core of the fuzzy region obtained with the intersection of all contributions, and the support of the fuzzy region shows all possible locations given the considered contributions (see Figure 4).

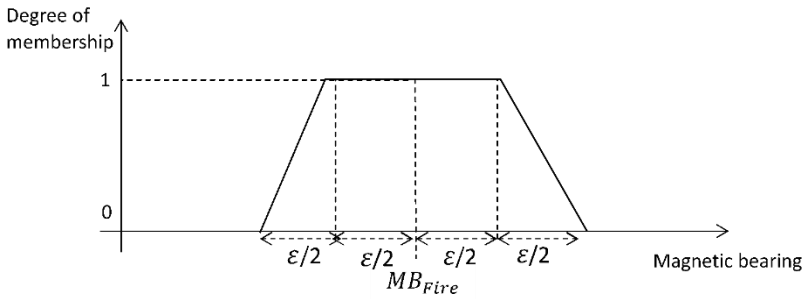

Figure 3 – Trapezoidal fuzzy intervals perpendicular to the line of sight expressing the orientation uncertainty.

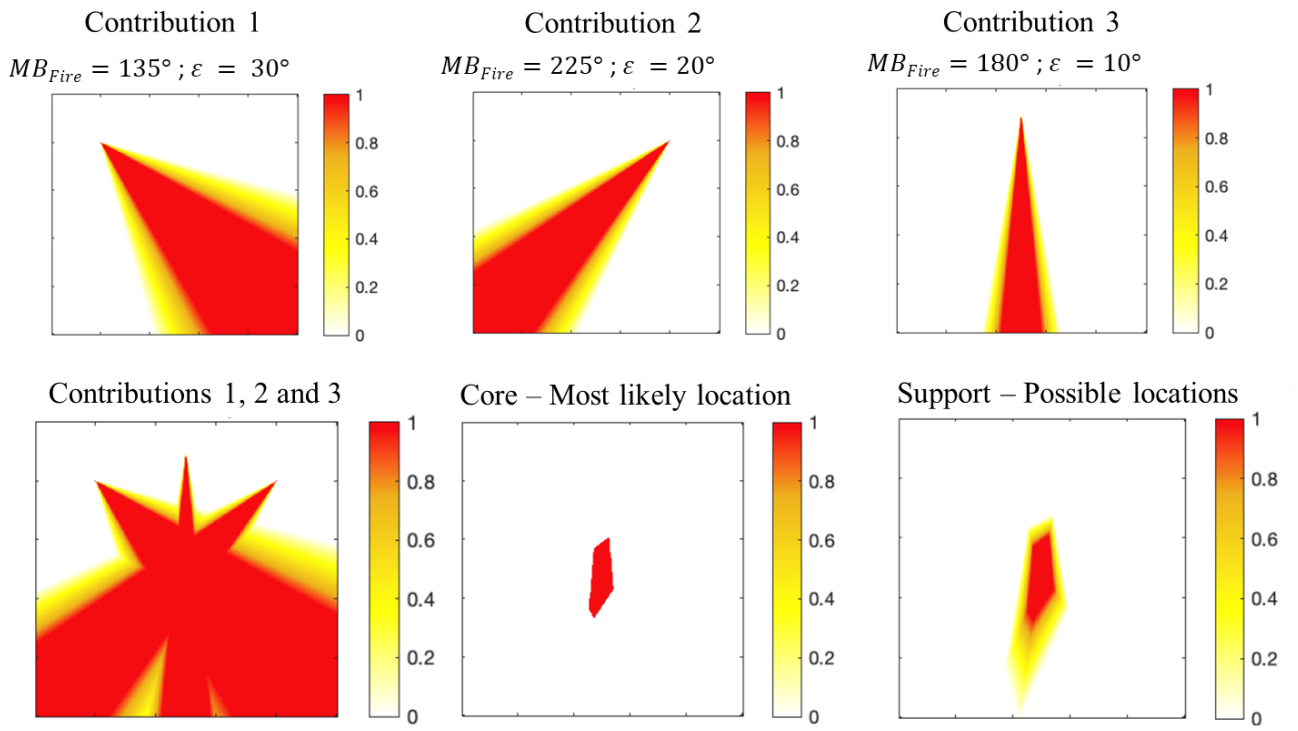

Figure 4 - Event geolocation considering the orientation errors.

4. Conclusions

This short paper describes some of the strategies developed to geolocate the fires observed by citizens with the data collected with the FireLoc app. Additional strategies will be developed based on statistical approaches and outliers' detection, so that the best strategy can be identified based on the data collected by the app.

Dynamic Global Vegetation Model, Landscape Fragmentation, Multiple-Day Fires

Abstract

Fire-enabled Dynamic Global Vegetation Models (DGVMs) are used to model fire-vegetation interactions and their impacts on global vegetation dynamics. Previously, these DGVMs have performed poorly in the boreal zone. The challenge of modelling fires in the boreal zone has been addressed by several DGVMs by increasing fire durations, from previous limits of less than a day, to multiple days. We investigate improvements to modelling boreal fires in the LPJmL-SPITFIRE DGVM by implementing a multiple-day fire spread algorithm. In addition, we include an empirically derived terrain fragmentation function to account for the impact of terrain ruggedness on limiting fire spread for larger, longer-duration fires. Our work is conducted in two parts: first, we use satellite data to investigate the impact of terrain ruggedness on burnt area at the 0.5° by 0.5° resolution typical of DGVMs, for latitudes greater than 50°. We demonstrate that terrain fragmentation acts as a significant limit on fire size, and derive an empirical function based on our data analysis that describes this effect. The second part of our work consists of the implementation of a multiple-day fire spread algorithm in combination with the terrain ruggedness limitation function in the LPJmL-SPITFIRE model. We find that this results in a significant improvement of fire spread calculations in the boreal zone. The results of this work represent a useful addition to LPJmL-SPITFIRE, in addition to DGVMs in general that do not incorporate the effects of terrain-based landscape fragmentation.

1. Introduction

Dynamic Global Vegetation Models (DGVMs) model processes including vegetation establishment, growth, and mortality as they respond to solar radiation and global water and carbon cycles. An important component of many such models is the incorporation of a coupled fire model to calculate fire-related plant mortality as well as fire impacts on the global carbon cycle. The Lund-Potsdam-Jena managed Land (LPJmL) Dynamic Global Vegetation Model calculates vegetation dynamics on a grid with cells of size 0.5° × 0.5° and is coupled to the Spread and InTensity of FIRE (SPITFIRE) global fire model (Schaphoff et al., 2018; Thonicke et al., 2010). SPITFIRE models ignition events and fire danger, and takes a process-based approach to modelling the spread of the resulting fires, based on the Rothermel equation (Thonicke et al., 2010; Rothermel, 1972; Albini 1976). The work described herein focuses on the fire spread component of SPITFIRE, coupled with the latest version of LPJmL, LPJmL5.3.

A common issue in DGVMs has been inaccuracy in predicting fire in boreal regions (Ward et al., 2018). Fires in boreal forests often have longer durations (Andela et al., 2019). Therefore, several models have sought to improve fire modelling in boreal regions by introducing longer fire durations (Ward et al., 2018). LPJmL-SPITFIRE currently limits fire duration to a maximum of 241 minutes, relying on a modelling approach that replaces large fires with a larger number of small fires (Thonicke et al., 2010). While this approach is successful at lower latitudes, the model currently under-predicts burnt area in the boreal zone to a significant extent.

To improve upon this, we examine the impact of introducing longer fire durations in LPJmL-SPITFIRE. As a consequence of introducing these longer in duration, and therefore larger, fires, the impacts of various fuel bed fragmentation barriers on fire size become more significant. We therefore examine the impact of terrain ruggedness on limiting fire spread, and implement a function to represent this in the model.

While some fire-enabled DGVMs account for the effect of landscape fragmentation on limiting burnt area, the functions used for this are based on heuristic arguments, and are not derived from theoretical calculations or observed data, and many models omit this effect entirely (e.g. Pfeiffer et al., 2013, Rabin et al., 2017). We seek to improve upon this by deriving an empirical function, based on a satellite data analysis, that can be implemented in DGVMs. A combination of this function and multiple-day fire spread results in significant improvements to the fire spread component of LPJmL-SPITFIRE in the boreal zone.

2. Terrain Limits on Fire Spread

We examine the impact of terrain ruggedness on fire spread using the 250 m GMTED2010 Digital Elevation Model (DEM), courtesy of the U.S. Geological Survey. We compute the Vector Ruggedness Measure (VRM) at the original resolution of the DEM and take the median of this value over 0.5° × 0.5° grid cells, matching the resolution of LPJmL-SPITFIRE, using Google Earth Engine (Gorelick et al., 2017). We then compare these values for each grid cell to the size of individual fires in the grid cells from 2003 to 2016 using data from the Global Fire Atlas (Andela et al., 2019). We divide fires by the main landcover type burned and report results for landcover types with over 10 000 observed fires that have ignition points at latitudes greater than 50°.

We bin fires by VRM, with bin widths calculated using the Freedman-Diaconis rule found to produce the most consistent results. We find that the most significant impact of VRM on fire size is its role as a limit on the size of the largest fires, with significantly less impact on the median fire size calculated in each bin. The left panel in Figure 1 shows functions of the form: $\text{maximum fire size} = \frac{a}{\text{VRM}+b}$, where a and b are constants, fit to the maximum fire size in each bin using least squares regression, with R^2 values shown in the legend.

These functions collapse into two bands, with Evergreen Needleleaf Forests, Mixed Forests, and Grasslands generally having higher maximum fire sizes and Open Shrublands, Deciduous Needleleaf Forests, and Woody Savannas having smaller maximum fire sizes. A potential explanation may be that additional causes of fuel bed fragmentation beyond those due to terrain ruggedness may result in reduced fuel bed connectivity for the lower band of functions, amplifying the effect of terrain fragmentation. However, further study is required to examine the differences between the two bands.

We use the function derived for Mixed Forests for the initial implementation of a maximum fire size function in LPJmL SPITFIRE. This is due to several factors, including that 70% of fires in the landcover types we examine at latitudes over 50° fall into the upper band of maximum fire size functions, of which the mixed forest function imposes the largest limit, and that the landcover types in the lower band are not well represented in the LPJmL DGVM. The function is:

$$\text{maximum fire size} = \frac{60}{\text{VRM} + 1.6 * 10^{-4}},$$

and is plotted in the right panel of Figure 1. Maximum fire sizes in each bin, to which the function is fit, are shown in black, and raw individual fire sizes are shown in grey. This limit is significantly closer to the bulk of the fire size distribution for VRM values above 0.003, potentially due to fires before this value being extinguished before they can reach their significantly higher and, at low VRM values, potentially non-existent, maximum terrain limits. While our current implementation treats this as a fixed maximum fire size, further work should be undertaken to examine the conditions under which this limit can be surpassed due to extreme fire behaviour, in particular to avoid artificially strong fire size limitation under extreme fire conditions.

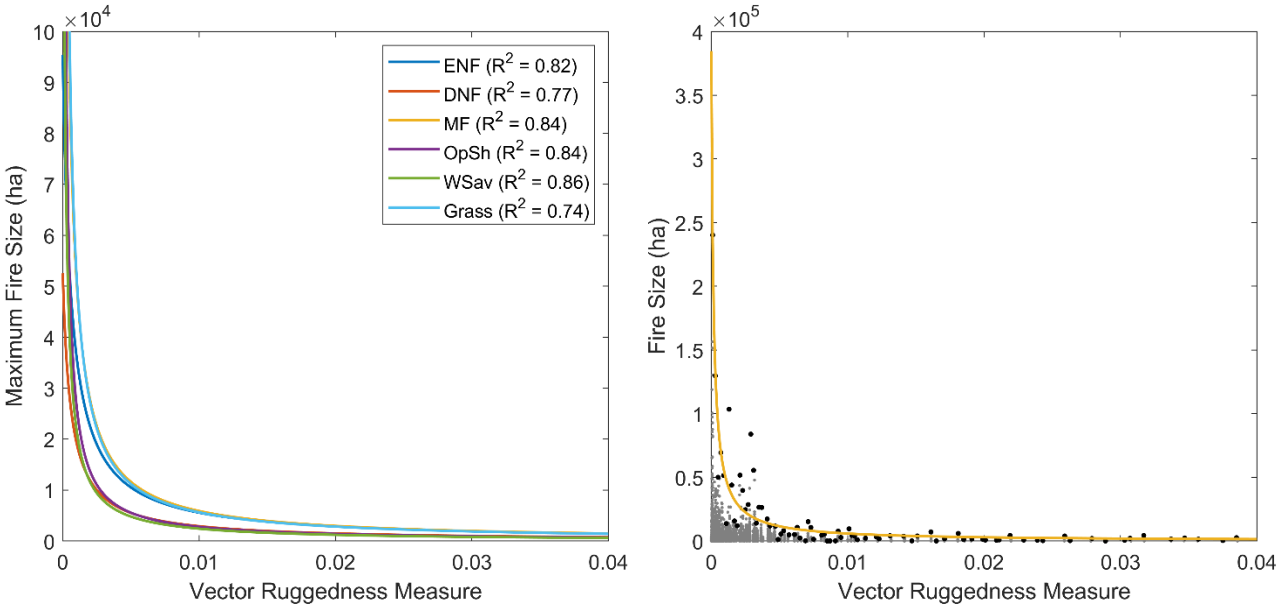

Figure 1 – Derived functions for the maximum fire size as a function of median vector ruggedness measure over a 0.5° × 0.5° grid cell for various landcover types (left panel). Abbreviations are as follows: ENF – Evergreen Needleleaf Forests, DNF – Deciduous Needleleaf Forests, MF – Mixed Forests (combinations of broadleaf and needleleaf trees), OpSh – Open Shrublands, WSav – Woody Savannas, Grass – Grasslands. The function for Mixed Forests is shown in the right panel with the bin maxima to which this function is fit as black points and individual fires from the Global Fire Atlas shown in grey.

3. Implementation into LPJmL-SPITFIRE

To improve the modelling of boreal fires in LPJmL-SPITFIRE we implement a function that calculates fire spread over multiple days. This function calculates burnt area based on fire spread in an elliptical shape, as in the original SPITIFRE formulation by Thonicke et al. (2010), with ellipses continuing their growth on subsequent days in the absence of extinction events, or the reaching of terrain limits. All active fires in a grid cell are extinguished if there is no calculated increase in fire size for any fires on a given day, or if the Fire Danger Index (FDI), which we calculate based on the Vapour Pressure Deficit (VPD) as in Drueke et al. (2019), falls below a threshold value of 0.005. While this produces reasonable results, further investigation is required to implement a more sophisticated approach to fire extinction caused by, e.g., precipitation in future versions of this model. At present we rely on the impact such events have on reducing the Fire Danger Index.

To avoid excessive computational costs, we limit the number of days that fires burn to 14. This is longer than 95% of fires in the Global Fire Atlas and should therefore not be excessively limiting. In addition, we modify the fire duration function from Thonicke et al. (2010) to allow for longer burning on individual days. The current function results in very short median fires, lasting about 1 hour even when allowing for a maximum fire duration of 12 hours. We set a fixed fire duration of 12 hours per day, relying on a reduced rate of spread to limit fire sizes under wetter conditions. We choose 12 hours per day as fire spread often reduces significantly at night (e.g. Balch et al., 2022). This may be further refined in future, e.g. by limiting fire spread to times when the VPD thresholds derived by Balch et al. (2022) are exceeded.

We examine the impact of this change in fire duration by starting a fire in the model on the day, and in the same grid cell of each fire in the Global Fire Atlas. We then compare the burnt area in the model to the Global Fire Atlas, effectively comparing the fires in the model to their observed counterparts. This approach allows for an examination of the model's fire spread calculations without the additional ambiguity introduced by the parametrization of ignition events and their conversion into spreading fires based on an FDI. Because the FDI, which requires some tuning, is only implemented in the extinction threshold, this significantly reduces the impact of tuning on the model results examined here.

Figure 2 shows a timeseries of burnt area for model simulations with multiple-day fires compared to the Global Fire Atlas, and to a previous version of SPITFIRE (described in Schaphoff et al., 2018). The implementation of multiple-day fires results in a significant improvement in the model at latitudes greater than 50°, and the implementation of terrain fragmentation fire size limits improves the model further. The previous version of SPITFIRE simulates a negligible amount of burnt area for these fires due to the low fire duration.

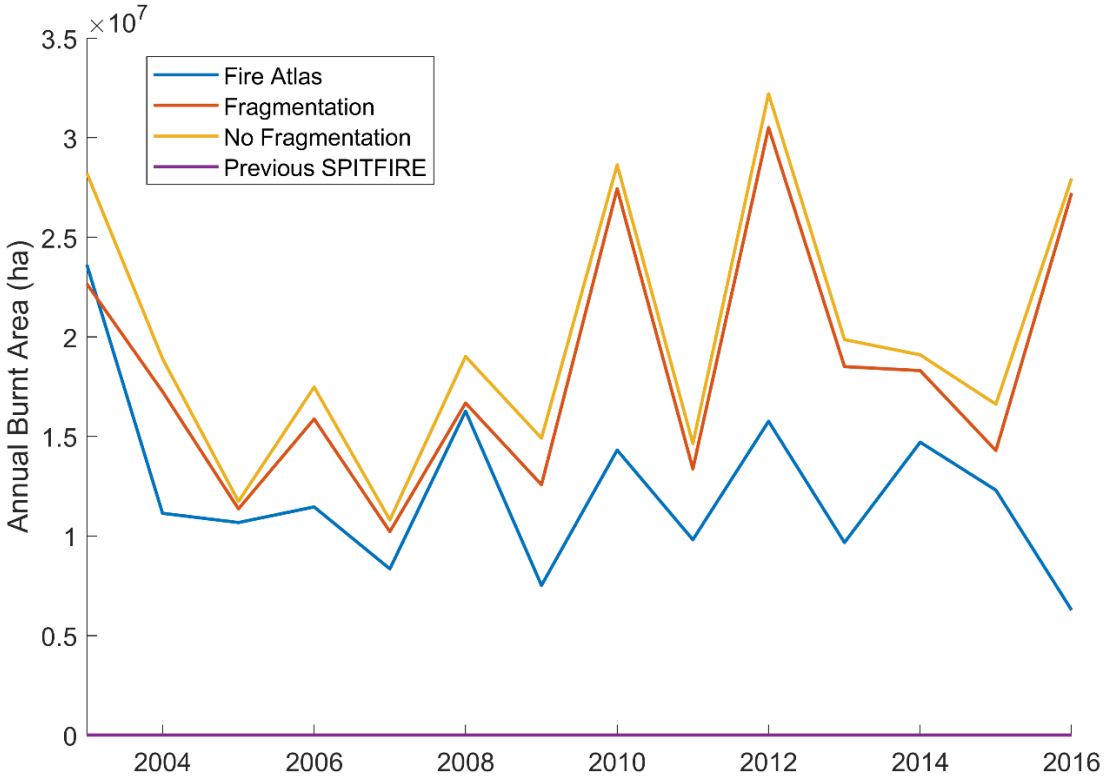

Figure 2 – Annual burnt area as a function of time for latitudes over 50° in LPJmL-SPITFIRE and for the same fires in the Global Fire Atlas. The two implementations of LPJmL-SPITFIRE with multiple-day fires (Fragmentation and No Fragmentation) show a significant improvement in reproducing these fires over a previous version of SPITFIRE.

Therefore, the parametrization introduced here represents a significant improvement at the examined latitudes. However, modelled values appear to diverge slightly from the Global Fire Atlas burnt areas in later years. One potential cause for this may be that the Global Fire Atlas divides large burn patches into too many individual fires, e.g. as described by Artés et al. (2019), which grow into individual large fires in LPJmL-SPITFIRE. An additional cause for the difference may be that LPJmL simulates significant encroachment of vegetation into higher latitudes over the examined time period.

This increase in vegetation in the model may also explain excessively high values of burnt area at higher latitudes shown in Figure 3. Of additional interest, a difference map between model runs with terrain fragmentation limits imposed and those without, shown in the bottom right panel, shows the locations where the terrain fragmentation function has the greatest impact. Modelled fires in eastern Russia and Alaska are particularly prone to reaching the terrain fragmentation limits. Therefore, accounting for these limits may be particularly important for studying fires in these areas.

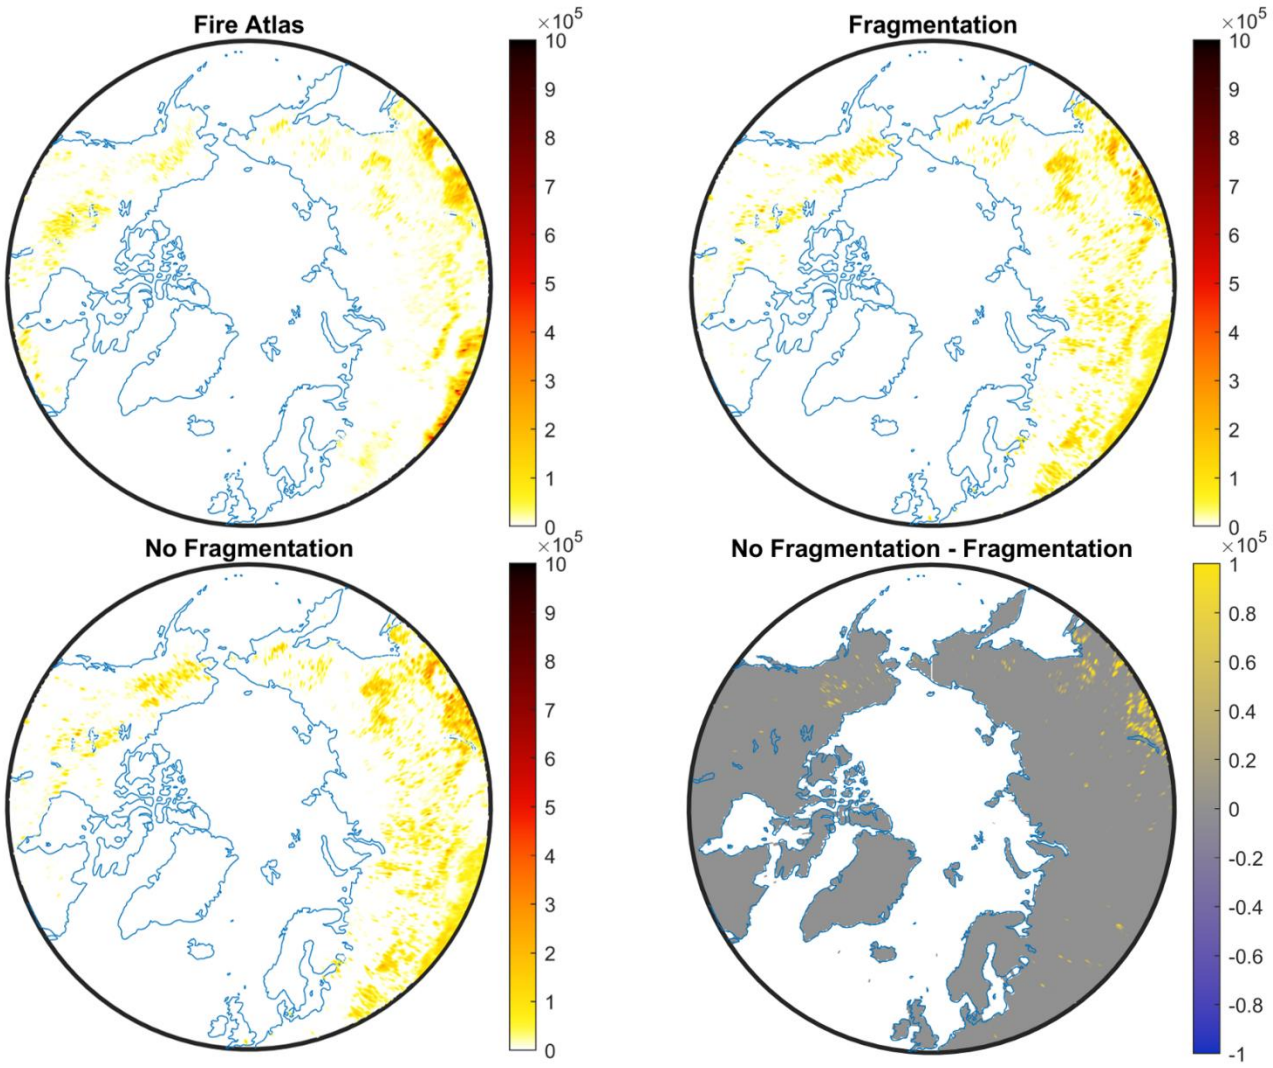

Figure 3 – Burnt area per 0.5° × 0.5° grid cell (in ha) at latitudes over 50°, summed from 2003 to 2016, due to fires in the Global Fire Atlas and the same fires implemented in LPJmL-SPITFIRE with and without fuel bed fragmentation due to terrain ruggedness in the model. The bottom right panel shows the difference between these two sets of results. Colour maps were obtained from www.colorcet.com, based on Kovesi (2015).

4. Conclusions

We implement a multiple-day fire spread algorithm, and a function to account for the effect of terrain fragmentation in LPJmL-SPITFIRE at latitudes greater than 50°. Terrain fragmentation is accounted for by fitting a function of the Vector Ruggedness Measure to the maximum fire sizes observed in the Global Fire Atlas. This function is then implemented as a limit to fire sizes in the model. The multiple-day fire spread algorithm allows fires to burn for 12 h per day up to a maximum of 14 days. In general, our model results compare favourably with the Global Fire Atlas burnt area when simulating the same fires, with differences likely caused in large part by inaccuracies in vegetation modelling at high northern latitudes. Therefore, our results show a significant improvement on LPJmL-SPITFIRE in the boreal zone.

Fire management, fire risk assessment, fuel models, forest fire modeling

Abstract

In terms of the average number of forest fires (7,188) in 2010-2019, Poland was third in Europe after Portugal (19,362) and Spain (11,860). The average burnt area, which is a kind of efficiency indicator for the forest fire protection system, in the analyzed period was 0.42 ha in Poland. The functioning fire protection system in the State Forests, which covers 76.9% of the forest area in the country, is constantly improved thanks to close cooperation with the Forest Research Institute. The results of the research conducted by the Institute are thus implemented in forestry practice, examples of which are presented in this article.

The basis for planning and organizing rescue operations is the assessment of potential forest fire risk, which is carried out using the method of classifying forest areas to the forest fire risk category. It is determined for the forest district (average area 17500 ha) for 10 years on the basis of the frequency of fires, forest stand, climatic and anthropogenic conditions according to the formulas developed for each of the factors. The category determines the distribution of funds for fire protection and the method of forest preparation in the event of a fire, concerning fire detection, communication and alarm systems, the density of fire access roads and water supply points, and fire extinguishing equipment. The macroscopic method of forest fire risk categorization is complemented by the method of forest stand flammability classes, which determines their susceptibility to fire due to the presence of flammable material. It is based on the forest habitat type and soil cover type and is determined at the level of separation (average area 3 ha), with the possibility of generalization to the division (20 ha) and forestry (1300 ha). Both methods are used to map the potential fire risk of forests in Poland. The method of determining the degree of forest fire risk on the basis of air temperature and relative humidity, precipitation and direct measurements of moisture content of pine litter (*Pinus sylvestris*) is used to assess the dynamic forest fire risk, shaped by weather conditions. Determining the degree of risk is performed from the 1st of March to the 30th of September, daily at 9.00 and 13.00 in 60 forecast zones with the use of an automated network of 145 meteorological measuring points. Information on the degree of risk determines the operational readiness of ground and air forces. In the event of a fire and determination of its forest address, we can download from the Information System of the State Forests, data on the flammability class of the forest stand and the characteristics of the flammable material (type, fuel load), using the developed fuel models for 7 types of soil cover, the fires of which constitute nearly 90 % of all events.

The possibility of a soil cover fire turning into a crown fire is determined based on the developed algorithms, taking into account the age of the forest stand, habitat and stand conditions, meteorological conditions and the duration of the fire. Organizing a firefighting action, including in particular having the right amount of forces and resources to extinguish a fire with the smallest possible area, can be supported by the application "Model of a forest fire", which the forest service has at its disposal. It was developed on the basis of laboratory and field research on the conditions of the emergence and spread of forest fires. The result of these works was the development of algorithms in the form of mathematical equations, enabling the calculation of the basic parameters of a forest fire (speed of the front, surface and perimeter of the fire) depending on the wind speed, moisture content of the flammable material, fuel load and the time of free fire development. Model calculations can be performed for forest bed, grass, heather and total fires. Early fire detection, reliable alarming and extinguishing action at the earliest possible stage of fire development, supported by the above-mentioned actions contribute to the effective protection of state forests in Poland. The examples cited and discussed above indicate a high level of usefulness, practical application and full implementation at the national level of the results of the research work of the Forest Research Institute in the structures of the functioning and constantly improved system of fire protection of the State Forests in Poland.

1. Introduction

According to EFFIS data {Forest fires in Europe, Middle East and North Africa 2020. JRC Technical Report. 2021], in Poland in the years 2010-2019, on average, 7188 forest fires occurred in Poland. More fires were recorded only in Portugal (19,362) and Spain (11,860). Taking into account the average burnt area, which can be treated as a kind of efficiency indicator for the organization of the forest fire protection system, in the analyzed period it amounted to 0.42 ha in Poland. For comparison, the average in Portugal and Spain was at a similar level, amounting to 7.13 and 7.97 ha per fire, respectively. The maximum average burnt area was in Croatia (56.48 ha), followed by Serbia (28.10 ha), Greece (25.60 ha) and North Macedonia (21.40 ha). The functioning fire protection system in the State Forests, which cover 76.9% of the forest area in the country, is constantly improved thanks to close cooperation with the Forest Research Institute. Thanks to this, the results of the conducted research are implemented in practice, and selected examples of them in the field of supporting the planning and organization of firefighting actions are presented in this article. Its beginning is the assessment of the potential and dynamic fire risk, then the acquisition of forest stand data from the place where the fire started from the IT system and finally forecasting the spread of the fire.

2. Assessment of the potential risk to the forest

The basis for the operational planning and organization of rescue activities is the assessment of the potential fire risk of forests. The analysis determining the forest susceptibility to fire is performed by determining the potential fire risk at the following levels: national - classification of the Regional State Forests Directorates, of regions (NUTS 2) and subregions (NUTS 3), regional - classification of forest districts and counties, and local - classification of stands. The method of classifying forest areas into the forest fire riskcategory {Szczygiel et al, 2020] and the method of forest fire risk classification according to flammability classes [Kaczmarowski et al, 2021], developed by the Forest Research Institute, are used to evaluate the fire risk. The forest fire risk category is determined on the basis of the frequency of fires, forest stand, climatic and anthropogenic conditions according to the formulas developed for each of the factors. It decides on the distribution of funds for fire protection and the method of forest preparation in case of fire, concerning fire detection, communication [Szczygiel et al, 2020] and alarm systems, the density of fire access roads and water supply points, and fire extinguishing equipment. The categorization of forest fire risk is made on a macroscopic scale, because the minimum area for which it is determined is the area of a forest district, amounting to an average of 17.5 thousand hectares. The macroscopic method of forest fire risk categorization is complemented by the method of forest stand flammability classes, which determine their susceptibility to fire due to the presence of combustible material. It is based on the forest habitat type and the type of soil cover and is determined at the level of separation (average area 3 ha), with the possibility of generalization to the compartment (20 ha) and forest range (1300 ha). The classification of forest stand flammability can be used: when carrying out rescue and extinguishing actions of small and medium forest fires (risk assessment at the level of sub-compartment), when planning the target network of fire access roads and water supply points, and conducting rescue and firefighting actions when extinguishing large fires (risk assessment at the level of sub-compartment, compartment) and in determining the location of observation points and equipment bases for extinguishing forest fires (risk assessment at the forest range level).

3. Assessment of dynamic forest fire risk

To assess the dynamic forest fire risk, shaped by weather conditions, the method of determining the degree of forest fire risk is used on the basis of air temperature and relative humidity, precipitation and pine litter moisture content (*Pinus sylvestris*) [Szczygiel et al, 2017]. The determination of the degree is performed from March 1 to September 30, daily at 9.00 am and 1.00 pm in 60 forecast zones with the use of an automated network of 145 meteorological measurement points, making measurements with a 10-minute frequency. Their distribution density depends on the forest fire risk category. The method makes it possible to determine the current degree of risk on the basis of the measurements made, and to calculate the projected degree 24 hours in advance. The projected degree of risk is calculated on the basis of the forecasted values of meteorological parameters obtained from the numerical weather model (COSMO) and the projected moisture content of pine litter, calculated on the basis of equations developed for this purpose. Information on the degree of risk provided to the forest service and fire brigade determines the operational readiness of the ground and air forces.

4. Determining the data on the place where a forest fire occurred

In the event of a fire and determination of its forest address, we have the option of downloading from the Information System of the State Forests, data about the stand (habitat type, species, age, type of soil cover), which allow to determine the flammability class of the forest stand and the characteristics of the combustible material. For the fire characteristics (eg type, fuel load), developed fuel models are used for 7 types of soil cover, where fires account for nearly 90% of all events [Kwiatkowski et al, 2016]. The main features that characterize the type of fuel (fuel model) were: fuel load (kg / m^2), moisture of combustible material (%), heat of combustion and calorific value (KJ / kg) and fuel volume density (kg / m^3). In order to facilitate the mapping of the existing types of combustible materials, a matrix of the occurrence of fuel models was developed depending on the habitat type of forest and the type of cover, which allows to generate a map for any forest area after collecting forest stand assessment data.
The typology of fuels enables the identification of the occurring fire risk and is used in the fire spread forecasts.

5. Modeling of fire spread

From the point of view of the person managing the rescue operation, the key information is the type of fire, the expected size and speed of fire spread, which affects the amount of forces and resources necessary to extinguish the fire. The "Forest Fire Model" application is used to forecast fire development, which was developed on the basis of laboratory and field research on the conditions of the formation and spread of forest fires. The result of these works was the development of algorithms in the form of mathematical equations, enabling the calculation of the basic parameters of a forest fire (speed of the front, surface and perimeter of the fire) depending on the wind speed, moisture content of the flammable material, fuel load and the time of free fire development (time from the start of the fire to the start of the extinguishing). The amount of extinguishing agents needed (water and foam) is also calculated for the three fire extinguishing variants (extinguishing the entire surface, extinguishing the edges or location with barrier zones). Model calculations can be performed for litter cover, grass, heather and total fires [Szczygiel 1991, Szczygiel et al, 2013]. The possibility of a soil cover fire turning into a crown fire is determined based on the developed algorithms, taking into account the age of the forest stand, habitat and stand conditions, meteorological conditions and the duration of the fire [Szczygiel 1991]. The use of the application for forecasting the development of a fire can be used by the commander of the firefighting operation, because all alarm and disposition points of forest districts are equipped with it. This application can also be used for post-fire analysis and training purposes.
The process of supporting planning and organizing firefighting actions discussed in this article is presented in figure 1.

6. Summary

The forest fire protection system operating in Poland is based on three principles: early fire detection, immediate alerting of the rescue forces and starting fire extinguishing at the earliest stage of its development. Rapid fire detection is ensured by a comprehensive forest fire detection system, consisting of 693 lookout towers, 7 patrol planes and 320 patrol and firefighting vehicles. Moreover, nearly 50% of forest fires are reported by outsiders. Quick alarming about a fire is possible thanks to the created network of communication and alerting the forest service and fire brigade, which means that the average time of starting fire extinguishing is from 30 to 45 minutes. IT tools supporting operational planning, from the assessment of potential forest fire risk, through the assessment of fire risk depending on meteorological conditions, have an impact on the readiness of rescue forces to act. Data on the place of the fire allow assessing the risk of fire spreading there and at the same time are used to forecast the basic parameters of the fire, which allows you to have the required amount of forces adequate to the local risk and fire situation. This procedure of actions undoubtedly has a decisive influence on the effectiveness of extinguishing actions, expressed in the average area burned, and consequently also on the amount of losses caused by fires in the forest.

Wildfires, Coupled fire-atmospheric modelling, High-performance computing, Large-scale fire simulations

Abstract

With the changing climate, fire-exclusion, and expansion of wildland-urban interfaces, the frequency and severity of wildfires are expected to increase, putting substantial stress on fire management and authorities to mitigate the risk of wildfires. Improved physical models in conjunction with advanced high-performance computing resources offer new opportunities for operational use in examining potential fire-spread scenarios and planning. This work presents an open-source, high-fidelity modelling framework for simulating large-scale wildfire scenarios, taking into consideration atmospheric/fire coupling, complex terrain, and heterogeneous fuel loading. The framework is implemented using the TensorFlow programming environment on tensor processing units (TPUs). TPUs are a dedicated high-performance computing architecture to accelerate machine-learning applications and high-performance scientific computing. This framework solves the Favre-filtered reacting Navier-Stokes equations and the unclosed terms describing turbulence/chemistry interaction and turbulence transport are modelled using large-eddy simulation (LES) closures. Wildfire dynamics is described by a one-step solid-fuel pyrolysis/combustion model that is coupled to atmospheric flow dynamics using a Boussinesq-type approximation. A second-order finite-difference discretization is employed in a variable-density, low-Mach number formulation to discretize the governing equations, and an immersed-boundary method is adapted to represent complex terrain. In conjunction with the coupled atmosphere/fire model and physical models for turbulence/atmosphere/fire interaction, the resulting simulation framework enables high-resolution simulations (with spatial resolution below 2m) of large-scale fires that cover up to ~100,000 acres. Following the summary of validation results against a prescribed fire experiment to assess the overall accuracy at well-controlled conditions, we employ this coupled atmosphere/fire modelling framework to simulate a large-scale wildfire scenario that is representative of the 2017 California Tubb's fire. To this end, we extract the terrain of the North Bay region of Calistoga and Santa Rosa, spanning an area of 20×20 km2, and consider a North-Eastern wind. The simulation results illustrate the rapid fire-spread dynamics and the coupling of the fire with the terrain and atmosphere. With relevance to operational and research applications that include parametric studies to examine effects of wind, fuel-density, other environmental factors, and fire-management strategies, we discuss the scalability and further extensions of the physical fidelity towards enabling real-time applications on TPU-compute architectures.

1. Introduction and Motivations

Wildfires can threaten livelihood and properties and impact the environment and health [Kollanus et al., 2016; van der Werf et al., 2017]. Over the last few decades, wildfire management has changed profoundly, facing longer fire seasons and more severe fires with more acres burned on average each year [Westerling et al., 2006]. Now, extreme fire events are becoming the norm rather than the exception [Zhongming et al., 2020], with some of the most destructive wildfires in California's history occurring over the last ten years [Khorshidi et al., 2020]. While the number of total fires in the United States has stayed the same, the scale of these extreme fires and subsequently the cost to suppress them and the devastation they cause on forests and communities has grown [Hazard HQ Team, 2021]. In addition, wildfires significantly impact the climate and are estimated to contribute to 10% of the CO2 emissions per year worldwide. Main issues in reliably predicting wildfires are variability in atmospheric conditions, fuel loading, moisture content, and uncertainties in physical models. Therefore, ensemble simulations are required, which provide a statistical representation of the effects of wildfire behaviour

and the prediction of extreme-fire dynamics, ultimately to improve early-detection, prevent, and mitigate impacts [Brillinger et al., 2003].

By leveraging emerging computing architectures, the objective of this work is to develop a scalable high-performance simulation tool that enables the reliable prediction of realistic wildfire scenarios under consideration of representative terrain topographies, fuel distribution, and atmospheric conditions. Here, we will present recent progress toward the development of such a simulation framework using the TensorFlow programming environment. The underlying combustion-physical models and the key features of this solver to efficiently run on Tensor Processing Units (TPU) are presented. The application of this solver is demonstrated by performing simulations of a wildfire scenario that is representative of 2017 Tubbs fire.

2. Numerical Methods

2.1. Governing Equations and Discretization

In this work, we present a simulation framework that solves the three-dimensional Navier-Stokes equations in a low-Mach formulation. The physical model describes the interaction between wildfire spread behaviour and atmospheric flow dynamics. The combustion of the fine-grained fuel is described using a single-step reaction that accounts for solid-fuel pyrolysis and combustion. The states of the solid fuel, including the fuel density, moisture content, and solid temperature, are modelled with a set of ordinary differential equations. The fire behaviour is represented by two prognostic variables, namely the potential temperature and the oxygen mass fraction. The evolution of these variables is modelled by two transport partial differential equations in conjunction with the Navier-Stokes equations, which couples the fire dynamics with the hydrodynamics of air flows using a Boussinesq formulation [Linn & Cunningham, 2005]. Effects of turbulence are considered using eddy-diffusivity-based subgrid models through LES filtering. Specifically, the Smagorinsky-Lilly model [Lilly, 1962] is used as the sub-grid scale closure to represent small-scale turbulence in atmospheric flows.

The governing equations are discretized using a finite-difference formulation with a time-explicit iterative scheme. This simulation framework was examined through benchmark simulations for non-reacting and turbulent conditions [Wang et al., 2022], confirming second-order temporal and spatial accuracy, and excellent weak and strong scalability thanks to the graph-based computing architecture and the optimization through the accelerated linear algebra compiler for TPUs.

To consider complex terrains, we employ the immersed boundary method with feedback-force [Zhang & Zheng, 2007]. In this method, an additional forcing term is added to the momentum and scalar transport equations for the potential temperature and oxygen mass fraction. With this method, the ground is represented as a non-slip isothermal interface. The boundary conditions were tested in canonical flow configuration to confirm expected solution accuracy.

2.2. Tensor Processing Unit

A main contribution of this work is the implementation of the wildfire simulation framework on TPU platforms using the TensorFlow programming interface. The TPU architecture is an application-specific integrated circuit that specifically targets accelerated dense matrix multiplications for machine-learning applications and high-performance scientific computing. The simulation framework is based on a recently developed CFD-solver [Wang et al., 2022] that was developed for high-fidelity reacting and non-reactions fluid-flow applications.

To provide context, we briefly summarise salient features of the TensorFlow TPU implementation. The TPU architecture consists of a TPU board with four independent chips. Each chip contains two tensor compute cores that are optimised for vectorized operations and dense-matrix operations. Up to 1024 chips are connected through a dedicated high-speed inter core interconnect network, forming a TPU pod [Jouppi et al., 2017, 2021]. Main benefits of this computer architecture, making it particularly interesting for large-scale wildfire simulations, are high-peak performance, the flexible programming environment, and the compilation of the executable taking into consideration data management, memory allocation, hardware execution, and inter-chip communication.

3. Results

3.1. Validations for prescribed fire experiments

We validate our wildland fire simulation framework against the FireFlux II experiment [Clements et al., 2019], which is a prescribed grassland fire over a flat ground with homogeneous fuel distribution. Extensive parametric studies have been performed and will be published in a forthcoming study [Wang et al. 2022], and this presentation focuses on illustrating key results from this study. Simulations were performed in a Cartesian domain of size $1\,km \times 0.5\,km \times 0.6\,km$ along the wind-direction, lateral, and height. The domain is discretized using a structured regular mesh with resolution $2\,m \times 2\,m \times 0.5\,m$ along the three respective directions. The atmospheric boundary layer is prescribed by a logarithmic velocity profile with a bulk-velocity of 5 m/s and neutrally stratified atmosphere [Clements et al., 2019], and is modelled by the Monin-Obukhov similarity theory [Porté-Agel et al., 2000]. We consider a homogeneous grassland that is 1.5 m tall, having a fuel density of 0.4 kg/m^3. The simulation is advanced over a total of 200 s at a time-step size of 0.01 s, which corresponds to a CFL number of 0.4. The simulation is performed using 128 TPU cores, taking 0.15 s wall-clock time to complete one temporal iteration. Considering the scaling to a full TPU-pod with 1024 cores and linear scalability, suggest that these simulations can be performed at near real-time conditions, opening unique opportunities for operational services.

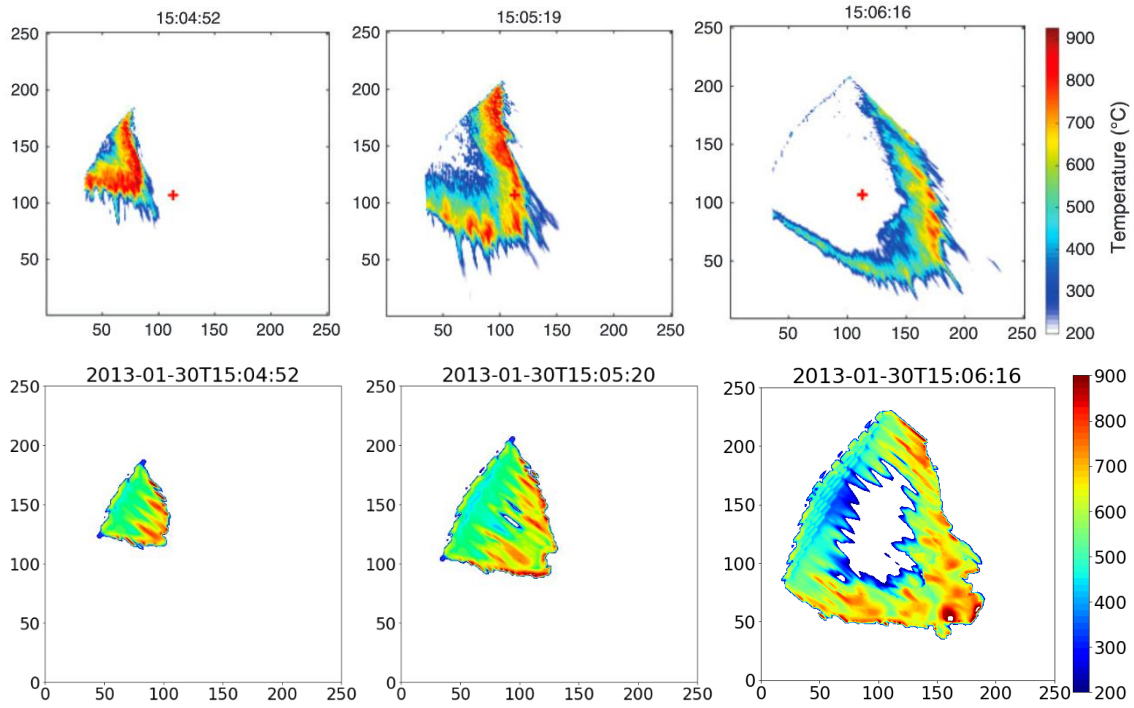

Figure 1- Time sequences of the temperature profile. The first row shows results from the experiment [13] , and the second row is results from the simulation at the corresponding time.

Quantitative comparison of simulation results against published measurements for temperature fields are presented in Figure 1, with the top row showing experimental data (taken from LIDAR) and the bottom row showing temperature fields at a fuel-bed height of 0.5 m above the ground. Results for three different time instances are shown, indicating overall good agreement in predicting the head-fire spreading rate and lateral extent of the fire. The perimeter and key topology of the fire are captured by the simulation. Additionally, the overall good agreement in peak temperature suggests that the heat release and corresponding fire intensity is well captured by the simulation. Differences are evident for the backfire, with the simulation overpredicting the fire residence time. We attribute these differences to the ignition and variability in the fuel load [Wang et al. 2022].

3.2. Large-scale wildfire simulation

Following the validation of the wildfire simulation framework against a prescribed fire experiment, we proceed by considering a large-scale fire scenario. For this, we consider a fire scenario that is representative of the Tubbs fire [Martinez et al. 2017]. The domain for this simulation takes a size of $20\,km \times 20\,km \times 2\,km$, as shown

in Fig. 2, with the *x*-axis aligned with the north-eastern wind direction [Martinez et al. 2017]. The mesh resolution is 20 m horizontally and 4 m in vertical direction. The elevation map is obtained from the USGS database [The National Map-Data Delivery, n.d.] with the latitudes and longitude coordinates sampled in the selected area, which are then interpolated onto the computational mesh. We assume that the ground is covered by homogeneously distributed tall grass of height 1.35 m with a bulk density of 1 kg/m^3, which corresponds to a fuel load of 1.35 kg/m^2. The velocity field is initialised with a Blasius boundary layer that conforms with the terrain. The inflow velocity profile is set to a bulk flow of 10 m/s on which we superimpose turbulence fluctuations that are generated with a digital filter [Klein et al., 2003] with a turbulence intensity of 20%. A convective outflow boundary condition is applied at the downstream exit of the domain. The two boundaries at the lateral sides are set as free-slip walls. A Reighley damping layer is applied at the top boundary, covering 10% of the domain. Within this layer, we prescribed values for all velocity components and prognostic variables. Before ignition, the flow is advanced for one flow-through time (corresponding to 2000 s) to establish a fully developed atmospheric boundary layer. Following this initialization period, we ignite a square region of size 500 m^2 at the location where the fire was first spotted. The solution is advanced for another 4000 s until the fire reaches the end of the domain (near the region of Santa Rosa).

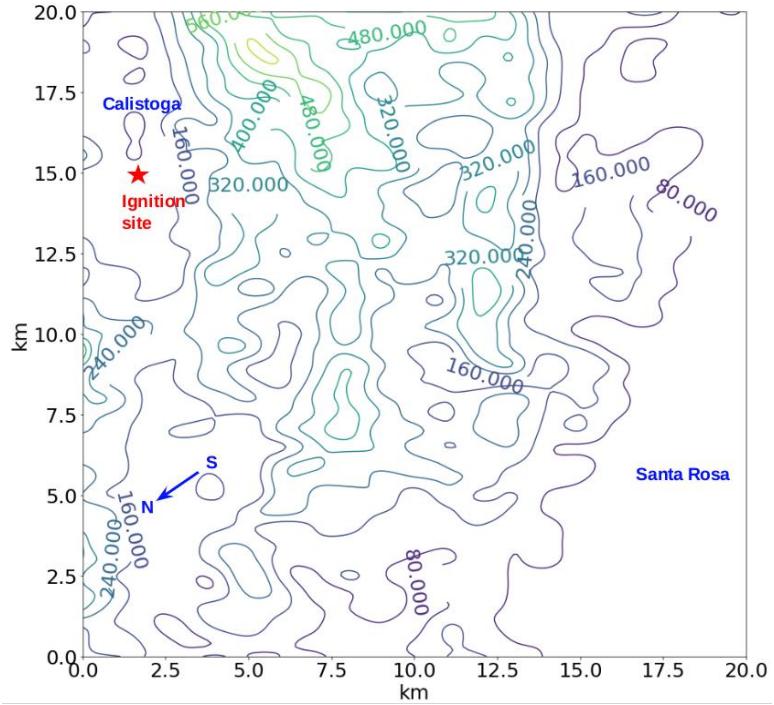

Figure 2- Simulation domain over (20 km)^2 area covering the spread of the Tubbs fire in the first 2 hours.

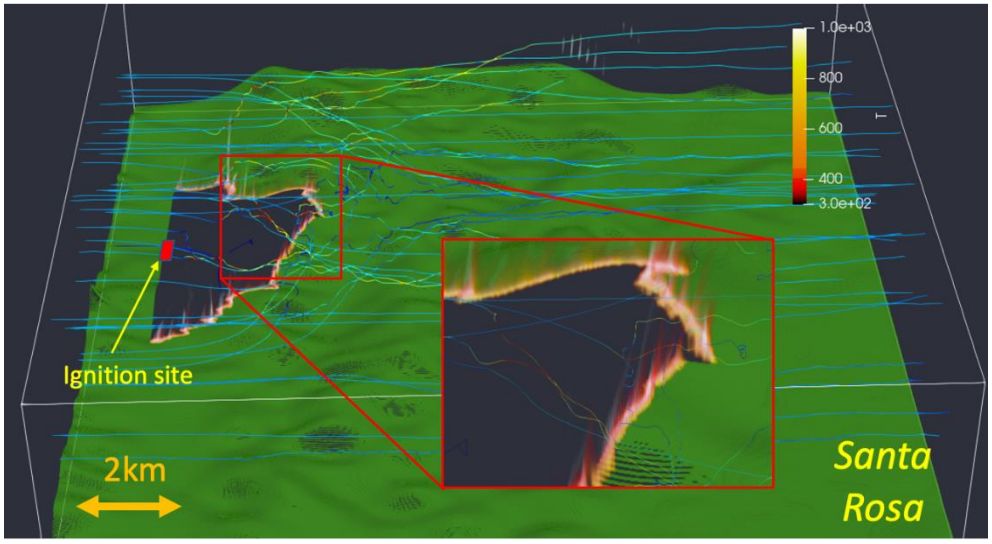
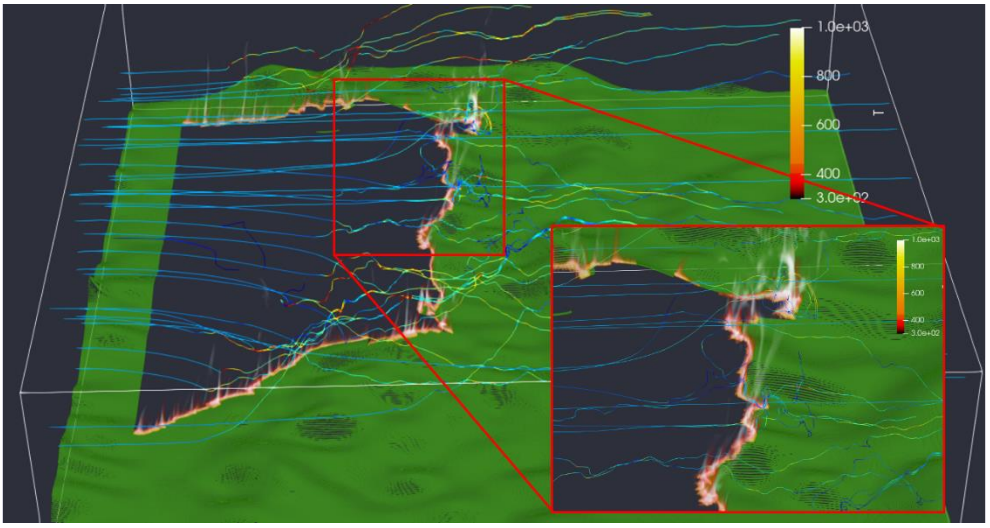
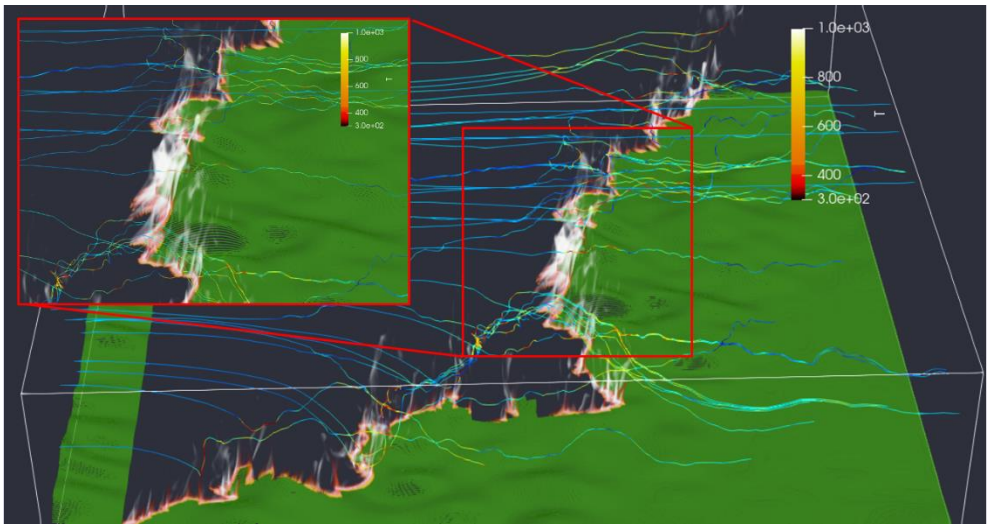


(a) time: 1000 s



(b) time: 2000 s



© time: 3000 s

Figure 3- Simulation of large-scale wildfire behaviour over (20 km)^2 area in Northern California near Santa Rosa, representative of the Tubbs fire, showing time-sequence of fire front (colored by temperature at a height of 6 metres above the ground) over the topography (with elevation map shown in green, scaled by a factor of 2.5). The red square in (a) indicates the ignition location.

A time-sequence at three instances after the ignition is shown in Fig. 3, together with an enlarged view of the fire front. This transient fire sequence illustrates the coupling of the fire plumes with approaching wind. The fire front exhibits severe corrugation due to the conforming terrain and increasing spreading rate on uphill slopes. It can be seen that after 1000 s (~15mins) the fire completely traversed the valley and approached the mountain ridge to Santa Rosa. We note that our current simulations consider homogeneous fine grassland, which is not representative of the vegetation in this area. Because of these important differences in the vegetation and time-dependent wind, we note that these results are not fully representative of the Tubbs fire scenario, but illustrate the capability in predicting large-scale fire events at affordable computational cost.

4. Conclusions

High-fidelity numerical simulations for realistic wildfires are helpful for physical analyses of atmosphere/fire coupling yet too expensive to generate. In this study, we demonstrate that these simulations are within reach using advanced HPC architectures by showing simulations of two realistic fire scenarios. The first scenario considers a prescribed grassland fire over a flat ground. Validations with the experimental results show good predictability of the simulation framework regarding fire statistics including rate of spread, perimeter, and fire intensity. The second scenario considers a historical fire in California 2017. This simulation covers an area of $400\ km^2$ with 0.5 billion mesh points. With the current simulation setup and partition, we simulate the 1 hour duration of the fire that propagates from Calistoga to Santa Rosa in a 12-hour wall-clock period. The performance of this simulation can be further improved by optimising the time step size and refining the partitioning strategy, which makes the simulation close to real time.

Abstract

After the fires that occurred in 2017 and 2018 in Portugal, the imperative need to plan for sustainable and fire resilient landscapes led to the implementation of the Landscape Transformation Program. However, it is still lacking a landscape planning methodology to achieve those resilient landscapes. This paper presents a landscape plan for a fire-prone landscape located in the Centre region of continental Portugal - Serras da Lousã e Açor. This landscape is characterised by steep slopes (70% of the total area) and is dominated by highly combustible coverings, such as eucalyptus (27.89 %), maritime pine (28.06 %), other coniferous (10.08 %) and shrubs (18.91 %). Fires have occurred frequently and 96 % of the case study's total area was burned between 1975 and 2020.

The landscape plan here presented was based on the FIRELAN model and goes a step further by proposing a progressive landscape transformation. FIRELAN integrates fire resilience, ecological sustainability, and economic viability. In this model, the landscape components, which can be physical, biological or cultural, are organised in two main infrastructures - the Ecological Network and the Fire Resilient Landscape Network - and in Complementary Areas.

The Ecological Network ensures the ecological functioning of the landscape by emphasising the quality or potentiality of biophysical components, in articulation with the nature conservation and at-risk areas, underlying the provision of multiple functions valuable to society.

The Fire Resilient Landscape Network integrates fire behaviour knowledge related to land morphology, promotes the landscape discontinuities according to it, is made of less combustible land uses, and includes the cultural management in the urban-rural interface, roads, and power grid. This network is divided in two, the Primary and the Secondary Fire Resilient Landscape Networks. The last one includes the areas with slopes greater than 25%, located outside the Fire Resilient Primary Network.

As to the Complementary Areas, these correspond to the interstices (compartments with slopes less than 25%) of both of networks. Since these areas have low ecological value, they can allocate more artificial land uses.

The implementation of the landscape plan is defined in two temporal phases: the landscape plan for the Scenario 2030, which consists on the implementation of the Primary Fire Resilient Landscape Network (51%), and the landscape plan for the Scenario 2050, that adds the implementation of the Secondary Fire Resilient Landscape Network (37%) and Complementary Areas (9 %). This landscape plan represents a paradigm shift from a landscape dominated by eucalyptus and maritime pine to a dominant forest of native species (such as oaks), archetypical species (such as chestnut, walnut - both for wood or fruit - the wild cherry and others) and also riparian species (alder, willows, poplar, ash, elm, etc.).

Differentiating the final proposal into two phases makes it possible to distinguish implementation priorities, since the application of the model implies a substantial transformation of the current landscape, with high implementation costs. The payment for ecosystem services to the landowners during the paradigm transition period, which is expected to be 20 to 30 years, is recommended to allow the plan implementation.

1. The landscape planning model

Despite long Portuguese forest legislation, only in 2020 the transformation of vulnerable into sustainable and fire resilient landscapes via landscape planning has been formally introduced in legislation with the Landscape Transformation Program (RCM No. 49/2020). However, the methodology to achieve those resilient landscapes

is not regulated. The planning of rural landscapes to prevent rural fires must include sustainable land uses and well-defined management measures. This approach goes beyond obtaining marketable goods of materials and energy since it delivers other ecosystem services provided by a multifunctional and biodiverse forest, including water quality, soil and biodiversity conservation, climate regulation, tourism and scientific data. In addition, it offers intangible benefits such as human contact with nature, recreation and leisure. The availability of forest ecosystem services depends on forest planning and management to avoid and prevent uncontrollable fires.

The three major factors influencing rural fires are climatic conditions, land morphology and land cover. Assuming that it is impossible to radically change the first two factors, the proposed landscape planning methodology assumes that the transformation of the landscape by changing the land cover and land use reorganisation should guarantee the three significant vectors of sustainability: fire resilience, ecological sustainability, and economic viability. Landscape fire resilience is determined by several interrelated factors, namely: fire behaviour as a function of the land morphology (Viegas, 2006), combustibility of plant species (Calviño-Cancela et al., 2017; Silva et al., 2009), landscape discontinuities (Agee et al., 2000, Cui et al., 2019, Povak et al., 2018), and rural-urban interface (Gibbons et al., 2018, Badia et al., 2019). Ecological sustainability of the landscape is achieved by the delimitation of the Ecological Network (EN) (Forman, 1995; Magalhães, 2001; Cunha e Magalhães, 2019) and its correct implementation, supported by land suitability analysis for land uses (McHarg, 1967).

Regarding fire behaviour, biophysical factors can contribute to some extent to reducing fire risk and therefore should be taken into account when planning, namely: i) slopes facing north, with a slope greater than 25%, as they receive less radiation throughout the year, burn less than other slopes (Oliveira et al., 2014); ii) The rate of fire progression doubles for every 10º (about 17%) increase in slope and can increase continuously on steep slopes, from bottom to top, at approximately 5-6 km/h fire speed (Viegas, 1989); iii) Above slopes greater than 30º (57%), the relationship between slope and fire velocity is almost exponential (Viegas, 2006); iv) When the fire reaches the top of the watershed (the ridge), if it does not advance to the opposite slope, due to the slope's breeze, it starts to plough along the contour lines, losing speed. Thus, steep slopes, ridgelines, headwaters and valley bottoms should be strategically covered with less combustible vegetation, to break fire progression.

The proposed landscape planning methodology is based on the landscape transformation model named FIRELAN (Magalhães et al., 2021; Pena et al., 2021) developed in the SCAPEFIRE research project (PCIF/MOS/0046/2017) that includes the present study area as case study), integrates fire resilience, ecological sustainability, economic viability and the simulation of fire behaviour. This paper focuses on fire resilience and ecological sustainability. Other sub-teams dealt with the last two issues which are not covered in this presentation.

The planning design unit of the FIRELAN model is the watershed and is defined by the configuration of landscape infrastructures in its biophysical and cultural systems. Those landscape infrastructures consist of a **Primary and a Secondary Fire Resilient Landscape Networks,** including many components of the Ecological Network. The EN ensures the ecological functioning of the landscape by improving the quality and quantity of biophysical components (water, soil, and biodiversity) in articulation with the nature conservation and at-risk areas, underlying the provision of multiple functions valuable to society (Magalhães, 2013; Cunha & Magalhães, 2019).

Furthermore, the Fire Resilient Network assures the landscape discontinuities recommended by current knowledge of fire behaviour (Viegas, 2006) related to land morphology namely on streams and valley bottoms, ridges lines (Cunha et al., 2018), and the headwaters system areas (Pena et al., 2018). These discontinuities are obtained from less combustible land uses and vegetation types, as well as cultural system management/measures namely in the urban-rural interface, roads, and power grid. The protection buffers around rural settlements and roads contemplated in law and integrated in this methodology, are high priority intervention areas, as they contribute to the direct safety of local population and land properties in case of fire. The different FIRELAN components are presented in Table 1.

The FIRELAN model includes also the Complementary Areas that correspond to the interstices (compartments) of the infrastructures with low ecological value. Those areas have relevant socio-economic functions although less critical from an ecological point of view, therefore can allocate more artificial land uses (Magalhães, 2001; Magalhães et al., 2007).

Table 1 - FIRELAN components and its organisation in ecological network, fire resilient landscape network and complementary areas

System	***Sub-systems***	***Landscape Components***	***Ecological Network***	***Fire Resilient Landscape Network***		***Complementary Areas***
				Primary Network	***Secondary Network***	
Physical	*Water*	*Streams*				
		Valley bottoms				
		Water bodies				
		Headwater system areas				
	Soil	*Rocky outcrops*				
		Steep slope areas (slope> 25%)				
Biological	*Biodiversity*	*Vegetation with conservation interest*				
		Natura 2000				
		Low ecological value				
Cultural	*Agriculture*	*Existent agriculture*				
	Rural settlements	*Rural protection buffer area*				
		Rural protection buffer area in steep slopes (> 25%)				
		Rural settlements				
	Cultural Network	*Power infrastructure protection buffer area*				
		Road infrastructure protection buffer area				
		Road Network				

The proposed methodology promotes a paradigm shift from a landscape dominated by eucalyptus and maritime pine to a dominant forest of native species (such as oaks), archetypical species (such as chestnut, walnut - both for wood or fruit - the wild cherry and others) and also riparian species (alder, willows, poplar, ash, elm, etc.). The economy of this new forest is increasingly valued since it is composed of woody and non-woody products.

However, it can be noted that its profitability comes from producing much more valuable hardwoods that are scarce in the market and valuable non-wood products such as cork, mushrooms, honey, aromatic and medicinal plants, berries, etc. In addition, in a region where today there are few and mostly aged people, the installation of new activities as a result of the multifunctional and biodiverse landscape as management shepherding, hunting, tourism and management will involve new jobs and the settling of people.

2. Case study

The case study is located in the central region with an area of 54839 ha (Figure 1A). This area covers part of the Mondego river basin to the North, and the Tagus river basin to the South. Its dominant characteristics are hilly and rugged terrain with predominating altitudes above 500 m, such as Serra do Açor (1418 m) and Serra

da Lousã (1205 m). The geological formations are mainly schist with some quartzite outcrops, giving rise to an enclosed valley bottoms with abrupt and extensive hillslope morphology.

About 70% of the total area is characterised by steep slopes (greater than 25%). The southern area is represented by a less rugged morphology, although hillslopes between 12 and 25 % of slope predominate. It is noteworthy that only 7% of the intervention area has slopes below 12%, which are mainly in the surroundings of the two largest urban agglomerations of Castanheira de Pera and Pedrógão Grande.

The land use map (DGT, 2019) (Figure 1B) shows an occupation dominated by eucalyptus (27.89 %), maritime pine (28.06 %), other coniferous (10.08 %), shrubs (18.91 %), which together make up about 85 % of the area with highly combustible coverings. This situation significantly contributed to the fires between 1975 and 2020 (Figure 1C), corresponding to 52.656 ha of burned area, representing 96 % of the case study's total area.

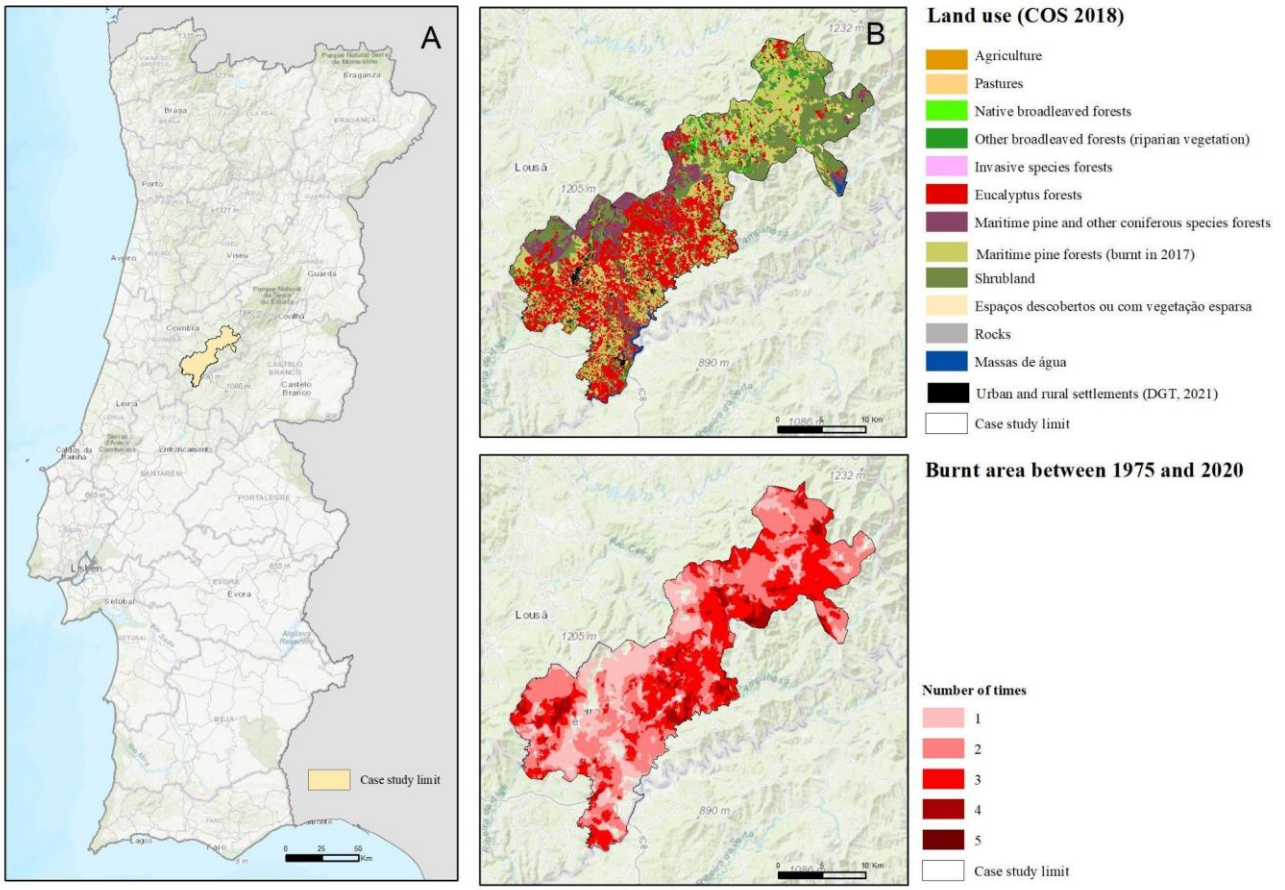

Figure 1 - Case study location (A), current land use (B) and fire frequency between 1975 and 2020 (C)

3. Landscape Plan of Serras da Lousã and Açor

The landscape plan of Serras da Lousã and Açor is the result of FIRELAN model application to the case study area. It corresponds to the biophysical and cultural systems according to the mapped landscape components (Table 1) and a set of potential land uses for each situation.

The implementation of the landscape plan is defined in two temporal phases, presented in the Scenario 2030 and Scenario 2050. The first temporal phase runs until 2030, an important goal in fulfilling European commitments, such as the Biodiversity Strategy 2030 (EC, 2020) and the New Forest Strategy for 2030 (EC, 2021), included in the European Green Deal (EC, 2019). The 2050 Scenario is coincident with the implementation of other long-term European targets up to 2050, such as the Climate Neutral Strategies by 2050 (EC, 2018). This phasing is intended to allow for a progressive transformation of the Landscape. The desired situation is one that should be considered as the "benchmark of a new economy of rural territories, which promotes a multifunctional, biodiverse and resilient forest that is more profitable, with greater capacity for

carbon sequestration and capable of producing better services from ecosystems" (RCM No. 49/2020). This will be achieved after the implementation of the two scenarios by 2050.

The 2030 Scenario (Figure 2) represents the first phase of implementation of the proposal and consists of Primary Fire Resilient Landscape Network (51% of the case study area), implemented with less combustible land uses, integrating the essential components for compartmentalised landscape:

- the two fundamental landforms/features that simultaneously play a role at the ecological level and in fire resilience:
  - i) streams and associated valley bottoms (riparian gallery; riparian forest or agriculture) - 2737 ha;
  - ii) headwater systems (native and archaeophytes mixed forest) - 15362 ha.
- the existing land uses:
  - iii) natural vegetation with conservation interest - 4239 ha;
  - iv) agriculture - 1694 ha.
- buffer protection areas:
  - v) to rural settlements (agriculture/pastures/native forest) - 1472 ha;
  - vi) to road network (pasture/native forest) - 1112 ha;
  - vii) to power grid (agriculture/pasture/lowland scrubland) - 582 ha.
- the Natura 2000 Network (to be intervened by structures and to guarantee the conservation of existing Habitats)

In this Scenario (2030), to be carried out in a first phase, also included is the intervention in all areas with invasive forests (114 ha), the "compartments" generated by the FRLPI, maintain their use until financing and other conditions for their implementation are in place. These areas are fundamentally characterised by:

- hillslopes with slopes greater than 25 % located outside the FRLPI (20085 ha);
- Low ecological value areas with slopes of less than 25% (4899 ha).

Although there is no intervention at this stage, these areas should be subject to silvo-environmental measures.

The 2050 Scenario (Figure 3) represents the second phase of the proposed landscape plan. It assumes the implementation of the Fire Resilient Landscape Primary Network 2030 and the implementation of interventions located in the Secondary Fire Resilient Landscape Network and Complementary Areas.

The Secondary Fire Resilient Landscape Network includes areas with slopes greater than 25%, located outside the Primary Network, occupying about 37% of the case study area (20085 ha). These areas present high risks of soil erosion, high velocity of water runoff, which decreases infiltration (this condition is aided by the nature of the geological substrate consisting of shale). These conditions together lead to soil loss and thus infertility in these areas and contribute to a faster rate of fire progression. The proposed uses are native hardwoods or native bushland.

The Complementary Areas are the "compartments" with slopes less than 25% generated by the Fire Resilient Landscape Network (4899 ha), represented in pink in Figure 3. In the case study area these areas are of low ecological value. Their use is more flexible, and alternatives depend on the suitability of the soil to the various trees and shrubs species or crops and the choice of their promoters.

Regarding soil and water conservation management techniques, minimum mobilization and the use of manual or mechanical-manual practices are recommended above slopes of 35%. Also, reforestation should be based on the promotion of natural regeneration and intensive forest management should be replaced by close-to-nature forestry (Carvalho, 2018), semi-intensive, extensive or very extensive.

Other recommended techniques are the green firebreaks, which are strips of vegetation with low combustibility, cultivated in strategic locations on the landscape with the aim of slowing down or stopping the progress of a fire. The headwaters, riparian galleries and other suitable hedges can be considered green firebreaks. When compared to the fuel management buffers contemplated in law, characterised by the absence of vegetation, green firebreaks represent a more sustainable option, with benefits such as increasing biodiversity, restoring ecosystems (soil, water and air) and the economic value associated with its products (Wang et al., 2021). In addition, although their installation is more demanding than that of the fuel management buffers, the maintenance costs are reduced in the medium to long term.

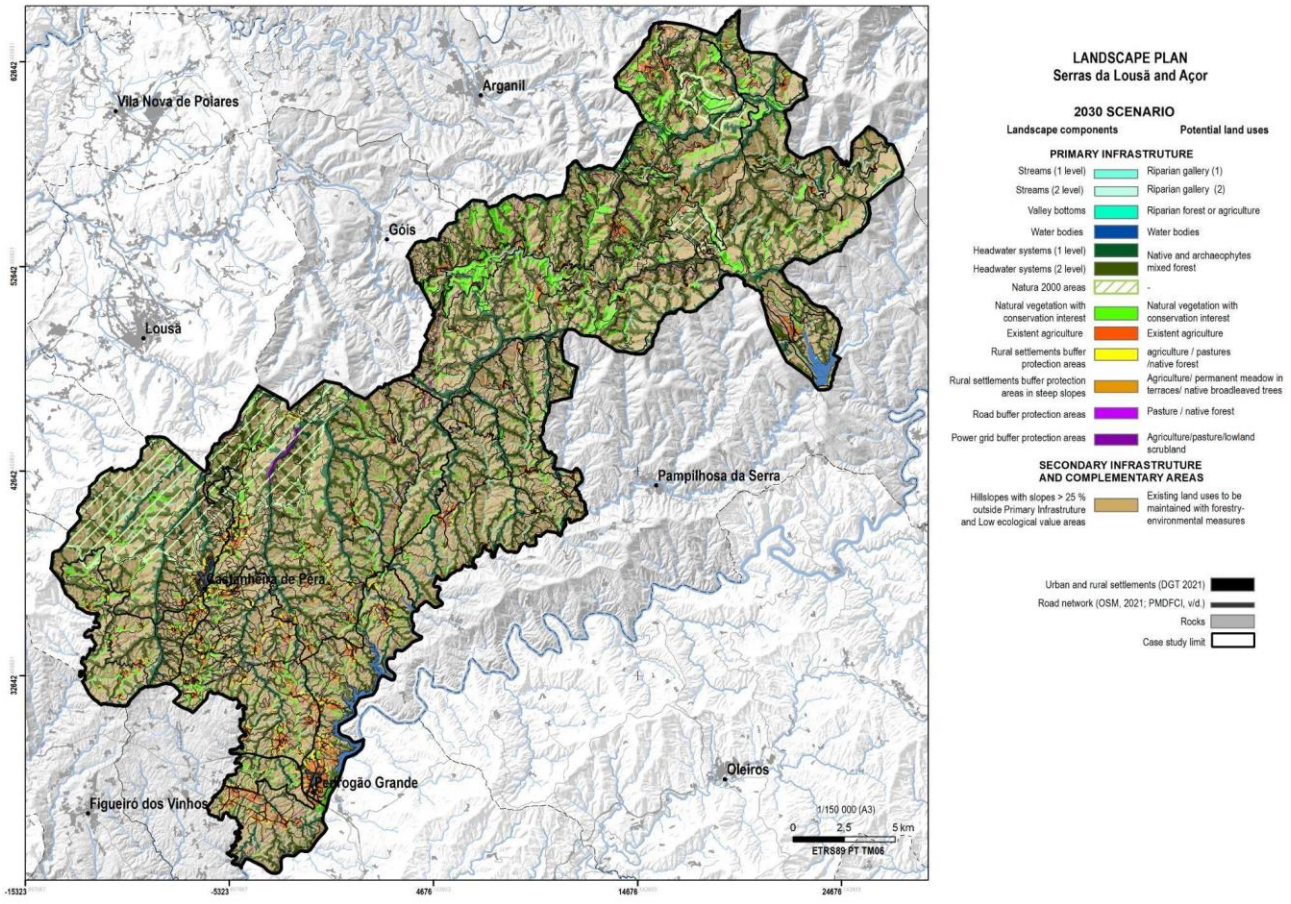

Figure 2 - Landscape Plan - 2030 Scenario

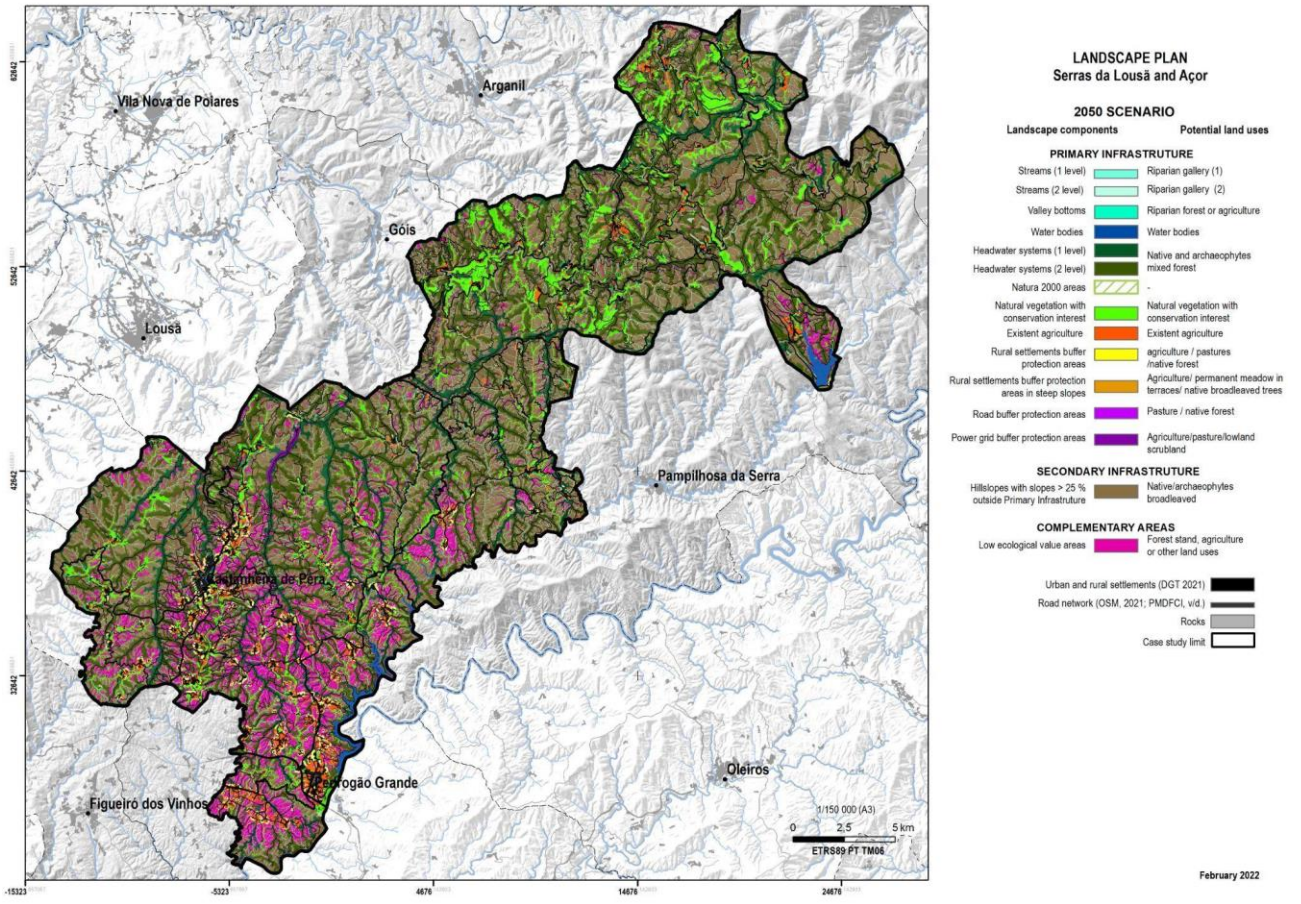

Figure 3 - Landscape Plan - 2050 Scenario

This landscape plan was accompanied by several public participation workshops, involving representatives of the landscape transformation stakeholders who were open to the transformation, except for pulp/paper companies and large landowners whose properties are covered with eucalyptus.

Specialised teams in the simulation of fire behaviour, the evaluation of implementation costs and also the evaluation of ecosystem services evaluated these two phases (Scenario 2030 and Scenario 2050). These components of the Landscape Plan are not developed in this paper. However, we refer to some of the conclusions obtained by specific teams.

The simulation of fire behaviour shows that the transformations proposed for the landscape leads to a reduction in fire intensity levels (and all associated characteristics), especially from the 2018 scenario to the long-term scenario (2050).

Regarding the evaluation of ecosystem services (ES), this was conducted in two phases. In a first phase, the evaluation of the ES (Biomass supply, Food supply, Regulation of water cycles, Soil protection, Carbon Sequestration, Biodiversity, Cultural Functions) in the current landscape and proposed transformations was based on a qualitative exercise of the supply potential. In a second phase, a quantitative assessment of the flow of ES in the different landscape scenarios and respective economic valuation was carried out. The analysis allowed to conclude that the proposed transformation improve the landscape's ability to provide regulatory and cultural services.

4. Conclusion

The final proposal of the FIRELAN model application to the case study was differentiated in two phases (scenarios) to allow for the distinction of implementation priorities, since the proposed transformation implies a substantial change of the current landscape, with high implementation costs.

It was therefore considered that, in a first phase, the linear components of the Fire Resilient Landscape Network should be implemented, fundamentally made up of the primary and secondary streams and valley bottom systems and the watershed headwaters, as these are the ones that, conceptually, will have a determining role in fire containment. Although the transformation of the Secondary Fire Resilient Landscape Network has been relegated to the 2nd phase, it is admitted that, given its characteristics, areas with slopes greater than 25%, also these, when covered by highly combustible uses such as eucalyptus and maritime pine, contribute greatly to fire risk, so it is also considered very important to implement these areas according to the plan.

The rationale for the option of low combustible land uses was based on existing literature and observation of post-fire landscape cases. This option implies a very significant change in the existing areas of eucalyptus and maritime pine (from 56% to a maximum of 9% in the 2050 scenario), so it is proposed to pay for ecosystem services to the landowners during the paradigm transition period, which is expected to be 20 to 30 years, depending on the species to be used.

Abstract

Portugal is recurrently affected by severe wildfires, the fire season of 2017 representing the most tragic year with half a million of hectares burned and 115 deaths. The events that took place on October 15 deserve special attention, not only because the area burned on that day represents more than 50% of that burned during the entire year, but also because it resulted from the combination of very strong winds steered by the passage of hurricane Ophelia, very dry vegetation because of a prolonged drought affecting the country, very low atmospheric relative humidity and a record number of ignitions. Meteorological fire danger is usually rated using the Fire Weather Index (FWI) that is part of the Canadian Forest Fire Weather Index System. However, wind direction is not taken into account when defining FWI, and therefore it is worth investigating how this factor may affect the evolution of a given fire keeping all the remaining factor unaltered. The role played by wind direction is assessed using a cellular automata (CA) model to simulate two wind-driven wildfires that took place at Pataias-Burinhosa and Quiaios on October 15, 2017. The CA model is first calibrated using winds derived from a regional weather forecasting model and sensitivity studies are then performed by systematically rotating the forecasted winds keeping all the other parameters constant. Results indicate a progressive decrease in probability of burning from a 45º to a 90º counterclockwise rotation. These results suggest improving FWI by defining an FWI vector, whose direction is that of the wind and magnitude is that of FWI. This vector should then be compared against the prevailing vegetation patch orientation, and the closer the alignment between the two directions, the greater the meteorological fire danger.

1. Introduction

Portugal is recurrently affected by severe wildfires with strong adverse impacts at social, economic, ecologic and environmental levels (Costa et al., 2011; Pereira et al., 2011). A recent tragic case is the year of 2017 with the highest record of total burned area since 1980 (above half a million hectares), 115 deaths and an involvement of about 1.5 thousand firefighters (ICNF, 2017).

Information about the likelihood of a large fire event on a given day and in a given location is of vital importance for fire management and fire prevention. The likelihood of a fire event is usually rated by means of meteorological fire danger indices (Finney, 2005), and in this respect the Canadian Forest Fire Weather Index System (Stocks et al., 1989) has shown to be particularly useful for the ecosystems of Mediterranean Europe (San-Miguel-Ayanz et al., 2012). The Canadian System consists of six components that account for the effects of fuel moisture and wind on fire behaviour and all components are derived from surface weather observations at local 12 noon, namely air temperature, air relative humidity, wind speed and cumulated precipitation. Wind direction is not considered in the Canadian System but, especially in cases of wind-driven fires, it is expected that the total area burned will also depend on the relationship between wind direction and the orientation of major flammable vegetation patches, with fire propagating longer distances when wind direction is closer to patch orientation.

The large fire events that started on October 15, 2017 in Central Portugal are especially worth being studied from the point of view of the relationship between wind direction and vegetation patch orientation. That day was marked by strong and persistent southerly winds associated to the passage of hurricane Ophelia; around 500 ignitions started on October 15 that combined with the extremely dry state of the vegetation due to a persistent drought that had affected Portugal and with the very low values of atmospheric humidity resulted in a daily amount of burned area representing more than 50% of the total burned area of that year (Pinto et al. 2022). Two of the events, at Pataias-Burinhosa and at Quiaios, took place along two coastal elongated bands of forested terrain, with 94% of pine and 2% of eucalyptus forests in Pataias and 64% of pyne and 18% of eucalyptus forests in Quiaios (Guerreiro et al. 2018). The orientation of the two coastal bands was very close to the prevailing south-north wind direction of the winds, a situation that is not common in Portugal at that time of the year.

The aim of this work is to assess the role played by wind direction on total area burned in the events of Pataias and Quiaios. After calibrating a cellular automata model to fire propagation observed in the two events using winds as derived from a regional weather forecast model, the models are run with winds rotated by constant amounts and keeping the remaining parameters constant and, finally, a sensitivity study is performed on total burned area to wind rotation.

2. Methods and Data

2.1. The Alexandridis CA model of fire spread

Cellular automata (CA) models are built up on a set of rules defined at a local level that yield global complexity that can resemble fire propagation. Space is defined by a regular grid where each cell is found to be in one of a number of possible states. Cells can only interact with cells in a neighbourhood by means of evolution rules. For every time step, each cell's state is updated according to these rules and depending on the previous states of the cell as well as of its neighbours (Wolfram 2002). We will use a simplified version of the Alexandridis CA fire spread model (Alexandridis et al. 2008) to simulate fire spread. Fire modelling is probabilistic in the sense that a set of simulations is performed and the probability that a given cell will burn is derived from the fraction of simulations where the cell did burn.

In order to run the model first we need to identify the cell that is burning, then consider a squared-cell grid around it, the eight surrounding cells, called neighbours, translating the eight directions along which the fire can propagate. Each cell can be in one of four states: 1) void of fuel content (being assumed that it cannot be ignited at any future instant); 2) contains fuel (it can be ignited); 3) has been ignited (fire can propagate in the next time step to its neighbours); 4) the fire is extinguished (the cell remains in that burnt state until the end of the run).

The model considers three factors when evaluating the likelihood of fire propagating from a cell to another cell in its neighbourhood: wind, slope of the terrain, and type of vegetation. The three factors considered are included in the weight of the probability of a fire to spread to a cell (p_{burn}) in the neighbourhood of a cell classified as in fire, according to the expression:

$$p_{burn} = p_h(1 + p_{veg})p_w p_s \qquad (1)$$

where p_s, p_{veg} and p_w are the slope, the vegetation type and the wind contributions, respectively, and where p_h corresponds to the value of p_{burn} for a certain cell with no slope or wind ($p_h = 0.58$ by optimisation).

Four transition rules are then applied:

1) If $state(i,j) = 1$ at t, $state(i,j) = 1$ at $t + \Delta t$.
2) If $state(i,j) = 3$ at t, $state(i,j) = 4$ at $t + \Delta t$.
3) If $state(i,j) = 4$ at t, $state(i,j) = 4$ at $t + \Delta t$.
4) If $state(i,j) = 2$ at t, $state(i \pm 1, j \pm 1) = 3$ at $t + \Delta t$ if the factor p_{burn} is higher than a value obtained by a random generator.

Following Freire and DaCamara (2019), a wind rule was added in order to simulate spotting. This rule allows fire to spread to a number of cells placed along the wind direction instead of only spreading to the direct neighbour as described in the baseline model. The number of cells to be burned when applying the wind rule was obtained from a step function of the wind speed. According to the rule, i) only cells whose p_{veg} value is greater than a certain threshold can be set on fire when applying this rule, and ii) fire can jump over cells with no fuel or with low values of p_{veg} so that spotting effect is captured.

2.2. Case studies

The model was used to simulate the two coastal wildfires of Pataias-Burinhosa and Quiaios, that started on October 15, 2017. As shown in Figure 1, the two fire events present an elongated shape which reflects the strong influence of the prevailing wind (from south to north). The Pataias-Burinhosa wildfire started with an ignition in Pataias at 2:01 pm, followed by a second ignition at 2:33 pm, in Burinhosa (northeast from the first ignition). Most of the 16,949.6 ha of burned area did occur on the first day. The Quiaios wildfire originated from a single ignition located at the most southern point of its fire perimeter. It was first reported at 2:36 pm. This wildfire was dominated at 11:16 pm on the following day. During that period, an area of 19,025.5 ha was consumed by fire.

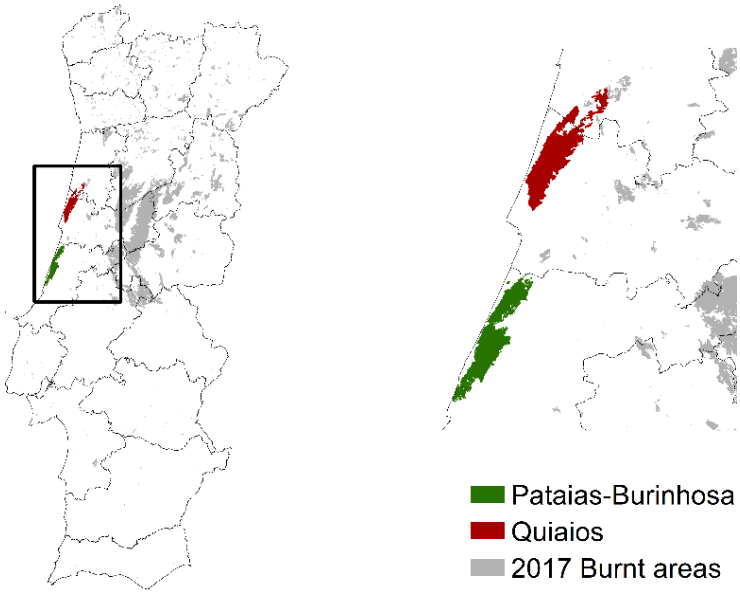

Figure 1- The burned areas of the Pataias-Burinhosa (in green) and the Quiaios (in red) fire events within the context of the burnt areas in 2017 (in grey).

2.3. Input data

Elevation profiles were provided by SRTM (Shuttle Radar Topography Mission) digital model (Farr et al., 2007). Land cover data were extracted from 100-m resolution CORINE land cover maps (CLC2012) to build the initial state and vegetation type matrices. The regional model WRF (Weather Research Forecast, version 4.0) (Skamarock et al., 2019) was run to obtain wind data which was subsequently corrected for wind interaction with topography with software WindNinja (version 3.4.1) (Forthofer et al., 2014). Wind information was updated every hour in the simulation. Information on starting ignitions and duration of fire events was provided by ICNF (Instituto da Conservação da Natureza e das Florestas) burned area maps (ICNF, 2022; ICNF, 2017). We also resorted to the official report (Guerreiro et al., 2018) to check the data.

Calibration of the model was performed by comparing the simulated burned area against shapefile maps provided by EFFIS (European Forest Fire Information System) (San-Miguel-Ayanz et al., 2012) in the case of the Pataias-Burinhosa event and, in the case of Quiaios, against a Sentinel-2 product of burned areas and implementing the methodology described in the RUS-Copernicus tutorial (RUS-Copernicus, 2017).

3. Results and discussion

Results presented in Figure 2 are the outcomes of ensembles of 100 simulations with time steps of $\Delta t = 4$ min covering a period of 21 hours for Pataias-Burinhosa and 35 hours for Quiaios, these values corresponding to the period where virtually all the area was burnt.

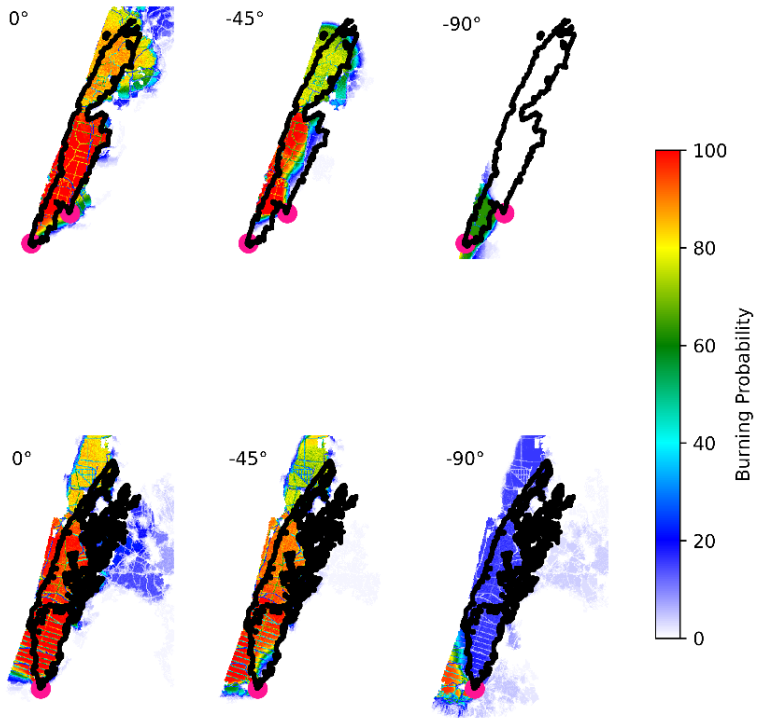

Figure 2- Maps of burning probability (%) as obtained for the simulations of the Pataias-Burinhosa (top panel) and the Quiaios (bottom panel) events. Left column shows the results from model calibration using winds derived from the regional weather forecast model, and the middle and right columns show the results from simulations when the winds are rotated counterclockwise of 45º and 90º, respectively. Black lines represent the real fire perimeters and the pink circles indicate locations of the ignition points.

Maps of probability of burning that resulted from the 100 simulations for model calibration, i.e. using winds derived from the regional weather forecast model (Fig. 2, left column) show an overall agreement with the observed fire perimeter (lines in black), and it is worth stressing that no barriers were defined representing actions of firefighting. Simulations using winds rotated counterclockwise show a progressive decrease in probability of burning from a 45º (Fig. 2, central column) to a 90º (Fig. 2, right column) rotation. In this latter case, simulations for the Pataias-Burinhosa event indicate that most of the area does not even burn, whereas for Quiaios most of the area presents values of probability lower than 20%.

Results obtained suggest that incorporation of wind direction in the Canadian System represents an added value when rating meteorological fire danger. For instance, this information could be incorporated in the Fire Weather Index (FWI), that rates fire intensity, leading, e.g. to the definition of an FWI vector, whose direction is that of the wind and magnitude is that of FWI. This vector should then be compared against the prevailing vegetation patch orientation, and the closer the alignment between the two directions, the greater the meteorological fire danger.

4. Ackowledgements

This work was supported by national funds through FCT (Fundação para a Ciência e a Tecnologia, Portugal) under project FIRECAST (PCIF/GRF/0204/2017) and IDL (UIDB/50019/2020).

Fire modelling, Wildfire Analyst,

Abstract

The use of wildfire simulators allows estimating fire spread and behaviour in diverse and complex fire environments, supporting fire planning and analysis of incidents in operational environments. However, uncertainty derived from the spatio-temporal estimation of input variables and model's inherent inaccuracies related to its limitations and assumptions may undermine the utility of such predictions. Here, we assessed the performance of well-known operational surface and crown fire spread models used in California through the analysis of the rate of spread (ROS) of 1,853 wildfires occurring in the State from 2019 to 2021. For each detected wildfire, we retrieved the observed fire progression using the FireGuard (FG) database which provides the fire progression through geo-spatial polygons every 15 minutes approximately. Based on this data, we developed an algorithm that characterises the ROS for each FG polygon and the average ROS in the first 8 hours of the fire. Also, we ran a fire simulation for each wildfire with Wildfire Analyst Enterprise using high-resolution fuel and weather data to estimate the rate of spread. Then, we assessed 1) the accuracy of the fire simulations by comparing the real and simulated ROS based on the Mean Absolute Error (MAE), Mean Bias Error (MBE) and Mean Absolute Percentage Error (MAPE); 2) the most important factors influencing the accuracy of fire simulations, including the wind speed, and fuel types. Although the models clearly underestimated ROS in timber fuels, especially when no crown fire behaviour was predicted, most of the fire simulations had an acceptable error to be used in operational environments given the new techniques to adjust and calibrate the fires with field data. Finally, we used this analysis to present new approaches to optimise the fire predictions, including the optimisation of new custom fuels through genetic algorithms and enhancement of crown fire spread models.

1. Introduction

Wildfires are a natural disturbance of many ecosystems (Pausas and Keeley 2009) although they suppose a growing threat to the environment, economical assets and population (Molina-Terrén *et al.* 2019). Important amounts of financial resources have been invested in fire management aiming to reduce the substantial damage of wildfires and ensure safety for the population (Liang *et al.* 2008; Cardil and Molina 2015; Stocks and Martell 2016). In this sense, the estimation of the wildfire rate of spread (ROS) across complex landscapes is essential for effective planning and fire suppression, including the release of timely and operative public warnings for disaster management and evacuation orders (Cruz *et al.* 2018; Monedero *et al.* 2019; Ramirez *et al.* 2019).

Several mathematical approaches have been developed in the last decades aimed at predicting fire behaviour. The capability of accurately predicting the fire spread is directly linked to the model's inherent inaccuracy derived from its limitations and assumptions (Albini 1976; Ascoli *et al.* 2015; Vacchiano and Ascoli 2015) and input data, factors that may undermine the utility of such predictions for decision-making (Cruz and Alexander 2013; Benali *et al.* 2017; Ramirez *et al.* 2019). Cruz and Alexander (2013) quantified errors and biases of several wildfire ROS models after conducting a comprehensive survey of studies gathering a database comprising 1,278 paired predicted vs observed ROS values. Other studies assessed model's performance in several fire-prone

areas and analysed how new improvements in fire spread models may enhance the performance to their previous ones (Cruz *et al.* 2018).

This work assesses the predictive accuracy of fire spread models currently used in California in operational settings under different environmental conditions using 1,853 fires from 2019 to 2021. The analysis identifies in what conditions the models may over or under-estimate the ROS and, subsequently, the burned area and associated fire impacts on buildings or other assets. The analysis is based on well-known error metrics and statistical approaches (Cruz *et al.* 2018) aiming to compare the predicted with observed ROS values. Finally, we propose several improvements in the current fire spread models to enhance their performance.

2. Methodology

2.1. Study area

This study was developed in California, a region dominated by Mediterranean climatic conditions, known to foster recurrent large wildfires (Pyne *et al.* 1998). Fire-prone weather situations such as long and dry summers with thunderstorms episodes, low relative humidity and strong dry winds are typical of this region (Sugihara and Barbour 2006).

2.2. Fire progression data (FireGuard)

The National Fireguard Detections product (FG) provides wildfire detection and monitoring across the USA at all times. It allows the detection of new wildfires as well as areas of significant fire growth which is especially useful in remote regions and during the first 24 - 48 hours when this information is usually scarce. Updates on the fire progression are often provided every 15 minutes.

We retrieved all FG polygons in California from October 2019 to November 2021 and removed prescribed fires. Then, we clustered FG polygons based on distance and fire arrival time to aggregate them to real incidents and create progression maps of individual fires (Figure 1). For each cluster, we selected the first FG polygon later used as ignition source. As a result, the progression of 1,853 wildfires was obtained for further analysis. We used the first burning period (8 hours from the fire start) to compare the simulated ROS with the real ROS obtained through FG. We developed an algorithm to analyse the ROS for each FG polygon (see ROS vectors for some fires in Figure 1) to finally estimate the average ROS during the first burning period. Also, for each fire we retrieved a set of environmental variables for identifying in what conditions the models may over or under-estimate the ROS and, subsequently, the burned area and associated fire impacts on buildings or other assets. This set of variables includes surface fuel types, canopy characteristics, weather conditions (forecast and stations), dead and live fuel moisture content.

2.3. Fire modelling with Wildfire Analyst Enterprise (WFA-e)

Fire modelling was carried out using Wildfire Analyst Enterprise (WFA-e) that provides real-time analysis of wildfire behaviour and simulates the spread of wildfires to directly support multi-agency wildfire incident management. Currently, many public and private entities, such as natural resource agencies, electrical investor-owned utilities, insurance and forestry companies strongly rely on WFA-e which facilitates optimal decision-making. We simulated 1,853 fires using the first FG polygon as an ignition source based on well-known semi-empirical fire spread models currently used in California including the Rothermel's (1972) surface fire spread model, van Wagner's (1977) crown fire initiation model, Rothermel's (1991) crown fire spread model, Albini's (1979) spotting model, and Andrews' (2012) conversion factor and wind profile and Minimum Travel Time time evolution algorithm (Finney 2002). We calculated the average hourly ROS and average simulated ROS during the real fire duration based on the FG fire progression up to 8 hours after the fire start (first burning period).

Improved high-resolution surface fuel types (Scott and Burgan 2005) and canopy characteristics maps (canopy cover, canopy height, canopy base height and canopy bulk density) were collected to perform the fire simulations. These maps were modelled by Technosylva Inc based on an Object-based Image Analysis by grouping homogeneous vegetation areas into vector objects later classified with machine learning algorithms and ground truth data with an accuracy of 90%. We used high-resolution weather data at 2 km using the Weather Research and Forecasting model, a mesoscale numerical weather prediction system designed for operational

forecasting applications. Nelson's 2000 model was used to estimate dead fuel moisture content and live fuel moisture content was retrieved from the US National Fuel Moisture Database (WFAS; https://www.wfas.net/index.php/national-fuel-moisture-database-moisture-drought-103).

2.4. Statistical analysis

We compared the ROS predicted by WFA-e and observed through FG based on four different metrics (Cruz *et al.* 2018): 1) *ROS residual* representing the difference between the predicted and observed ROS. Therefore, a positive residual indicates an over-prediction; 2) *Mean Absolute Error (MAE)*, representing an average of the absolute error (eq. 1); 3) *Mean Bias Error (MBE)*, representing an average bias between the predicted and observed values (eq. 2); 4) *Mean Absolute Percentage Error (MAPE)*, a measure of prediction accuracy of a forecasting method in statistics. It expresses the accuracy as a ratio (eq. 3).

$$\mathrm{MAE} = \frac{\sum_{i=1}^{n} |WFA_i - FG_i|}{n} \quad \text{(equation 1)}$$

$$\mathrm{MBE} = \frac{\sum_{i=1}^{n} (WFA_i - FG_i)}{n} \quad \text{(equation 2)}$$

$$\mathrm{MAPE} = \frac{100}{n} \sum_{i=1}^{n} \left| \frac{FG_i - WFA_i}{FG_i} \right| \quad \text{(equation 3)}$$

where *FGi* represents the ROS measures through FG, *WFAi* is the estimated ROS by WFA-e and *n* the number of wildfires.

We analysed the simulation accuracy based on these metrics considering input data for fire simulations and enhancements in our models through the use of simulated local wind fields (Windninja (Wagenbrenner *et al.* 2016)) and improved crown fire spread models.

3. Results and discussion

Rothermel (1972) model is the most widely evaluated fire spread model on Earth based on prescribed fires and some wildfires (Cruz and Alexander 2013). However, the amount, nature and quality of data provided in this work allows a better understanding of the model's performance under different environmental conditions in California. The observed (FG) and predicted (WFA-e) fire progression were compared analytically based on the methods described in section 2.4. However, as an example, we showed four fires in figure 1 to illustrate the ROS vectors calculated automatically from the FG data and the fire simulation for each fire. Although this visual assessment is useful to clarify how we compared the predicted and observed ROS, a statistical analysis was carried out to assess the performance of models for all the fires retrieved from FG in the study period considering the different combinations of environmental conditions influencing fire behaviour (fuels, weather, topography, etc).

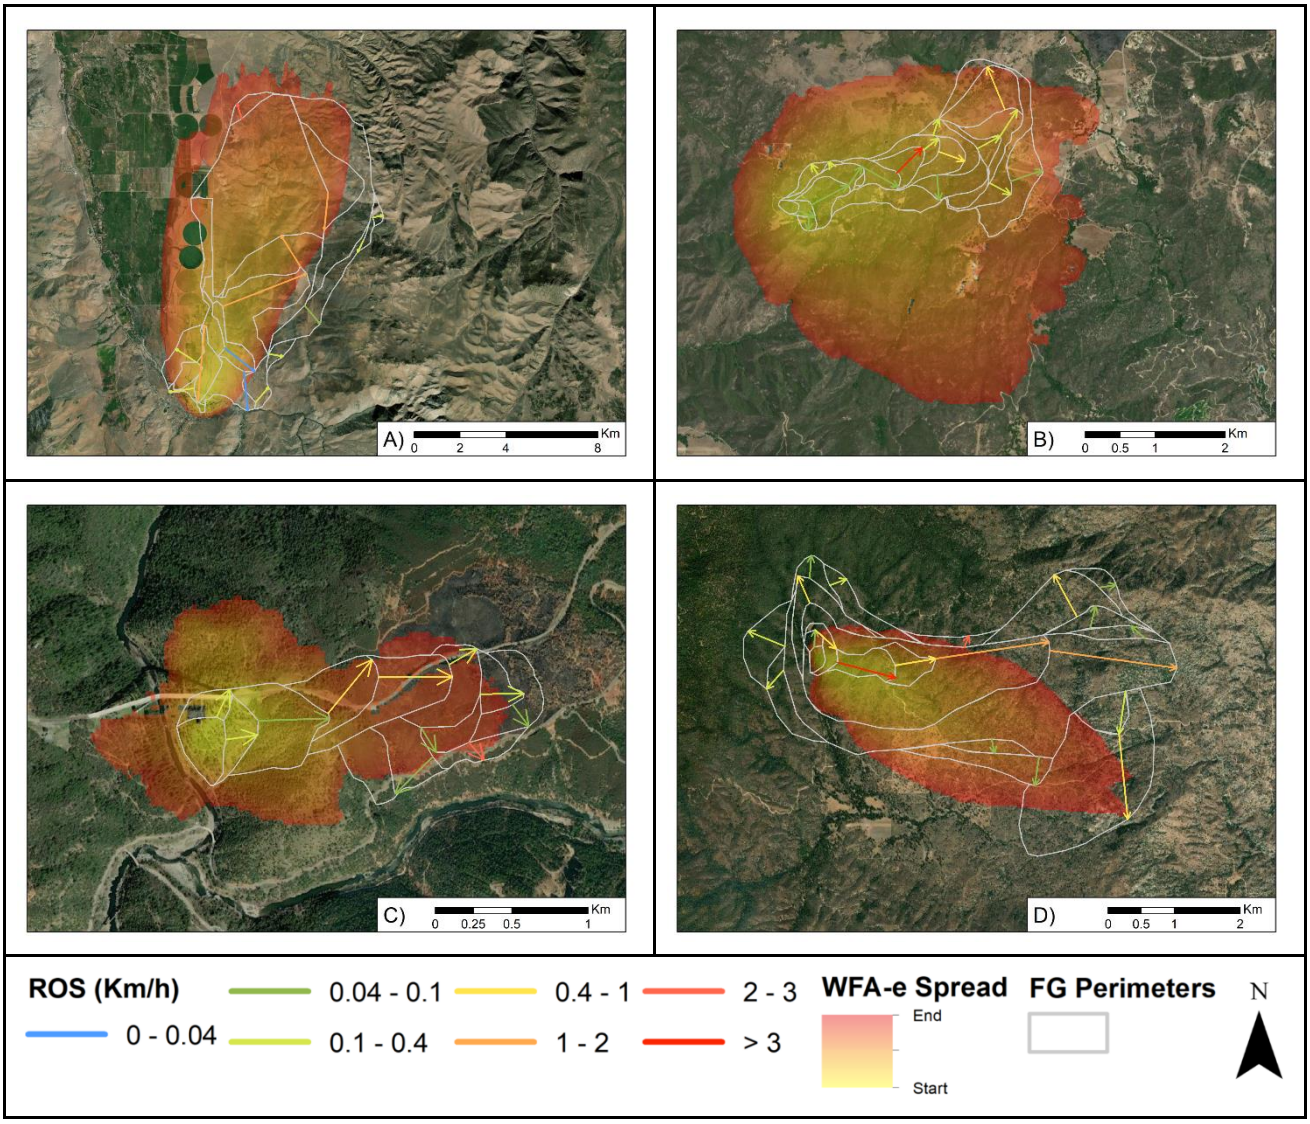

Figure 1. Fire progression and simulation of four wildfires in California. A) Mountain View fire (lat = 38.515; lon = -119.465; 2020/11/17); B) Chaparral fire (lat = 33.485; lon = -117.399; 2021/08/28); C) Bridge fire (lat = 38.921; lon = -121.037; 2021/09/05); D) French fire (lat = 35.687; lon = -118.55; 2021/08/18); Note that the FG polygons and WFA-e simulated fire progression have the same time duration.

Overall, the model produced the best predictions for Grass (GR), Grass-Shrub (GS) and Shrub (SH) Scott and Burgan (2005) fuel types with MAPE values of approximately 60% (Fig. 2) similarly to other studies (Cruz *et al.* 2018). The lowest MAE (0.31 km/h), MBE (0.016 km/h) and MAPE (59 %) values were found for the SH fuel types, followed by GS and GR fuel types. Thus, we found the highest error and bias in timber fuel types (Fig 2) with a MAPE value of 80%, also in line with other studies assessing the performance of Rothermel's model (Cruz *et al.* 2018). The histogram of ROS residuals showed a normal distribution for GR, GS and SH Scott and Burgan (2005) fuel types (Fig. 2A) with low bias in the predictions (MBE; Fig 2C). However, the models had a preponderant ROS under-prediction bias in most timber fires as shown by the histogram of ROS residuals, MAE and MBE metrics (Fig 2), an error type leading to potentially negative consequences in operational decision-making (Cheney and Gould 1995). This analysis suggests that new enhancements are needed to decrease the error and bias of fire spread models in line with other studies developed in other regions such as Australia (Cruz *et al.* 2018). Previous studies found the lowest MAE values in timber and logging slash fuel types but also the largest MAPE (76 %) values. This was derived from the range of observed ROS values in these fuel types that were substantially lower than in grasslands and shrublands fuel types (Cruz *et al.* 2018). However, in our study, we also found the highest MAE and MBE values in timber fuel types since the database contained fires with high ROS. The simulated ROS tended to be under-predicted in extremely fast fires (average observed ROS > 1.5 km/h) in all fuel types and specially in timber fuel types. This may be related to convective fire behaviour leading to local winds in the fire front not considered by the weather models.

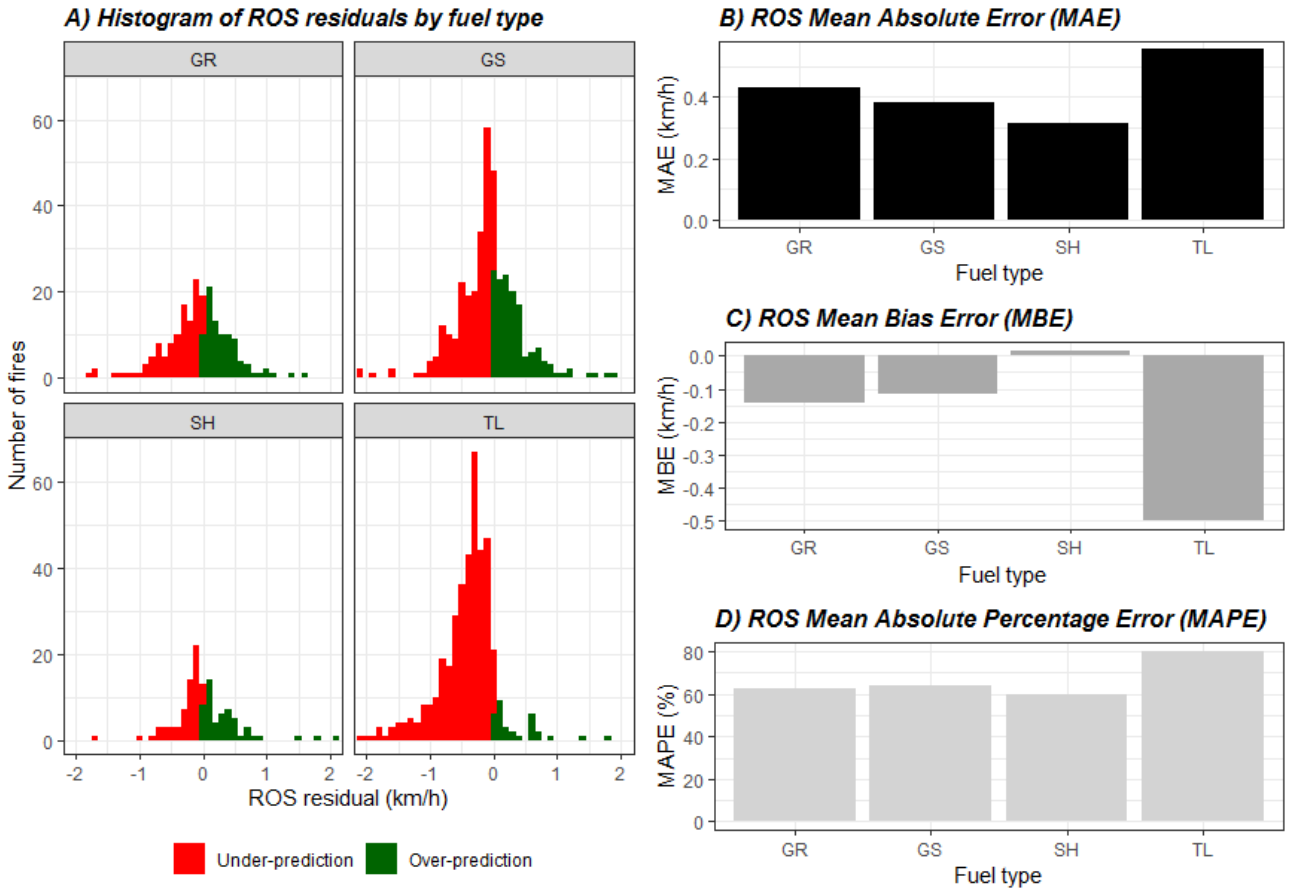

Figure 2. Fire spread model's performance analysis for 1,853 wildfires occurred in California in the 2019-2021 period. A) Histogram of ROS residuals by fuel type based on Scott and Burgan (2005); B) ROS mean absolute error (MAE); C) ROS mean bias error (MBE); D) ROS mean absolute percent error (MAPE). GR: Grass Fuel Types 101 to 109; GS: Grass-Shrub Fuel Types 121 to 124; SH: Shrub Fuel Types 141 to 149; TL: Timber-Litter-Understory Fuel Types 161 to 189.

Fire spread model's accuracy was also influenced by other environmental variables beyond fuel types (fuel moisture content, wind speed, etc), a fact not deeply studied in previous research studies. In general, high wind speeds led to ROS overprediction and low wind speed to underprediction, especially in GS and TL fires. This effect may be amplified in TL fuel types given that the crown fire spread models often require high wind speeds to forecast crown fire activity. Also, these models often behave binarily given a specific set of environmental conditions dramatically influencing the predicted ROS. We tried to address this issue in this work decreasing the MAPE up to 60% by smoothing the active crown ratio as follows:

$$ROS = surfaceROS * (1-\alpha) + \alpha * crownROS \quad \text{(Equation 4)}$$

where surfaceROS is the surface ROS fire spread by Rothermel 1972, crownROS represents the crown ROS by crown fire behaviour models and $\alpha = activeRatio^{1/factor}$ is the active crown ratio that is modulated by a factor defined by the fire analyst.

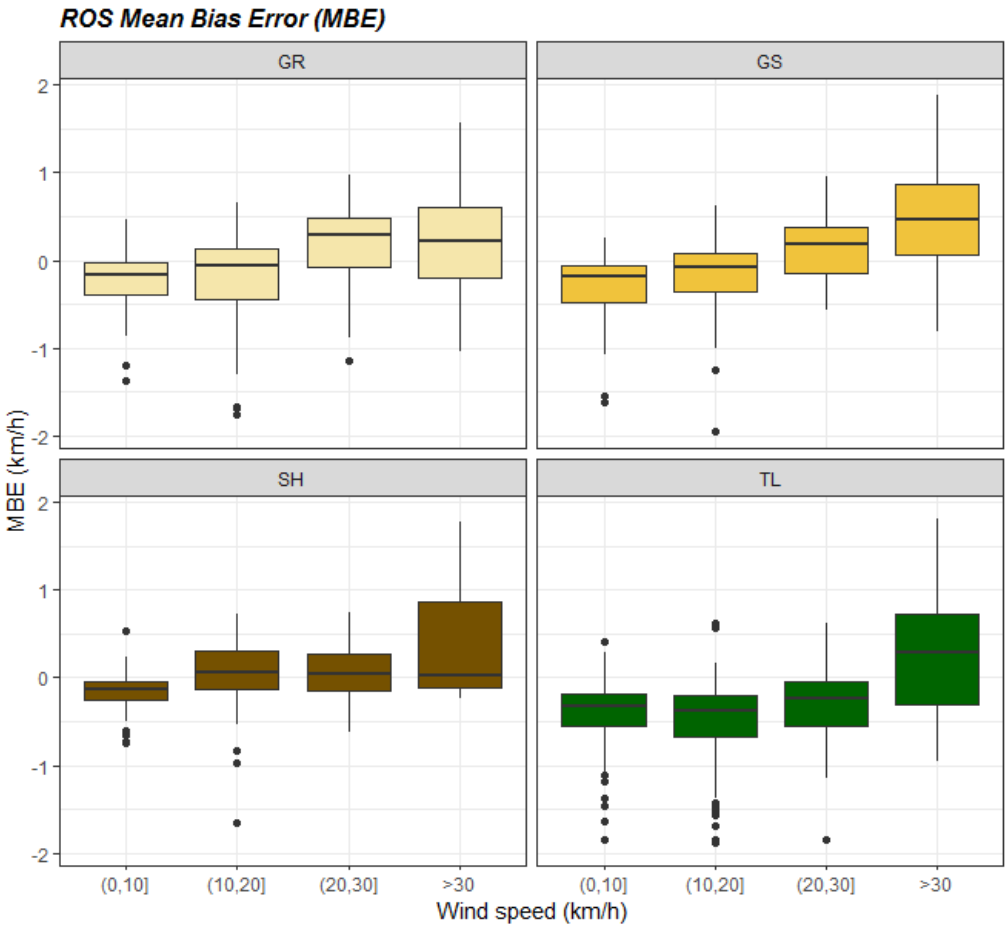

Figure 3. Boxplot of the ROS bias error (MBE) by fire and fuel type based on Scott and Burgan (2005) for 1,853 wildfires occurred in California in the 2019-2021 period. GR: Grass Fuel Types 101 to 109; GS: Grass-Shrub Fuel Types 121 to 124; SH: Shrub Fuel Types 141 to 149; TL: Timber-Litter-Understory Fuel Types 161 to 189.

4. Conclusions and further research

This work concludes that the fire spread model's performance for California is in line with previous studies developed in other regions and the accuracy of fire behaviour outputs are modulated by environmental conditions, especially wind speed. Therefore, the models are accurate enough to be used in real-time operations, especially with the use of adjustment modes that allow the calibration of predictions using field data (Artès *et al.* 2015; Cardil *et al.* 2019). However, we also recognize that there are challenges regarding the effect of pyroconvection on local wind fields and the estimation of ROS in timber areas. The results of this evaluation suggest that the accuracy of fire simulations may be improved with newer models aiming to address the modelling of crown fire behaviour.

The FG data and the algorithms developed in this research work to calculate ROS vectors represent a crucial enhancement to better analyse the fire spread model's performance and calibrate and provide new models and fuel families. Our approach addresses issues arising from the use of long fire runs, encompassing at times variations in fuel types, the estimation of fuel characteristics across the landscape, and the averaging of wind speed over broad spatial and temporal scales.

Vegetation classification, Sentinel 2, Random Forest, Accuracy Assessment, Independent Variables, GLCM texture feature

Abstract

Vegetation mapping requires accurate information to allow its use in applications such as sustainable forest management against the effects of climate change and the threat of wildfires. Remote sensing provides a powerful resource of fundamental data at different spatial resolutions and spectral regions, making it an essential tool for vegetation mapping and biomass management. Due to the ever-increasing availability of free data and software, satellites have been predominantly used to map, analyze, and monitor natural resources for conservation purposes. This study aimed to map vegetation from Sentinel-2 (S2) data in a complex and mixed vegetation cover of the Lousã district in Portugal. We used ten multispectral bands with a spatial resolution of 10 m, and four vegetation indices, including Normalized Difference Vegetation Index (NDVI), Green Normalized Difference Vegetation Index (GNDVI), Enhanced Vegetation Index (EVI), and Soil Adjusted Vegetation Index (SAVI). After applying Principal Component Analysis (PCA) on the 10 S2A bands, four texture features, including Mean (ME), Homogeneity (HO), Correlation (CO), and Entropy (EN), were derived for the first three Principal Components. Textures were obtained using the Gray-Level Co-Occurrence Matrix (GLCM). As a result, 26 independent variables were extracted from S2. After defining the land use classes by object-based, the Random Forest (RF) classifier was applied. The map accuracy was evaluated by the confusion matrix, using the metrics of Overall Accuracy (OA), Producer Accuracy (PA), User Accuracy (UA), and Kappa Coefficient (Kappa). The described classification methodology showed a high OA of 90.5% and Kappa of 89% for vegetation mapping. Using GLCM texture features increased the accuracy up to 2%. The ME and CO had the highest contribution to the accuracy of the classification among the GLCM textures. GNDVI had outperformed other vegetation indices in variable importance. Also, using only S2A spectral bands, especially bands 11, 12, and 2, showed a high potential to classify the map with an OA of 88%. This study showed that adding at least one GLCM texture feature and at least one vegetation index into the S2A spectral bands may effectively increase the accuracy metrics and tree species discrimination.

Notation

B_2 S2A band2
B_3 S2A band3
B_4 S2A band4
B_8 S2A band8
N Number of grey levels
P Normalized symmetric GLCM of dimension $N \times N$
$P(i, j)$ Normalized grey level value in the cell i, j of the co-occurrence matrix
d Distance
θ Direction
$\bar{x}$ Mean of P_x
$\bar{y}$ Mean of P_y
σ_x Standard deviation of P_x
σ_y Standard deviation of P_y

1. Introduction

Wildfires have wide-ranging effects on people's lives, wildlife, the natural environment, and the economy worldwide. Wildfire is a key component of the Mediterranean landscapes and ecosystems due to climate change, changes in the Land Cover and Land Use (LCLU), agriculture abandonment and expansion of forests and shrublands, expansion of Wildland-Urban Interfaces (WUI), and reduction in forest management (Xavier et al. 2006). Southern European nations such as Spain and Portugal with Mediterranean Basin (MB) forests would face the greatest fire dangers, given they are already prone to severe and frequent wildfires (Investment in Disaster Risk Management in Europe 2021, Costa H et al. 2020). Portugal experienced an unprecedented fire season in 2017, with a record of 540,000 ha burnt, 119 deaths, and millions of euros in losses and damage (Benali and Fernandes 2021, Monterio-Henriques and Fernandes 2018). Severe drought and the emergence of meteorological conditions conducive to large wildfires amplified the Portuguese 2017 fire season (Benali and Fernandes 2021). According to the Portuguese Institute of the Sea and the Atmosphere (IPMA), May 2022 was the warmest May in the past 92 years because of severe drought conditions, unusually high temperatures, and low average precipitation (IPMA 2022). Consequently, MB forests' protection from wildfire and climate change will be critical, necessitating large-scale fuel mapping and management (Kolström et al. 2011).

Conventionally, vegetation mapping has been performed using field surveys, image interpretation, and ancillary data analysis. Nowadays, remote sensing data with active and passive sensors are the main source of information for earth observation and producing up-to-date LCLU classification (Aragoneses and Chuvieco 2021, Xie et al. 2008, Chaves et al. 2020). Forest mapping and monitoring can be significantly improved by using freely available middle-resolution remote sensing data such as the Sentinel constellation. Sentinels' data provide high temporal frequency, different spatial coverage, and characterize various fuel types and their conditions with several spectral bands ((Aragoneses and Chuvieco 2021, Xie et al. 2008, Zeng et al. 2020, Kaplan 2021). Sentinel-2 mission with two satellites, Sentinel 2 level A (S2A) and Sentinel 2 level B (S2B), was launched by the European Union's Copernicus Earth Observation program of the Europe Space Agency (ESA) in 2015 and 2017, respectively. Sentinel-2 mission offers spatial resolution varying between 10 m and 60 m and a revisit frequency of 5 days (Sentinel-2 User Handbook. Vol. 2). Sentinel-2 includes three red-edged vegetation and the SWIR bands that are highly susceptible to chlorophyll content and amend distinguishing different vegetation types and LCLU classification accuracy (Chaves et al. 2020). Several studies found Sentinel-2 data with high potential in different applications such as crop classification (Hernandez et al. 2020), tree species classification (Costa et al. 2022, Wessel et al. 2018, Persson et al. 2018), mapping burned area (Pacheco et al. 2021), and forest type classification (Kaplan 2021). Most of the recent studies have shown that non-parametric machine learning approaches such as Artificial Neural Network (ANN), Support Vector Machine (SVM), and Random Forest (RF) have a great potential to classify heterogeneous land covers (Wessel et al. 2018, Pacheco et al. 2021, Sheykhmousa et al. 2020). Ma et al. (2017) found RF as the mostly used supervised classifier and more stable object-based image analysis (OBIA) with the highest mean accuracy of 85.81%, followed by SVM through reviewing 173 publications on supervised object-based classification. For example, Wessel et al. (2018) classified tree species based on multitemporal Sentinel-2 data with the highest overall classification accuracy of 91% for the SVM object-based algorithm. Persson et al. (2018) also studied the classification of common tree species in Sweden by applying RF classifier on multitemporal Sentinel-2 data. They achieved the highest overall accuracy of 88.2% for the combination of all spectral bands for four image dates.

Several operational programs are undergoing to produce global land cover maps, such as CORINE Land Cover (CLC), Land Change Monitoring, Assessment, and Projection (LCMAP), North American Land Change Monitoring System (NALCMS), and recently WorldCover produced by ESA at 10m resolution (Costa et al. 2018). These harmonized LCLU mappings have great potential for providing valuable information on Earth's surface; however, they face several challenges. The thematic accuracy of these global or continental land cover maps is spatially dependent on a low-frequency basis (e.g., every five years or more). Usually, they cannot comply with the user-specific requirements in space and time (Costa et al. 2018). Several researchers found the Mediterranean countries, such as Portugal and Spain, with the lowest overall accuracy, below 70% out of all European countries mapped (Costa et al. 2022, Liu et al. 2021). National land cover mapping with higher accuracy and up-to-date and detailed data can use as a complementary product for larger mapping scales (Costa et al. 2022).

SMOS (Sistema de Monitorização de Ocupação do Solo) is the land cover monitoring system for mainland Portugal which is in preparation by Directorate General for Territory (DGT) based on COS (Cartografia de Uso

e Ocupação do Solo), the traditional LCLU map of Portugal. An annual land cover cartography product of mainland Portugal (COSsim) based on sentinel-2 was started to overcome the limitation of COS. Costa et al. (Costa et al. 2022) presented an approach to map COSsim for 2018 with an overall accuracy of 81.3% using Random Forest (RF) classification and Sentinel-2 multi-temporal data. Although they achieved an accuracy of over 90% for southern Portugal, the classification overall accuracy for the center and North Portugal was below 80%, especially for the Coimbra district with approximately 75%. Their methodology was developed based on the following stages such as image classification, spatial stratification, knowledge-based rules (combination of expert knowledge and auxiliary data), intra-annual change, and manual editing. They classified this map into 13 thematic classes including the predominant species such as evergreen oaks, Eucalyptus, Maritime pine, and Stone pine (Costa et al. 2022). Costa et al. (2018) also studied a methodology with the combination of supervised and rule-based classification under the scope of the Land Use and Coverage Area frame Survey (LUCAS) to produce annual land cover statistics over Portugal from 2010 to 2015. They collected temporal Landsat data and auxiliary data such as Land Use and Land Cover map (COS2010) and Land Parcel Identification System (LPIS). ANN, SVM, and RF have been used for classification in their study and final classification with 15 classes obtained through the voting process. They reached the highest overall accuracy of 87.5% for the year 2010 and the lowest accuracy of 86.4% for the years 2014 and 2015.

The main objective of this study is to apply RF classification algorithms on S2A data to map the vegetation in the Lousa region, Portugal. The specific purpose of this study is to increase the interclass separability of forest and vegetation classes. According to the literature, no up-to-date vegetation mapping with Sentinel-2 and high overall accuracy was seen for the mentioned study area. Principal component analysis (PCA) was applied to the S2A spectral bands resampled to 10m resolution. Four common Vegetation Indices (VIs) and 12 GLCM-based textural variables, extracted from three first principal components (PCs), were integrated into the S2A spectral bands to better classify various vegetation in complex land cover. A comparison has been performed between the classification with all 26 independent variables and three different combinations of S2A spectral bands, vegetation indices, and GLCM textures. The importance of input variables has been analyzed based on Mean Decrease Accuracy (MDA) and Mean Decrease Gini (Gini). The obtained high-accuracy vegetation map can be used for biomass management and wildfire risk assessment.

2. Materials and Methodology

2.1. Study area

The study area is in the central region of Portugal. The study area is 138.4 km^2 (13840 ha) in size, latitudes 40º and 40º 3' N and longitudes 8º 09' and 8º 19' W, and is located in the municipality of Lousa in the Coimbra district of Portugal, as shown in **Figure 1**. The Lousa district has an elevation ranging from 57 m near the River Ceira in the north to 1205 m at Trevim in the south, which is the highest point of Serra da Lousa. Over 68% of the territory is below 400 meters of altitude. Slope values vary from the flat region in the northwest, with slopes typically less than 10°, to mountainous areas in the southeast, with slopes larger than 20° (Plano Municipal de Defesa da Floresta Contra Incêndios 2020).

The forest area (about 10,385 ha) is the municipality's dominant land use, accounting for approximately 75% of the municipality's total area. Agriculture land occupies 1399.27 ha. As a result, forestry and agricultural areas comprise most of the land, covering approximately 85% of the total area (Incêndios 2020). The predominant vegetation cover includes *Pinus pinaster* and *Eucalyptus globulus* species represent about 50% and 25% of the total forest species in the municipality, respectively (Incêndios 2020).

The climate of Lousa is the Mediterranean, with moderate, rainy winters and hot, dry summers. The months of autumn, winter, and early spring see the most precipitation. Their values are highly dependent on altitude and range, on average, between 1000 and 1800 mm annually. In 2017, 28 distinct wildfires burned about 4560 ha of forest in the municipality. The largest fires detected in Lousa municipality happened during the summer when temperatures average above 30 C°, and relative humidity falls below 30%, except for October 2017, which was affected by Storm Ophelia (Incêndios 2020). The severity of the Portuguese 2017 wildfires was exacerbated by a severe drought and the occurrence of meteorological conditions conducive to large wildfires (Viegas et al. 2017).

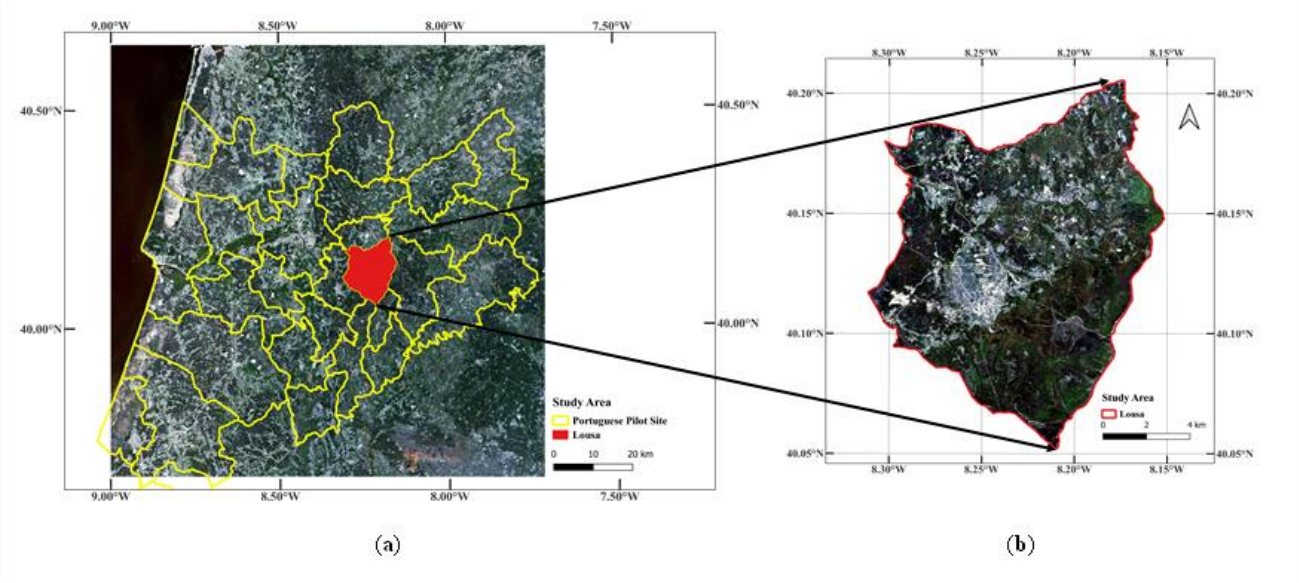

Figure 1- Geographical framework of the location and limits of the study area within a firEUrisk project and mainland Portugal: a) Sentinel-2 false-color composite image and b) study area- Lousa.

2.2. Materials, Data, and Model Algorithm

The S2A image processing procedures are synthetically represented in the workflow (**Figure 2**). Several processing stages were needed to achieve the vegetation mapping.

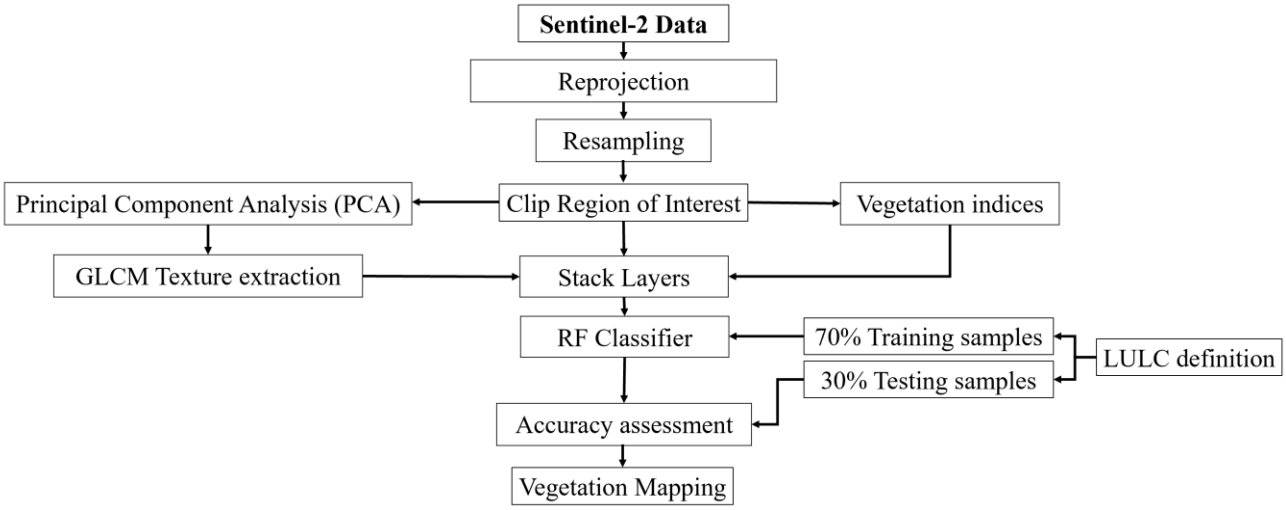

Figure 2- Scheme of vegetation mapping with Sentinel-2 data.

2.3. Dataset and preprocessing

Sentinel-2A MSI Level-2A images taken on July 18th, 2020, were derived from the Sentinels Scientific Data Hub for the study area (https://scihub.copernicus.eu/). The image was taken during the dry season to have less cloud coverage percentage (0.25%). The image was projected from WGS84 Geographic latitude/longitude coordinates to EPSG:3763 - ETRS89 / Portugal TM06, which preserves the area measure.

Sentinel-2 is equipped with MultiSpectral Instrument (MSI), which has four 10 m bands (visible and infrared – NIR), six 20 m bands (red-edge vegetation and short-wave infrared – SWRI), and three 60 m bands (Kaplan 2021). It is possible to increase the spatial resolution of all bands to 10 m using the resampling method and downscale the coarse resolution to fine resolution (Kaplan 2021, Sentinel-2 User Handbook. Vol. 2 2015, Zheng et al. 2017). Pixels of 20 m bands were resampled to the pixel size of 10 m with the Nearest Neighbor technique using ArcGIS Pro (version 2.8).

The high spectral resolution of Sentinel-2 imagery enables the extraction of different features. Based on the literature review and the sensitivity of optical features to biomass, four common spectral vegetation indices (VIs) were derived, including Normalized Difference Vegetation Index (NDVI), Green Normalized Difference Vegetation Index (GNDVI), Enhanced Vegetation Index (EVI), Soil Adjusted Vegetation Index (SAVI) using ArcGIS Pro(Noi Phan et al. 2020, Xia et al. 2017). The complete list of formulas can be found in Table 1 (B2, B3, B4, and B8 are the correspondence S2A bands). NDVI is strongly related to vegetation content, and NDVI high values indicate denser and healthier vegetation. GNDVI is a modified form of NDVI that can detect varying chlorophyll concentration rates by using green reflectance instead of red reflectance (Gitelson et al. 1996). EVI was developed to increase the sensitivity of vegetation signals in high biomass locations (Bhatnagar et al. 2021). SAVI also is a vegetation index that aims to reduce the impact of soil luminance, particularly in areas with low vegetation cover (Somvanshi and Kumari 2020).

Table 1- Vegetation indices (VIs) and applications from S2A.

Vegetation Indices	Formulation	Application
NDVI	$\frac{B_8 - B_4}{B_8 + B_4}$	Detection of vegetation communities in various seasons (29) Estimating changes in vegetation state (28) Determining the density of greenness (31)
GNDVI	$\frac{B_8 - B_3}{B_8 + B_3}$	Determining water and nitrogen uptake in the crop canopy (32)(28)
EVI	$\frac{B_8 - B_4}{B_8 + (6 \times B_4) - (7.5 \times B_2) + 1} \times 2.5$	Detection of vegetation communities in various seasons (29) Land cover classification (26)
SAVI	$\frac{B_8 - B_4}{B_8 + B_4 + 0.5} \times 1.5$	Minimizing soil brightness influences (33) (30) Land cover classification (26)

In addition to VIs, the previous research proves that using textural features significantly improves classification accuracy, especially for the species with similar spectral characteristics but different spatial patterns (Gini et al. 2018). PCA is commonly used in data mining to explore data and reduce data dimensionality (Guo et al. 2002, Xiao 2010). It reduces dimensionality by identifying a new set of variables that is smaller than the original set and captures big principal variability in data while disregarding minor variability (Xiao 2010). The three first PCs with cumulative eigenvalues of more than 99% were extracted from the spectral bands in ArcGIS Pro, as shown in **Appendix A (Table A1)**.

A total of four textural variables, including Mean (ME), Entropy (EN), Homogeneity (HO or also called Inverse Difference Moment- IDM), and Correlation (CO), were derived using the first three PCs (Kattenborn et al. 2019). These textures were obtained through the Gray-Level Co-Occurrence Matrix (GLCM) statistical approach with Probabilistic Quantizer (Quantization levels of 32), the inter-pixel distance of 1, and window size of 5×5 using SNAP (version 8.0.0). The window size was optimized based on this particular study area since the texture measures are dependent on the window size (Chatziantoniou et al. 2017). The formulas of textures and their application are listed in **Table 2**. The GLCM method examines the distribution of gray levels across adjacent pixels by considering the pixels' spatial position in an image (Humeau-Heurtier 2019, Xu and Gowen 2020, Zhang et al. 2017). Humeau-Heurtier (2019) defined the GLCM $P(i,j \mid d,\theta)$ as a relative frequency of the occurrence of the same intensity value i (reference pixel) adjacent to the different intensity value j (neighbor pixel) in a specific spatial relation at the distance d and direction of θ. Based on these parameters, ME used the frequency of occurrence of a certain neighboring pixel to weight the pixel value (Held 1998). EN assesses the degree of disorder and complexity of the texture distribution in GLCM (Humeau-Heurtier 2019, Zhang et al. 2017). HO shows the level of homogeneity (Humeau-Heurtier 2019), and CO measures the linear relationship between pixel values for the grayscale in the horizontal or vertical direction (Humeau-Heurtier 2019,Xhang et al. 2017).

Table 2- Texture metrics Formula

Texture Metrics	Formulation	Application
ME	$\sum_{i}^{N}\sum_{j}^{N} i \times P(i,j\|d,\theta)$	Weighting pixel value based on the frequency of its occurrence in conjunction with a specific neighbor pixel value (42,43) Calculating the mean processing window value (44)
EN	$-\sum_{i}^{N}\sum_{j}^{N} P(i,j\|d,\theta)\log_2 P(i,j\|d,\theta)$	Assessing the disorder of the GLCM (39) Reflecting the complexity of the texture distribution (41)
HO	$-\sum_{i}^{N}\sum_{j}^{N} \frac{P(i,j\|d,\theta)}{1+(i-j)^2}$	Measuring the level of homogeneity in pairs of pixels (39)
CO	$\frac{\sum_{i}^{N}\sum_{j}^{N}(i-\bar{x})(j-\bar{y})P(i,j\|d,\theta)}{\sigma_x\sigma_y}$	Measuring grey level linear relation between pixels (39,41,45)

2.4. Reference Data

Training samples for each ground object must be selected separately since RF is a supervised classifier. The basis for the selection of training and validation samples was acquired visually from Portugal Directorate-General for the Territory (DGT; Direção-Geral do Território 2018), Portugal Institute for Nature Conservation and Forests (ICNF; Instituto da Conservação da Natureza e das Florestas 2015), and Google Earth (orthophoto maps). Vegetation category was selected and verified based on dominant species, as presented in **Table 3**, such as *Pinus pinaster*, *Eucalyptus*, *Castanea*, *Pinus pinea*, *Quercus (*including *Quercus robur*, *Quercus suber*, and *Quercus ilex)*, *Acacia*, and other land use including cropland and agriculture land, shrubland and grassland, Water and barren (area without vegetation including roads and urban area) (Incêndios C 2020). Therefore, samples' polygons were manually created based on visual interpretation and reference sources.

Table 3- Dominant species represented in ha and percentage adapted from (Incêndios C 2020).

Species	Area (ha)	Percentage of the Study Area (%)
Pinus pinaster	5190.17	37.5
Eucalyptus	2611.95	18.9
Quercus	1273.36	9.2
Castanea	510.93	3.7
Acacia	506.26	3.6
Pinus Pinea	11.18	0.1

2.5. Image Classification

A total of 26 independent variables (including 10 spectral bands, four vegetation indices, and 12 texture measures) were used as an input to supervised classification to improve the classification performance (Aragoneses and Chuvieco 2021). RF algorithm was applied as a machine learning algorithm for vegetation classification in RStudio (version 2022.02.3+492). RF algorithm, an ensemble classifier that produces multiple decision trees, is commonly used in LULC due to its' high accuracy results achieved, solving highly non-linear problems on relatively small-size databases, and handling a large number of input features (Kluczek and Zagajewski 2022, Wójtowicz et al. 2021, Adeli et al. 2022). Furthermore, RF enables input feature ranking through random permutation, which has been studied in this paper using the RandomForest package in R (Zheng et al. 2017). The number of trees (ntree) and the number of random samples per node (mtry) were 500 and five, respectively. As shown in **Appendix A (Figure A1**), by increasing the ntree, out-of-bag (OOB) Error decreases and becomes stable at around 200 (Feng et al. 2015, Hanes et al. 2022). Researchers showed satisfactory results with the default parameter for the RF classifier which is ntree of 500 trees (Immitzer et al. 2016,Wang et al.

2015). In addition, a mtry that is excessively small or large reduces the individual tree's prediction ability. The optimum value for mtry calculates through 1/3 or the square root of the number of input variables (43,53). In this paper, the optimum mtry was calculated as five through the tuneRF function in R, as it is shown in **Appendix A (Figure A2)**. Samples were randomly subdivided into 70% for the training of the classification algorithm and 30% to validate the model. Finally, an accuracy assessment of vegetation classification has been performed by calculating the confusion matrix.

2.6. Accuracy Assessment

Accuracy assessments have traditionally relied on a confusion matrix (Stehman and Foody 2019). The confusion matrix measures OA, PA, UA, and Kappa to describe the fitness between the generated classes and the reference data (Xie et al. 2008, Sheykhmousa et al. 2020). OA is directly correlated to the percentage of the study area that is correctly classified, and the Kappa is also measuring the performance of RF (Stehman and Foody 2019, Landis and Koch 1977). OA is a relatively coarse measurement since it does not provide information on class-specific accuracy, while PA and UA respectively provide class-specific accuracy on the reference and classified area per class (Stehman and Foody 2019). The AO, PA, and UA may consider high precision with accuracy above 79% (56), and the Kappa greater than 80% represents a high degree of agreement (Landis and Koch 1977).

3. Results and Discussion

A total of 26,100 pixels were selected for the training and validation samples by visual interpretation using reference sources, including DGT, ICNF, and Google Earth. The effective sample size is suggested to be between 0.2% to 3% of the total dataset pixels (Blatchford et al. 2021). The sampling size of this study is approximately 1.3% of the total pixels. Increasing the training sample size generally boosts classification accuracy. Many researchers have found a positive correlation between classification accuracy and sample size (Ma et al. 2017). According to Moraes et al.(2021), there is no recommended minimum sample size, and the sufficient sample size depends on several parameters such as the classifier, predictor variables, class definition, and size and spatial features of the study area. They analyzed the influence of sample size on the LCLU in the North of Portugal using S2 data and the RF classifier. They compared OA for the sample size of 50 to 6000 per class. They found a similar OA value with a variation of 2%, and the highest value of 73.7% indicated the low sensitivity of the RF classifier to the sample size (Moraes et al. 2021). According to the actual occupied area in (Incêndios C 2020), Pinus pinaster and Eucalyptus have the greatest number of pixels, and other classes have a similar proportion of actual occupied. Samples were divided into 70% (17394 pixels) as training samples and 30% (8706 pixels) as validation samples using Stratified random sampling in R. **Appendix B (Table B1)** shows the total of 10 classes for this study.

Accuracy assessment of the classification was evaluated based on the confusion matrix and OA, PA, UA, and Kappa metrics. The rows and columns of the confusion matrix shown in **Table 4** indicate the map classification and the reference classification, respectively. Diagonal cells of the matrix show the correct classifications, and off-diagonal cells indicate misclassifications. The repetition of 10 times was conducted for an unbiased evaluation, and the mean accuracy metrics are presented in **Table 5**. OA 90.9% (±1) and Kappa of 89% (±1) have achieved for this classification, indicating a high classification accuracy. The lowest and highest PA was obtained for *Acacia* and Water, respectively. The other classes have a high accuracy of over 90%, except for *Quercus,* with a PA of 79.5%. In the case of UA, barren has the highest accuracy of 97.1%, while *Acacia* has the lowest with a value of 70.1%. Predominant species of *Pinus pinaster* and *Eucalyptus* has a high UA and PA of over 90%.

Figure 3 shows the classified vegetation map based on the proposed methodology. **Figure 4** represents the area and percentage of each class in the classified map and reference data. According to the result, the largest area is occupied by *Pinus pinaster* followed by *Eucalyptus* mostly in the south and north of the study area, respectively. However, the Pinus pinaster has the majority in the reference data and occupied approximately 37% of the study area (Incêndios C 2020,DGT 2018,ICNF 2016). Since the reference data were based on COS2018 (DGT 2018), they were not up-to-date and accurate. It is necessary to perform a field measurement to detect the changes and assess the final classification of this paper. Land cover changes may happen due to wildfire or cutting trees either for commercial purposes by private land owners or forest management. In addition, the study area is very heterogeneous and has several areas with mixed species that it is also hard to distinguish visually using Google Earth. Also, Cropland/Agriculture land class has a greater area than the reference data mentioned in **Section2.1**. Some of these misclassifications were due to the new plantation field of tree species and confusion with the Shrubland/Grassland class. Both of these fields have a similar pattern and spectral features of Cropland/Agriculture land class. The other six classes' areas predicted similar results compared to the reference data with an error of less than 3%, referring to **Appendix B (Table B1)** for more information. According to Costa et al. (2022), there is always expected to have spectral confusion between shrubland and tree species or grassland and agricultural land because of similar spectral features of some classes. They also mentioned the broad conceptual definition of the classes as another factor of misclassification (Costa et al. 2022). Shrubland/Grassland class may have a broad conceptual definition since it includes natural, semi-natural, and agricultural grassland and also shrubs. Costa et al. (2022) also found several classification contradictions between their LCLU classified map and COS2018 (DGT 2018) for the land cover of mainland Portugal. They presented a significant increase in the occupied area of shrubland and grassland as one of the major land covers of Portugal in comparison with COS (DGT 2018). Problematic classes may also result from the fragmented species distribution, either rare or mixed with other classes, especially for tree stands (Immitzer et al. 2016). The major reasons for different classification statistics may relate to the higher resolution imagery of S2A with 10 m compared with traditional maps, including COS, class definition, and impact of the 2017 wildfire and burnt area on land cover changes (DGT 2018). Immitzer et al. (2016) mentioned the effect of a parameter such as a stand age and density, crown coverage, and understory on the spectral behavior of the tree species and their intra-class separability. Several Pine and Eucalyptus stands have been seen in this study area with different ages due to the plantation or cutting. All these effective factors have been considered in this study while comparing the result with the reference data.

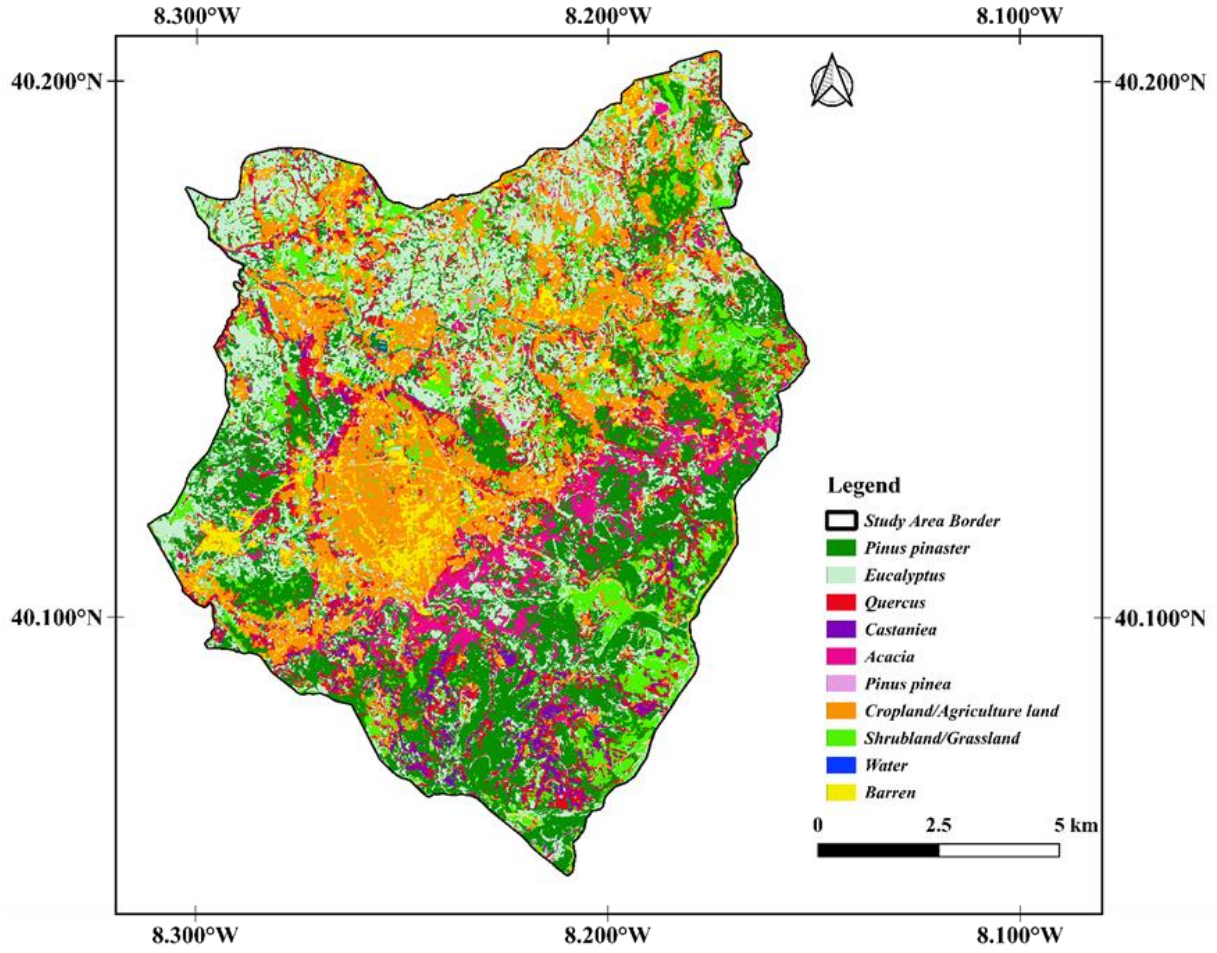

Figure 3- Vegetation map generated based on 26 independent variables of S2A imagery using RF classification for Lousa, Portugal.

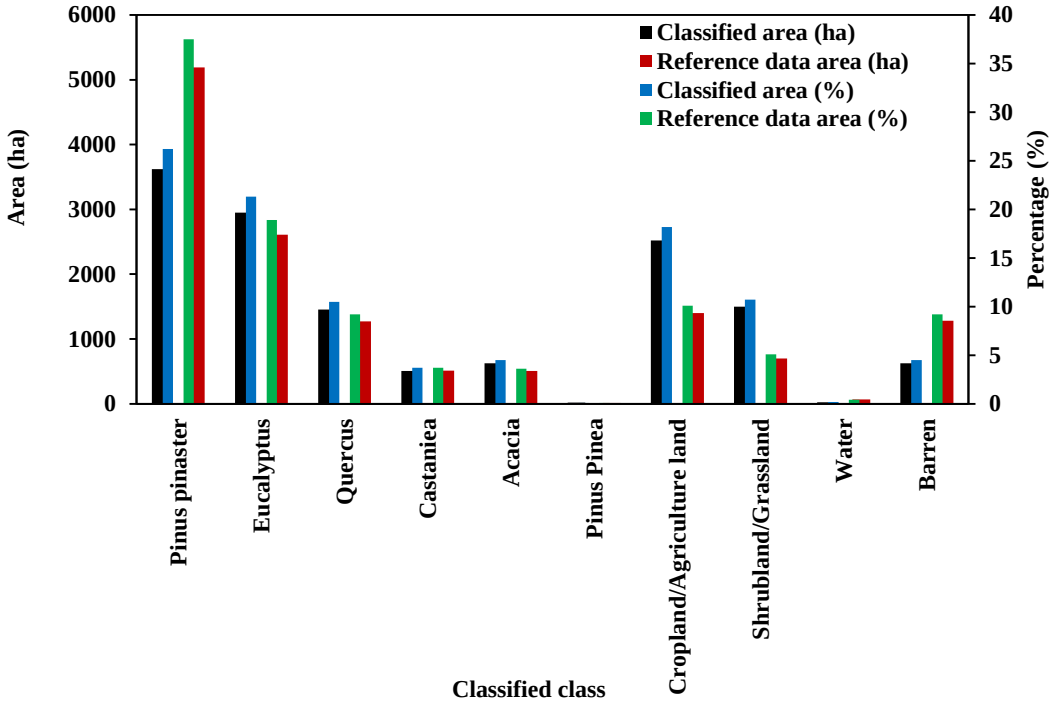

Figure 4- Comparison of classification result and reference data represented in the area (ha) and percentage.

3.1. Importance of Independent Variables

In order to assess the importance of each variable in RF classification accuracy, MeanDecreseAccuracy (MDA) and MeanDeacreseGini (Gini) have been used through random permutation. **Figure 5 (a) and (b)** show the ranking of the variables based on their contribution to distinguishing the classes. This ranking was almost the same for all the repetitions. Band 11 and 12 (SWIR) and band 2 (Blue) have the highest MDA and Gini among the S2A spectral bands, although the NIR band of 8 achieved low scores. In the case of the GLCM textures, the ME and CO of the PC3 have the highest rank among all 26 variables in MDA. Generally, the ME and CO for the PC1 and PC3 were ranked among the top five variables in both MDA and Gini. Additionally, GNDVI and NDVI have the highest contribution among VIs.

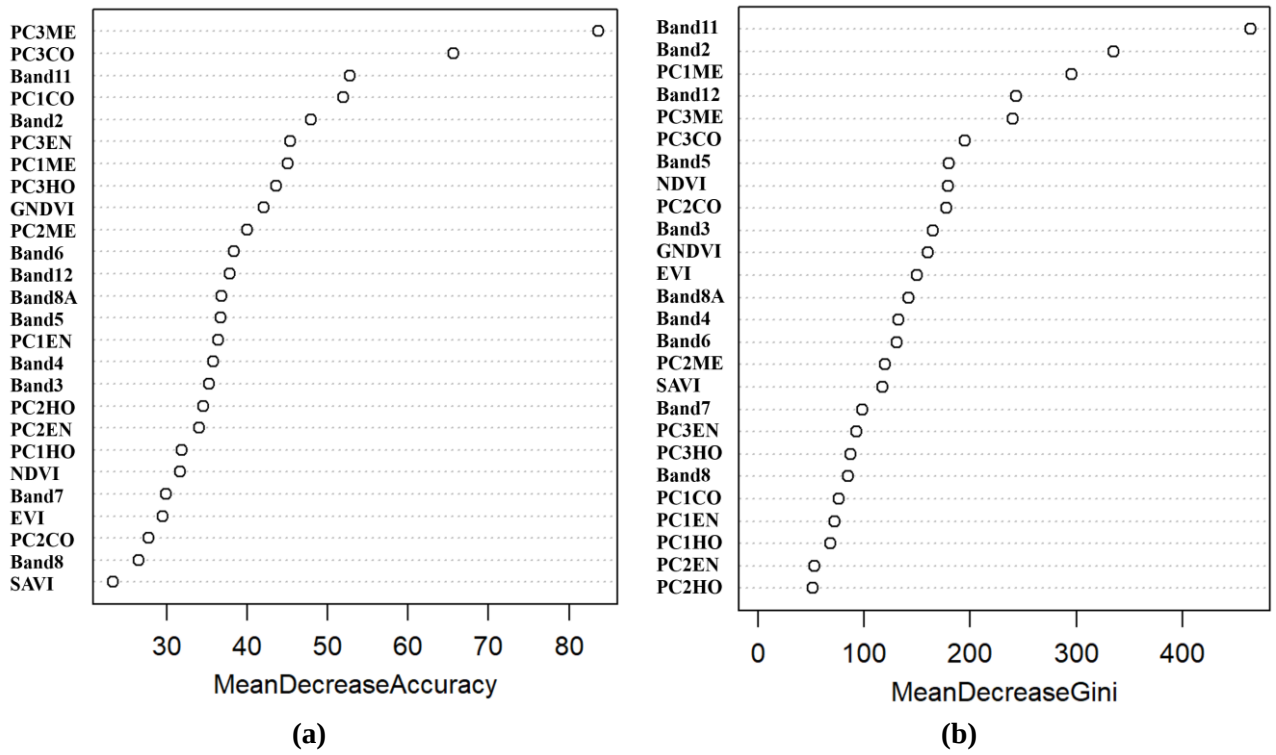

Figure 6 - Band Importance ranking based on mean decrease accuracy and mean decrease Gini.

The methodology has been applied to different independent variables input to analyze the importance of the GLCM textures. The classification was repeated for three additional scenarios of input bands: (I) Only S2A spectral bands, (II) S2A spectral bands and VIs, and (III) S2A spectral bands and GLCM textures. The Rf classifier based on S2A spectral band and GLCM texture achieved the maximum OA and Kappa, as presented in **Table 7**. Using all 26 variables has ranked second with a difference of 1.2%, lower than the combination of spectral bands and GLCM textures. Wang *et al. (2015)* also achieved high accuracy of 97.1% by using only GLCM feature on IKONOS multispectral bands, which is higher than the accuracy of the combination of all spectral bands and GLCM and GI features (96.9%). They believed that lower accuracy of all bands is associated with increasing omission and commission errors of some Gi features. In this paper, the lower accuracy of classification with all bands may cause by vegetation indices. However, the combination of spectral bands and four vegetation indices yielded higher accuracy than only spectral bands and improved the accuracy. The minimum OA and Kappa also were obtained for employing only S2A spectral bands. Adding GLCM texture to S2A spectral bands has increased the accuracy metrics by 4%.

Table 6- OA and Kappa for RF classification with different combinations of independent variables.

	All bands	**Spectral bands**	**Spectralbands+ VIs**	**Spectralbands+ GLCM texture**
OA (%)	90.8	88	88.6	92
Kappa (%)	89	86	86.1	90.2

Appendix B (Figures B1) shows the band importance for these three additional classifications. In all of the four scenarios of input variables, band11 and band 2, ME and CO of PC1 and PC3 outperformed other variables with the high value of MDA and Gini. It can be concluded that adding at least one GLCM texture may improve the classification accuracy. In this paper, the ME and CO have enhanced the RF classification with higher accuracy. Several studies have indicated the importance of texture feature extraction in increasing the accuracy of the classified map (Zheng et al. 2017, Zhang et al. 2017,Adeli et al. 2022). Wang et al. (2015) found the ME as the most important variable in mapping forest health conditions using IKONOS imagery. Zhang et al. (2017) emphasized the importance of GLCM texture feature extraction on classification accuracy improvement. These textures provide information about different objects with the same spectral, while spectral bands provide the data for the same objects in the different spectrums (Zheng et al. 2017). Zheng et al. (2017) have suggested using Extended Attribute Profiles (EAPs) in addition to GLCM textures, which can improve shrubland, agricultural land, and barren discrimination. Furthermore, S2A spectral bands have shown a high potential in the LCLU classification of the regional study area of this paper without using additional variables, which were also mentioned previously in several research studies (Chaves et al. 2020,Zheng et al. 2017, Immitzer et al. 2016). In this paper, bands 11 (SWIR) and band 2 (blue) were almost among the five first important variables in all combinations. Immitzer et al. (2016) found bands 2 and 11 as the highest score while NIR band 8A was the lowest score for forest species classification. Feng et al.(2015) declared that spectral features contribute the most in their study with the UAV for flood mapping. In their study, the red and blue bands followed by ME were the most important variables.

3.2. Effect of Bootstrap Sample Size

Rf classifier uses bootstrap aggregation, randomly creating different training subsets of the original training dataset to grow the individual regression trees (Immitzer et al. 2016, Wang et al. 2015). Wang et al.(2015) suggested using two-thirds of the validation dataset per subset for bootstrap sample size. The minimum value of the bootstrap sample size in this paper was equal to the minimum class pixels (Water), and the largest sample size was approximately equal to the extraction of highest and lowest class pixels (*Pinus pinaster* and Water). As shown in **Figure 7**, the lowest and highest OA and Kappa were calculated for the sampling size of 137 and 7000, respectively. The highest OA was increased by around 15.7%, and Kappa was increased by 19.3%. According to UA and PA, the lowest UA and PA has appeared in the sample size of 137 with zero percentage of water and *Pinus pinea* detection; more information was presented in **Appendix B (Table b2)**. The minimum PA remained below 70% until the sample size of 5000. Thomlinson et al.(1999) proposed the minimum OA and per-class accuracy of 85% and 70% for high precision classification, respectively. Although the bootstrap sample size of 6000 and 7000 has increased OA and Kappa by approximately 1%, the sample size of 5000 was used for this research to avoid overfitting and high computational process based on previous studies (Zheng et al. 2017, Thomlinson et al. 1999). 5000 bootstrap sample size is also equal to two-thirds of the validation dataset in this paper. Furthermore, the lowest and highest OOB error were obtained for the samples of 5000 and 137, respectively.

This paper has achieved high value for the accuracy metrics based on a single image of medium resolution S2A multispectral bands compared with previous studies that used multi-temporal or high-resolution imagery (Costa et al. 2022, Immitzer et al. 2016). The main purpose of this study was to increase the interclass separability of forest and vegetation classes and to provide up-to-date data based on S2A for the Lousa region, Portugal. However, the major limitation is the lack of recent reference data or fieldwork in Portugal. To better analyze the accuracy of the classified map, field measurement data and reliable and up-to-date ground truth data as reference data are needed. For future study, adding Light Detection and Ranging equipment (LiDAR) data, UAV imagery with finer resolution, Sentinel-1 SAR data, and knowledge of local experts are expected to increase the discrimination of the LCLU classes and provide more information on vertical features of the species. Recently, Portugal has started capturing LiDAR data for the whole country. Nevertheless, it is not yet covered in the study area of this paper.

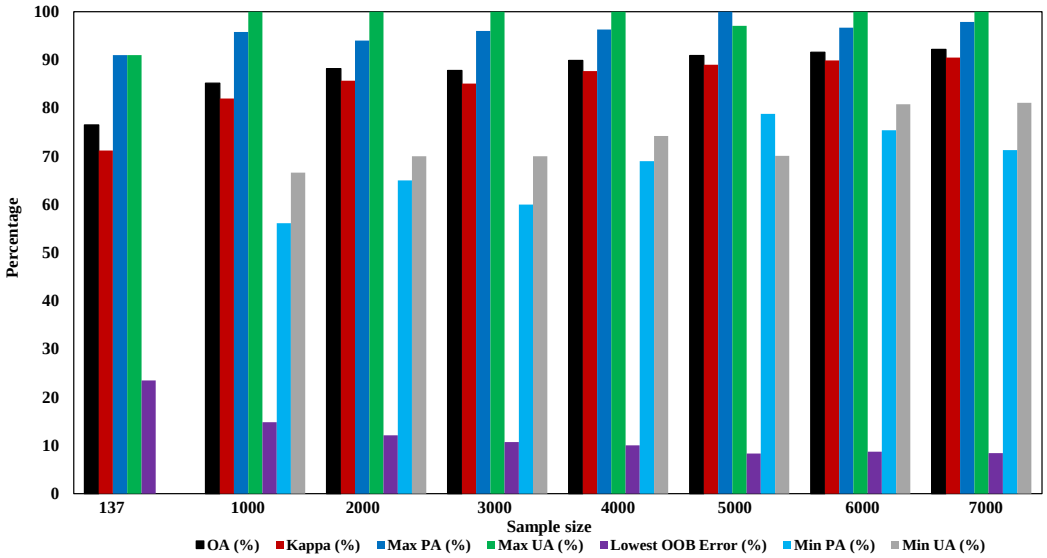

Figure 7- Effect of sample size on OA, UA, PA, Kappa, and OOB Error in RF classification.

4. Conclusion and Future Works

This paper proposed a methodology for vegetation mapping by applying a Random Forest classifier on the Sentinel2-A image. Twenty-six independent variables were used by combining ten S2A multispectral bands resampled to 10 m pixel size with four vegetation indices and 12 GLCM texture feature variables. These GLCM texture features were calculated from the three first principal components of downscaled S2A spectral bands using PCA. Training and validation data was acquired through forestry data of ICNF and DGT and visual interpretation using Google Earth. RF classifier with 500 *ntree* and 5 *mtry* was used to classify the study area into ten classes, including the predominant tree species. A high precision classification was performed with an overall accuracy of 90.5% and a Kappa coefficient of 89%. Nevertheless, employing all 26 variables did not achieve the highest accuracy compared to the combination spectral bands and GLCM textures with an OA of 92%. The comparison of classification accuracy for four different combinations of input variables shows the importance of GLCM textures especially ME and CO in improving the performance of the RF classifier. Spectral bands 11 and 2 also have high scores in MDA and GINI for all the scenarios. Generally, S2A 10m spectral bands have a strong potential for precise and rapid vegetation classification. GNDVI contributes the most to the accuracy of classification amongst vegetation indices. The results of this study indicate that incorporating at least one GLCM texture feature and at least one vegetation index into the S2A spectral bands can effectively improve the accuracy of assessment and tree species classification.

Few studies explored vegetation mapping with high accuracy in Portugal, mainly in the Lousa region, using Sentinel 2 images. Exploring the multispectral band and texture feature analysis can contribute to the spectral separability of vegetation, facilitating studies of aboveground biomass estimation and wildfire simulation. Accuracy assessment of the implemented methodology has shown a high potential for generating high-accuracy vegetation mapping over forestry areas. It is foreseen to expand the methodology for the data fusion of Sentinel 2 and Sentinel 1 to include data regarding the vertical structure of the vegetation and canopy. This data will enable the creation of a fuel type tridimensional semantic map to be used by fire behavior models and allow the definition of biomass management strategies towards wildfire risk reduction or accurate fire spread simulations for the decision support during wildfire occurrences. These results are relevant for the ESA 2025 Agenda, whose challenge is integrating information from Copernicus mapping carbon to promote sustainable land management and improved resilience against natural risks and impacts of climate change. Therefore, more studies are necessary to be conducted in order to cover more datasets in Portugal.

Vulnerable elements, Cross-border risk assessments, GIS-based platform, Extreme events, Emergencies

Abstract

The VESPRA project (Vulnerable Elements in Spain and Portugal and Risk Assessment), financed by the Union Civil Protection Mechanism UCPM-2020-PP-AG, is designed in a context of increased frequency and intensity of extreme events and emergencies, and in a current context where those responsible for the emergency often do not have sufficiently updated information on vulnerable elements. Indeed, there is cartography of these elements, but it is very quickly becoming outdated. It is therefore necessary to design a strategy that allows continuous updating of this information, and this is one of the main functionalities of the proposed solution in VESPRA.

VESPRA arises for the improvement of the risk management mechanisms for local risks such as forest fires, and also for other generic ones like those related to adverse meteorological phenomena or the dispersion of pollutants in wide areas. It is focused on the border area between Spain and Portugal and within the project, an international protocol will be defined for the collection of vulnerable elements and their characterisation regarding different hazards, and for their integration into a GIS-based platform specially designed to optimize their management and continuous updating. VESPRA will result in a system to assist decision-making in the event of an emergency in order to improve the harmonised identification and mapping of vulnerable elements and the integration of vulnerability in a joint information system for the evaluation and assessment of the transnational emergency response. The project targets three end-user groups: (I) the local authorities, (II) the general population, and (III) relevant institutions in civil protection.

Although the implementation for demonstration and validation purposes will be actually implemented as a baseline in three study cases, along the transboundary area between Spain and Portugal, VESPRA is developed with an European vocation aimed at the future adoption of the technological and procedural models in other transboundary European regions. These will be international, trans-boundary operational exercises based on the VESPRA system and on simulated scenarios in the selected study case regions. The first one will be a forest fire starting in Spain and moving towards Portugal. The exercise will evaluate the capability of the VESPRA system to help in the joint evaluation of potential risks and the coordination of responding forces, as well as the primary actions for the protection of the population and infrastructures. The second exercise will develop a combination of simultaneous nuclear and industrial emergency, one in each country, and will focus on the ability of VESPRA to provide accurate information and a channel of seamless interchange of key aspects for the ranking, evaluation and final decision making on such combined scenarios. The third one will be the simulation of an extreme weather episode, similar to the pass of Ophelia in 2017, affecting population and critical transportation and other infrastructures in both countries.

1. Introduction and objectives

We are in a new paradigm of change regarding emergencies, on the one hand due to the need for new scopes in the treatment of information across borders, and on the other hand in the context of global climate change. Most natural and man-made disasters imply risks that cross borders, due to their spatial dimension (earthquakes, forest fires, extreme weather events, floods) or their spread (pandemics, livestock epidemics, nuclear/industrial accidents).

Climate change has already led to an increase in the frequency and intensity of new extreme weather events such as the storm Ophelia, that occurred in 2017 and affected Portugal and Spain through a wave of fires never seen before. The increasing human, economic or environmental impacts of these new hazards, as well as their also increasing probability of occurrence, affect boths sides of the borders between countries. This increasing complexity and the emergence of new threats require greater intersectoral, transdisciplinary and cross-national cooperation at all stages of risk management (Benelux; 2016).

Risk analysis services and early warning systems have become basic tools in civil protection. Recent technological changes related to big-data, artificial intelligence, communication networks, and remote-sensing have created a shift in awareness of the emergency. In addition, the advances on the global and local weather forecast have led to an increasing improvement of their accuracy. Authorities and end-users of these services demand high quality, tailor-made information and solutions to their very specific problems in emergency management. To address this demand it is necessary to provide more innovative and holistic services with higher added-value, in an increasingly competitive market.

One of the main needs of emergency response services is to have updated information. They used to have vulnerable elements in cartography, but it became outdated very quickly, as changes in their location, characteristics, operating status, etc., as well as the appearance of new elements (for example, a new point of interest where visitors congregate), are very frequent. Thus, if for example an access road has been damaged last winter and is no longer suitable for emergency vehicles, or if there is a new point to protect in the event of a disaster, this information is essential for the emergency managers, and the outdated mapping is no longer useful, or may even be harmful. In this context, they need a solution allowing the constant updating of these vulnerable elements' information, and therefore allowing the assessment of the territory's vulnerability in a robust way..

VESPRA arises as an answer adapted to the new demands and offers flexible and demand-driven services that fit the end-users specific needs. Specialized end-users demand innovative solutions and bespoke system features. The main objectives of the VEPRA project are:

(I) The design, development and operationally implementation of a system for the evaluation and analysis of the transboundary vulnerability to the identified risks (forest fires, industrial/nuclear pollution cloud dispersion and extreme weather). It will be an open-source computer platform for vulnerable elements data and information exchange with a common methodology for: the harmonised collection and updating of data, vulnerability and impact assessment and assistance in operational and preventive decision-making in the emergency; and

(II) The other major objective is to improve emergency management through cross-border collaboration, taking into account civil protection and emergency management structures in each country. This requires the implementation of a network of competent authorities at national and sub-national level for the use of the platform applied to the identified risks, including: Technical specifications and protocols for the development and generation of operational vulnerability mapping to enhance cross-border interoperability and Design and implementation of joint cross-border small-scale exercises for previously identified risks.

2. Methodology

The VESPRA project seeks to establish an environment where vulnerability can be assessed prior to an emergency. To do so, it is necessary to know the vulnerable elements that could be affected, as well as current state of the art regarding vulnerability. For this purpose, available databases of vulnerable elements are reviewed along with an analysis of vulnerability in real events. These results form the basis for the establishment of a harmonised cross-border catalogue of typologies of vulnerable elements. This step is crucial for the subsequent development and implementation of a GIS system that will be fed by these typologies, and subsequently by the vulnerability models.

The system (VESPRA platform) is developed and adapted in two phases, a first phase that allows the collection of vulnerable elements (WP2) and a second phase that allows the design, development and implementation of vulnerability assessment models (WP4).

VESPRA platform is used to collect the vulnerable elements of the Spanish-Portuguese border in a database which is harmonized for both countries. In addition, the system allows the cartographic representation of all the results, so that possible cartographic alternatives can be analysed using the most modern representation techniques (WP3).

During the project, work is also carried out on the characterisation of vulnerable elements using different methodologies derived from the risks studied in the project (forest fires, industrial / nuclear accidents and extreme weather events, WP4). To this end, different models are applied according to the nature of the risk and the vulnerable element. All this is integrated in the GIS platform already developed to have a final system that allows the vulnerability assessment (WP5). This system has the following characteristics:

- Simplicity. The handling of the platform is practical and simple, as it should be used by non-technical people, without requiring any training, beyond reading the help and, occasionally, consulting the support centre;
- Flexibility. The platform allows the creation of new typologies of vulnerable elements, and new information related to each typology through its administration module without the need for software modifications. It also allows, through the administration module, the modification of the symbology and styles of the elements represented;
- Immediacy. Any change produced in the territory must be able to be immediately validated and incorporated into the system and into the systems connected to it. This is an essential characteristic, in order to allow the continuous updating of the vulnerable elements information;
- No licenses. As it will be 100% developed on free software libraries, operating system, database and languages, future maintenance costs will be limited to the maintenance of the hardware where it is installed;
- Transferability. The system is able to be subject to technology transfer, so it is easy to administer and easy to modify, with a clean and clear data model and a structured and commented code.

Once the system has been completed, it is validated by means of an operational implementation in which the results it provides, both cartographic and numerical, are evaluated. In addition, the platform is used in the three cross-border trainings in order to see its applicability and operability in quasi-real situations. Subsequently, all evaluation results are used to make adjustments in the final version of the platform(WP6).

Finally, the last work package (WP7) has as its main objective to promote the use and exploitation of the main VESPRA results ensuring their contribution to risk reduction in transboundary regions. This is done through dissemination and diffusion of technical and scientific documentation, organisation of workshops and the creation of public awareness and media working groups, among others, aimed at two relevant target groups: technicians and researchers; and different stakeholders (e.g. potentially affected populations or the media).

3. Preliminary results

The VESPRA project has achieved the objectives expected for the basic line of work of study and harmonisation of data, focusing on a rigorous analysis of the specific state of the art in the field, on which the fundamental bases of the VESPRA project have been built, searching for unmet needs in this area and technological innovation to make the most of them. Specifically, these first lines of work have been based on the following:

(I) the survey and harmonisation of the conceptual framework of vulnerability, hazard and risk and of the databases of vulnerable elements available in the regions, Member States and the Union. A total of 45 databases covering different geographical scales - global, European, cross-border, national, regional and local - have been evaluated, taking into account the data format, as well as their time frame and spatial resolution.

(II) the creation of an agreed catalogue of vulnerable elements (Annex 1), including a hierarchical classification by type and nature groups (i.e. static, dynamic), a universal definition and a preliminary description of the undesired consequences in case of exposure to hazard levels observed in real events. This catalogue includes more than 100 vulnerable elements divided into six main types related to each hazard: people, utilities, commercial and service facilities, industrial facilities, environmental elements and cultural heritage facilities and services. Each vulnerable element typology is divided into several sub-typologies with a simple attribute scheme that is used to analyse its vulnerability to emergencies.

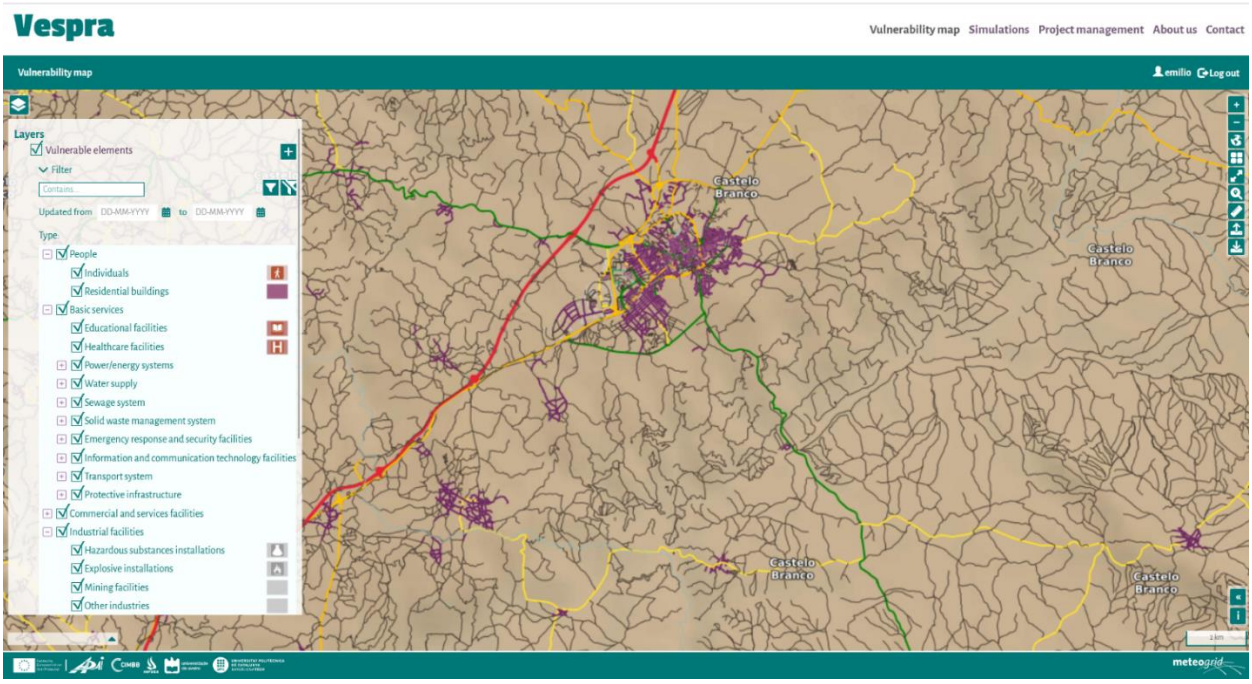

Figure 1. Overview of the system

As a result of the above it has been possible to complete a survey of the main databases of vulnerable elements and of the main hazards in the Member States, as described in the relevant Civil Protection Organisations, and to review and draw lessons learned from recent relevant events involving vulnerable elements, especially in population, infrastructures and the environment.

In parallel, the VESPRA project has devoted effort to the design, development and implementation of a data collection system and procedure linking several territorial levels. Given the trans-scalar and cross-border nature of the data collection, a special effort has been made for the interoperability of the process between Spain and Portugal, for which a multilingual graphical user interface has been developed. Portability and modularity have been at the core of the system design, including the use of mobile phones and tablets to facilitate its use down to a local level. The tools are based on a GIS-WEB with different solutions to manage the cartographic information generated with different user profiles (Figure 1). A mapping strategy has also been developed based on existing standards for the mapping coding of vulnerable elements and consistent with the rapid mapping of the Copernicus service. This makes VESPRA perfectly compatible with the products used by and for the Union Civil Protection Mechanism (UCPM).

The next step in the VESPRA project has been the study, definition, analysis and description of the vulnerability and risk models to be incorporated into the VESPRA tool. For each of the four hazards considered, the vulnerability models available in the state of the art have been studied and the most interesting ones have been selected for the purposes of the project taking into account the previous results. Once the models have been analysed and selected, the next step has been to describe an algorithm for their use and implementation in the VESPRA tool.

The risk assessment model followed in the VESPRA Project comprises several sequential steps. Each of these steps provides the user with a set of information of great operational and preventive interest, making the VESPRA tool usable in the prevention, preparedness and response phases, i.e. in the hypothesis of a future hazard event and in the course of a hazard event.

Figure 2 shows the general data flow and processing of the VESPRA approach to obtain mapping information on vulnerability and potential damage. This general approach has been specified for each of the hazards.

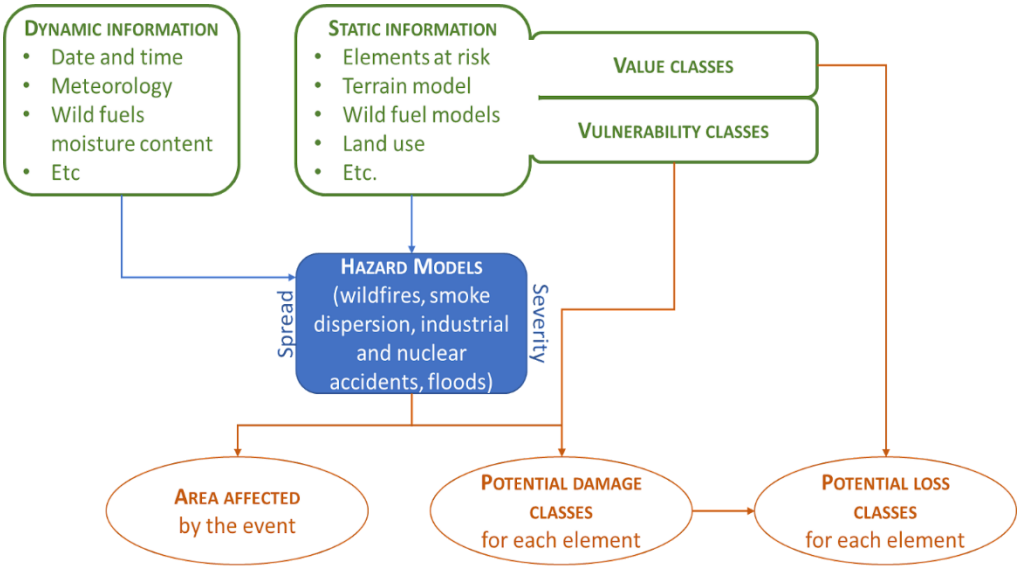

Figure 2. Data flow of the VESPRA Tool.

The VESPRA team is currently implementing these models in the decision support system (Figure 3), contributing to the specific end goal (cross-border disaster risk management through prevention and preparedness in Europe).

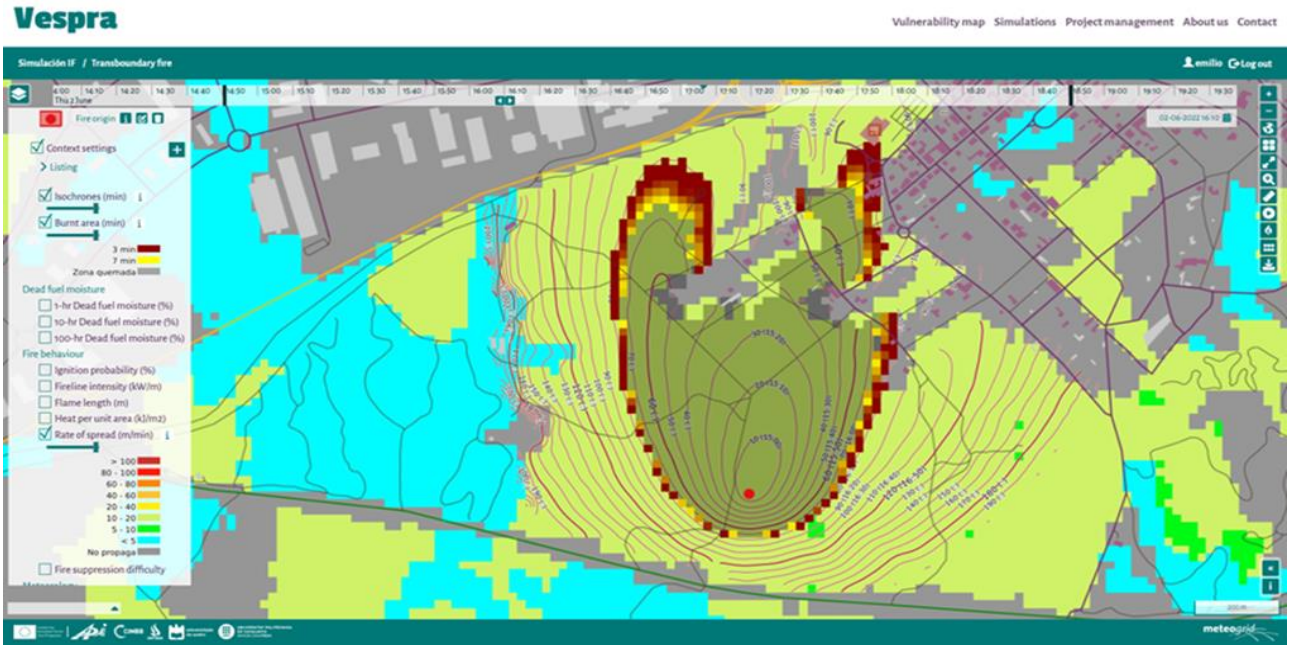

Figure 3. Potential Loss of the exposed elements for the demonstration area in the scenario.

4. Conclusions

VESPRA is a system based on web services that will incorporate the vulnerability geo-database, the catalogue, the weather forecasting services and the different vulnerability analysis models in diverse risk domains. This includes the capacity to project meteorological processes, the identification of possible scenarios, the estimation of possible consequences and the identification of possible vulnerable elements affected. In this sense, this last line of innovation is especially dedicated to the integration of all the components of the system under a single user interface, which will comply with the degree of interoperability required by the cross-border nature of the services. The system will be fully compatible with the existing legacy systems in the two selected countries (Portugal and Spain), but will also be fully interactive and allow information sharing in both countries.

Chapter 2:
Fire at the Wildland Urban Interface

A Comparison of Particulate Morphology of Wildland Fuels and Human-Made Fuels at the Wildland-Urban Interface

Particulates; Wildland-Urban Interface (WUI) Fires; Scanning Electron Microscopy (SEM)

Abstract

A major outcome of large outdoor fires is the production of combustion products. The most well-known type of large outdoor fires are wildland fires that spread into developed, urban areas, known as wildland-urban interface (WUI) fires. Particulate emissions from WUI fires in California in 2018 resulted in almost a complete closure of San Francisco. Improved knowledge of large outdoor fire particulate emissions is needed at the laboratory-scale. Here, samples of oriented strand board (OSB), a common human-made fuel abundant in cities, were ignited using a radiant heater coupled to a spark igniter. Particulate samples were taken to begin to look at the morphology of the generated particulates. Using a simple experimental setup affords the capability to investigate particulates produced from smoldering combustion as well as those collected from flaming combustion. In this short paper, some initial results are presented fro OSB combustion. Further comparison to vegetative fuels will be presented at the conference.

1. Introduction

A consequence of large outdoor fires is the production of combustion products. These combustion products are known to cause extreme visibility issues and worries about health. Globally, the combustion of vegetative fuels is thought to be the prime supplier of particulate emissions and the second most supplier of gaseous emissions [Akagi *et al.*, 2011]. Particulate emissions from WUI fires in California in 2018 resulted in almost a complete closure of San Francisco.

Methodologies to determine emissions from wildland fires or biomass have centered on the concept of developing specific emissions factors (EF) [Akagi *et al.*, 2011]. EFs are usually reported for carbon monoxide, carbon dioxide, and particulate matter less than 2.5 microns. In many cases, EF do not account for the combustion of human-made fuels. It is obvious the vegetation species are not solely suppling the gaseous and particulate emissions but also the combustion processes from buildings, cars, buses, and other human-made combustibles only add to the assortment of emissions. Yet, it is not obvious how to addresses these additional complications.

Another overlooked, key shortcoming is that many of the EFs for vegetative fuels are predicated on controlled/prescribed fires. Specifically, these are well-controlled fires conducted for a variety of fire/fuel management intentions. Such controlled burning has benefits since it is performed over real terrain, but the fire exposure conditions cannot possibly recreate what is observed in the most dangerous fires. Typically, controlled fires are undertaken, under low ambient wind conditions to ensure safety yet massive, destructive fires rarely occur in low winds.

Complimenting EF research, there have been studies that have looked at the particulates formed in the context of wildland fires and as well as from biomass [Akagi *et al.*, 2011, Posfai *et al.*, 2003, Reid *et al.*, 2005]. None of this important research has been extended to WUI fires, where many non-vegetative fuels exist. What has been observed is that the nature of particles formed depend highly on the nature of the smoldering or flaming combustion properties of the wildland fires or biomass.

The reasons for this lie in the details of the combustion processes. In the case of smoldering combustion, and therefore smoldering fires, this is a surface process. Oxygen moves to the surface and reacts with fuels at

relatively low temperatures. Since polycyclic aromatic hydrocarbons (PAH) are known to form at higher temperatures, smoke particles contain less soot for smoldering combustion as compared to flaming combustion. Particle formation are also known to occur around other nuclei other than PAHs [Lighty *et al.*, 2000]. For any type of large outdoor fire, there have been few studies of particulate formation in the smoldering phase and to the authors knowledge, almost no studies for engineered wood products found in WUI fires.

Results reported that for wildland fires or biomass that are in a state of smoldering combustion, the combustion processes are generally dominated by lower temperature regimes and therefore the collected particles have a liquid-like structure [Akagi *et al.*, 2011, Posfai *et al.*, 2003, Reid *et al.*, 2005]. For wildland fires or biomass that have higher temperatures, and are in a state of flaming combustion, these fires produce particles with more well-known fractal agglomerates and structure often seen in most soot formation studies in a state of flaming combustion (**see Figure 1).**

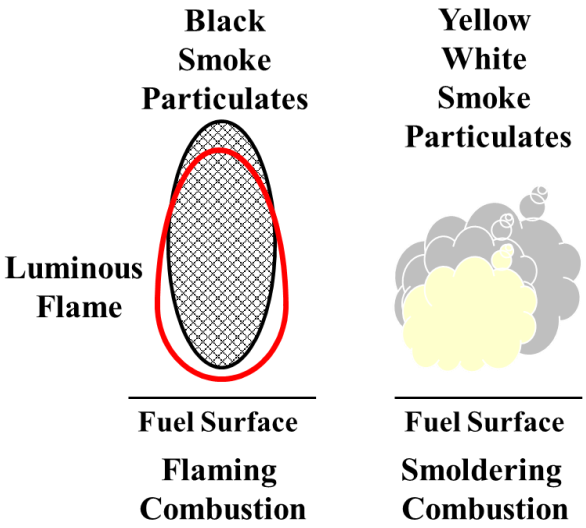

Figure 1- Differences in particulates observed during flaming combustion and smoldering combustion states.

Improved knowledge of large outdoor fire particulate emissions is needed at the laboratory-scale. Here, samples of oriented strand board (OSB), a common human-made fuel abundant in cities, were ignited using a radiant heater coupled to a spark igniter. Particulate samples were taken to begin to look at the morphology of the generated particulates. Using a simple experimental setup affords the capability to investigate particulates produced from smoldering combustion as well as those collected from flaming combustion.

As the nature of particulate samples were expected to be sensitive to the voltage of the electron beam for smoldering combustion in particular, scanning electron microscopy (SEM) was used as first step to investigate the morphology. Transmission electron microscopy (TEM) operates at higher acceleration voltages and this is expected to influence the samples. In this short paper, some initial results are presented fro OSB combustion. Further comparison to vegetative fuels will be presented at the conference.

2. Experimental Description

The experimental setup consisted of a radiant heater coupled to spark igniter (see **Figure 2**). Samples of OSB were cut into sizes of 100 mm by 100 mm. As commercial samples of OSB was used, the thickness was fixed at 11 mm.

The use of engineered wood products has been common worldwide. In the United States of America, there has been a move to replace plywood with OSB. In the past, plywood was more common. OSB is manufactured from smaller trees and is manufactured primarily of wood fragments, so it is cheaper to produce. Plywood requires thin, long sheets of wood veneers. Similar trends have been seen in other countries, including Japan.

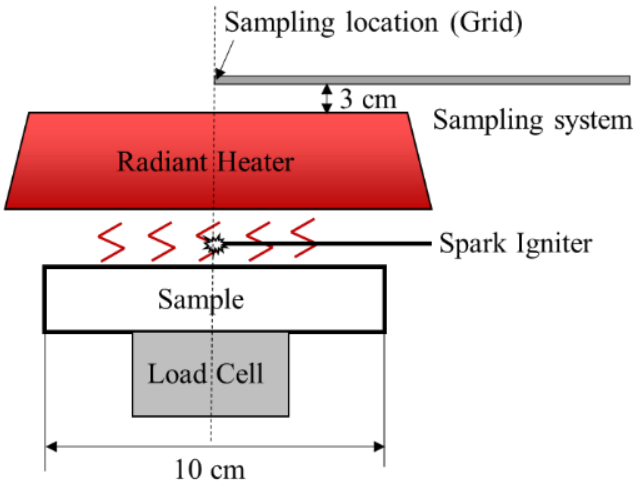

Figure 2- Schematic of Experimental Setup.

A radiant heat flux of 25-30 kW/m^2 was applied and the spark was operated continuously to produce flaming combustion. Under these conditions, the OSB samples ignited with sustained flaming ignition within 90 sec. Experiments were also conducted using a radiant heat flux of 25 kW/m^2, without the application of the spark, to produce smoldering combustion.

To sample particulates that are generated, the well-known principle of thermophoretic sampling was used. In the presence of a temperature gradient, the hot particles will be collected using cold grids that may be used for Scanning Electron Microscope (SEM) and Transmission Electron Microscopy (TEM) analysis. Presently, SEM was used a first step to image the overall structure of the particulate samples.

3. Results and Discussion

Experiments were conducted for one applied heat flux level and all samples were taken at the same time after the onset of sustained flaming combustion of the OSB sample. The total sampling time was varied from 1 sec to 3 sec. Figure 3 displays agglomerates imaged with the SEM for one of these sampling times.

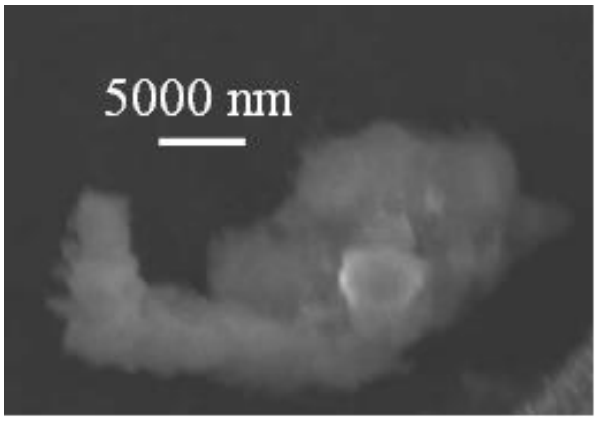

Figure 3 SEM image of particles collected from OSB in a state of flaming combustion (25 kW/m^2).

A series of experiments were conducted to sample the particulates generated from OSB samples in a state of smoldering combustion. The radiant heat flux was applied to the specimens and no spark was applied. Typical SEM images for the collected particulates from OSB undergoing smoldering combustion will be presented at the conference.

It is clear that the morphology of the particulates is indeed different depending on whether the OSB samples are in a state of flaming as opposed to smoldering combustion. Owing the higher temperatures during flaming combustion, the more well-known fractal agglomerate structures are observed for the OSB samples in a state of flaming combustion

4. Summary

Improved knowledge of large outdoor fire particulate emissions is needed at the laboratory-scale. Particulate samples were taken during both flaming combustion states and smoldering combustion states using thermophoretic sampling. As the nature of particulate samples were expected to be sensitive to the voltage of the electron beam for smoldering combustion in particular, scanning electron microscopy (SEM) was used as first step to investigate the morphology The nature of the combustion state resulted in vast differences in the morphology of the collected samples. Further comparison to vegetative fuels will be presented at the conference.

FTIR, GC/FID, Pinus palustris, compositional data, prescribed burning

Abstract

Pyrolysis products from wildland fuels are typically measured under tightly controlled conditions using fuels which have been processed to remove water content and physical shape. Different instruments can be used to identify and quantify the composition of these gases. Measurement of pyrolysis gases under conditions typical of wildland fires has seldom occurred. We used FTIR spectroscopy and GC/FID analysis to measure pyrolysis gases produced in wind tunnel experiments and small prescribed burns in longleaf pine needle fuel beds with live shrubs. Use of compositional data techniques on the 8 common gases measured by both methods showed that the compositions were affected by the measurement method and interaction between method and location was significant.

1. Introduction

A wide variety of methods and instruments are available to identify and quantify the hundreds of gaseous and particulate compounds produced by the heating and combustion of wildland fuels. The methods and instrumentation have been compared (e.g., Fehsenfeld *et al.* 1987; Christian *et al.* 2004; Li *et al.* 2019) as well as used in a complementary fashion to increase the detection and quantification of as large a suite of compounds as possible (e.g., Yokelson *et al.* 2013). Linking laboratory results to field scale phenomena has long been a topic of interest and the field of wildland fire and smoke emissions is no exception (Ward and Radke 1993).

Ward and Radke (1993) compared different methods of describing smoke emissions from bench-scale measurement to aircraft and satellite measurement. Combustion efficiency, defined as the ratio of CO_2 to the sum of CO_2, CO, hydrocarbons, and particulate matter emitted by a fire, was proposed as a measure to link results across scales. Further development of this concept led to the use of CO/CO_2 and modified combustion efficiency (MCE) as descriptors of a fire and as an "independent" predictor of other smoke components (Ward and Hao 1991; Yokelson *et al.* 1996) because MCE was often "well-correlated" with other emission components. However, the problematic use of correlation measures on proportional and relative data has long been known (Pearson 1896; Aitchison 1986) and the measured gas mixtures formally correspond with multivariate relative data known as compositional data. Thus, the widely assumed convention that CO/CO_2, and thus MCE, was an independent predictor for other smoke components has been shown to be in error (Weise *et al.* in press). Given the above, the objective of this manuscript is to properly compare the composition of pyrolysis gases measured in a series of wind tunnel and field fires by FTIR spectroscopy and GC/FID using a compositional data analysis (CoDA) approach to determine if the two sampling methods produced similar results.

2. Methods

Gas sampling was performed in a series of wind tunnel experiments and field prescribed burns in longleaf pine (*Pinus palustris* Mill.) needle fuel beds containing a live shrub component. See Scharko *et al.* 2019 and Weise *et al*. 2022 for details of the sampling methodology and analytical methods used to determine quantity and composition of the gases. Eight gases (CO_2, CO, CH_4, C_2H_2, C_2H_4, C_3H_6, C_4H_6 and C_4H_8) were measured by both FTIR and GC/FID. The relative amounts of these gases will be analyzed in this paper using version 4.1.2 of the public domain software R (R Core Team 2021). The data were preprocessed using the *multLN* function to impute random values below the minimum observed concentrations (Palarea-Albaladejo and Martín-Fernández 2013, 2015).

The common approach to analysis of compositional data is to express them through adequate log-ratios coordinates (balances) and then applying ordinary statistical techniques (Egozcue *et al.* 2003). The purpose of the various log-ratio transformations used in CoDA is to put the data in ordinary real space as opposed to their original simplex space. Seven log-ratio balances representing meaningful contrasts between subsets of gases were obtained by sequential binary partitioning (Egozcue and Pawlowsky-Glahn 2005). Multivariate analysis of variance (MANOVA) tested the effects of method (FTIR, GC/FID) and location (wind tunnel, field) on the entire composition and ANOVA tested the effects on these 7 balances individually. The data were unbalanced (Table 1); there are a variety of approaches to use ANOVA to test the significance of effects for unbalanced data. Based on Langsrud (2003), we used the *Anova* function which calculated Type II sums of squares to test the effects. Because there are only two levels of each factor, the significance of the difference between the two levels is tested by default; the probability was adjusted to account for the multiple t-tests using Benjamini and Hochberg's (1995) false discovery rate. A total of 21 t-tests (7 balances x 3 effects (method, location, interaction)) were performed because the intercept term was not included.

3. Results

The gases common to the GC/FID and FTIR samples were CO, CO_2, CH_4, C_2H_2, C_2H_4, C_3H_6, C_4H_6 and C_4H_8. These gas concentrations, constituting a subcomposition of the original composition, were "normalized" ("closed" in the CoDA parlance) to put them on a proportion (0,1) scale. Note that within a CoDA framework, these values can be expressed in the original ppm units, proportions or be converted to percentages without affecting the statistical results (scale invariance property). The relative amounts of the gases were similar in terms of highest to lowest proportions (Table 2); however, the relative amount of CO measured by FTIR at Ft. Jackson was an order of magnitude larger than the wind tunnel or GC/FID measurements. The MANOVA showed that the GC/FID and FTIR methods had a significant effect on the relative composition of the common gases (Table 2) and there was a significant interaction between location and method.

Because of the significant interaction, the mean values of the 4 combinations of location and method were calculated for each balance (Table 4). The overall mean for each balance is a weighted mean so the values were strongly influenced by the large number of GC/FID observations in the wind tunnel. The presence of significant interaction prevents clearly attributing differences in the balances to method alone. Since location was not significant as a main effect, the probability values are not presented.

Method significantly affected 4 of the 7 balances and the interaction term for method and location significantly affected a single balance. The 1st two balances containing CO_2 were smaller for the FTIR measurements at Ft. Jackson; relatively less CO_2 and more CO and CH_4 were measured (Table 2) resulting in smaller balances. The FTIR measured more CO relative to CH_4 than GC/FID; however, relatively more CH_4 was measured by GC/FID in the field burns. The interaction term affected the CO_2 vs CO & CH_4 balance. The FTIR balance values were smaller than GC/FID for Alkenes vs Alkynes. Note that the GC/FID values for this balance were close to zero which implies that the actual ratio between these subsets of gases was close to 1 in the original units, suggesting that the relative amounts of these two groups are approximately equal. The propene vs isobutene balance suggested that more propene relative to isobutene was present in the FTIR samples compared to the GC/FID.

Table 1. Number of pyrolysis gas samples analyzed by FTIR and GC/FID in the wind tunnel (RFL) and prescribed fires in Ft. Jackson, SC (FJ).

4. Discussion and Conclusions

Direct comparison of gas measurements in a fire environment produced with different instruments is challenging and influenced by many factors. Different instruments and analytical techniques may measure the same gases with differing resolution or are unable to detect the same compounds (Ward and Radke 1993). Because of this, a wide variety of instrumentation is deployed to measure a large suite of compounds (e.g., Yokelson *et al*. 2013). The present study used two methods readily adapted to field use. The inherent spatial, temporal and compositional variability in fuels as well as the conditions under which the fuels were heated can affect the composition of the pyrolysis and combustion products. Some of this variability can be controlled by using a common sample line or assuming sample collection points in close proximity are true replicates. In small-scale experiments, fuel variability is reduced by homogenizing samples to eliminate shape and moisture effects and heating methods are closely controlled. In the present study, the assumption was made that samples taken in proximity in wind tunnel fuel beds or in small, prescribed burns in natural fuels each represented true replicates. In 3 of the 4 location × method combinations, samples were collected in canisters for subsequent analysis (either later in the day (FTIR) or several weeks after collection (GC/FID). The wind tunnel FTIR spectroscopic measurements were collected in real time.

While all these factors may affect the values of the absolute values for the pyrolysis gases collected, it is the relative values which are important since these are compositional data. Based on the subcomposition of gases measured by both FTIR and GC/FID, it is not possible to state that fire location (wind tunnel versus field) did not significantly affect relative composition of pyrolysis gases based on the presence of significant interaction. While the analytical method effect was significant, it cannot be separated from location. In the present study, the FTIR sampling was confounded with real-time measurement in the wind tunnel versus analysis of canister samples from the field. Canisters were used as a necessary safety precaution since the field fires were much less

controlled than the wind tunnel burns and the FTIR setup precluded field use. Use of real-time measurement by FTIR provided other benefits (Banach *et al.* 2021).

Pyrolysis gases have been successfully measured in a wind tunnel and in small field prescribed burns using two different methods: FTIR-spectroscopy and GC/FID analysis. Using CoDA techniques on the subcomposition of gases measured by both methods showed that the compositions were affected by the measurement method.

Table 4. Estimated mean values for selected log-ratio balances of pyrolysis gases by method, location and overall mean. P-values adjusted to control false discovery rate (Benjamini and Hochberg 1995) < 0.05 are in bold.

Balance	Gases involved	RFL		FJ		Mean	p-values	
		FTIR	GC/FID	FTIR	GC/FID		Method	Interaction

Abstract

The WUI expansion and climates changes are causing an increasing number of dramatic consequences on the socio-ecosystem in Southern Europe. In France, to reduce the fire threat to infrastructure and human lives, a specific prevention policy provides for many regulatory measures to address forest fire risk in urban planning and forest management. This approach to assessing risk is highly technical and hazard-centred. The shortcomings are the difficulty in appropriating the issue for those who do not have this standardised approach and legitimise less attention paid to individual and collective practices having an effect on vulnerability.

Our research focuses on landscape as a means of analysing the representation of forest fire risk by local stakeholder groups. According to the European Landscape Convention, landscape is defined as 'an area, as perceived by people, whose character is the result of the action and interaction of natural and/or human factors'. Landscape therefore has both a factual and a subjective value. As an intermediary tool, the landscape allows an inclusive dialogue between various stakeholders since it belongs to the common register and does not have an immediate scientific connotation (Dérioz, 2008).

On this basis, we develop a landscape mediation on forest fire risk to analyse how can landscape help to build a shared knowledge of risk in local communities. Landscape mediation is an engineering of public involvement applied to the landscape which eases mobilising stakeholder experience and feelings in territorial diagnostic and spatial planning (Paradis, 2010). We experiment the benefits of landscape mediation to develop a local risk culture by using a case study in Martigues city in the southeast of France. The study site is subject to strong development pressure due to its proximity to the Aix-Marseille Provence metropolitan area, is located nearby two forested areas - Côte Bleue and Castillon forests -, which are regularly affected by fires, and has a scattered residential area and therefore a relatively large WUI zone.

The landscape mediation project consists of two stages. In spring 2022, residents of the study site are invited to participate in a walking tour through their living area. Using a booklet, the participants assess the characteristics of the landscape and describe the uses of the WUI and its associated fire risk attributes. A collective risk knowledge emerges from sharing contrasting feelings and opinions on WUI and ways to limit vulnerability individually and collectively. In a second stage, the participants present their landscape diagnostic and their views and concerns on forest fire risk prevention management to a group of local stakeholder representatives of spatial planning and forest fire risk experts. The diversity of thought reveals new ideas that benefit spatial planning initiatives. This landscape mediation is a collaborative approach to increase public acceptance of forest fire management placing the inhabitant in a collective consideration of vulnerability reduction in his living area. The research helps sharing residents' perceptions of forest fire with decision-makers and fire risk experts to better understand how the community influences action or inaction on forest fire risk prevention management.

1. French fire risk prevention is complex in its implementation and understanding

Public policies for wildfire risk management operate mainly in 32 departments in the south of France, with coordination of the local strategy at the regional level (articles L.133-1 and L.133-2, Forestry Code). Local government agencies are principally in charge of wildfire prevention policies. However, certain competences are shared with local territorial authorities in particular the maintenance of firefighter infrastructures in the forest, equipping neighbourhoods with fire hydrants, clearing regulation around houses and roads, public

information on the wildfire risk and ensuring that urban development considers natural hazards. Those local jurisdictions adopt regulatory wildfire prevention tools in different ways according to local political will, which creates variations in prevention strategy between territories.

As a result, residents have to deal with regulations that affect the design of their garden, their house and their development project. Resident common practice is to make comparisons with the neighbour's situation, but it hardly helps to understand the individual case. Requests for information to clarify the fire risk management measures are therefore inevitable. People then face with the complexity of the stakeholder network, each jurisdiction acting in line with its own competencies in reducing the vulnerability of wildland-urban interfaces (WUI) - the area where combustible vegetation intermingles with buildings -. Given the regulatory measures that affect residents, their involvement in wildfire prevention strategy is necessary. They are resident experts on local knowledge of the territory and are therefore a source of realistic solutions to reduce vulnerability.

How can we develop a local risk culture that could facilitate dialogue between residents and spatial planning stakeholders and encourage collective initiatives to reduce vulnerability in neighbourhoods prone to wildfire? In this respect, we propose to develop a local fire risk culture using a landscape mediation event.

2. Landscape mediation for wildfire risk prevention

2.1. What is a landscape mediation?

EU members signed the Landscape Convention in 2000. According to this act, "Landscape" means an area, as perceived by people, whose character is the result of the action and interaction of natural and/or human factors. This definition gives recognition to all types of landscapes - including common everyday landscape -, a continuous temporal dynamic, but also a feeling dimension. The feeling dimension of the landscape corresponds to the description that the person makes of a place based on the experienced moments and feelings. When description of a place is shared, then certain aspects of the landscape are collectively valued (Bouisset & Degrémont, 2015). Thus, the landscape is subjective, and the transition from an individual representation to a collective culture depends on the degree of information sharing in the community (Devine-Wright, 2011; Raymond et al., 2015).

A landscape mediation is a public participation engineering applied to the landscape which eases mobilising stakeholder experiences and feelings in territorial diagnostic (Paradis, 2010). Spatial planning studies regularly employ this type of process (Labat & Donadieu, 2013). It was initially developed as an analysis tool for landscape enhancement, for example in the diagnostic of landscape charters. Also thereafter, landscape mediation has been used as a medium for analysing land-use management mainly in rural territories with environmental concerns (Dérioz, 2008; Ferrario, 2018), for example in regional natural park plans or in urban planning schemes. With regard to natural risk management, landscape mediation approaches serve to facilitate the development of a risk culture. They are not yet well developed and are mainly found in flood risk management (Wake, et al., 2020). We have not found any example of landscape mediation for wildfire risk prevention in the literature.

Thematic landscape mediation on wildfire risk has specific aspects. Generally, landscape analysis leads to imagining landscapes at their best value. For wildfire risk, we try to imagine the situation of a landscape on fire. The task could be therefore difficult, because the landscape valorisation only comes into play when visualizing the least critical crisis scenario for the territory. Moreover, in participatory approaches using landscape, participants are usually asked to imagine the territory at a fixed moment in the future (e.g in 2050). The temporal dimension is more complex for wildfire risk prospective; because the projected moment is not a date, but the next fire event, thus a phenomenon that occurs randomly in the forest and is not predictable. Furthermore, landscape is a common term and has no immediate scientific connotation. Conversely, wildfire risk is a complex concept that requires knowledge and a technical vocabulary for its management. Applying landscape mediation to the context of WUI materializes the wildfire risk to a known and shared place and makes the subject accessible to all for discussion.

2.2. Case study: the “walk-workshop” event on the WUI in Martigues

The study case is the city of Martigues (Bouches-du-Rhône), in southeastern France. This municipality is facing strong urban development pressure due to its inclusion in an attractive metropolitan area, the Aix-Marseille

Provence metropolis. The urban fringes are fragmented, which increases the length of the linear contact between the inhabited and the natural areas. Wildfires in Martigues often threaten dwellings, campsites and industrial areas. The issue of managing the WUI is a major concern and involves considering the consequences of wildfires from a landscape and ecological perspective as well as for community safety.

For the landscape mediation we develop, the landscape analysis focuses on the WUI (Calkin et al., 2014). Our research focuses on the use of landscape as a means of analysing and sharing the representation of fire risk by the inhabitants. Our objectives are i) to mobilise and interact between inhabitants and land management actors around the issue of fire risk ii) to carry out a shared diagnosis of the landscape focused on vulnerability to wildfire in WUI iii) to identify good planning practices at different spatial scales.

The main stakeholder in the project is the local authority of the Aix-Marseille Provence Metropolitan Area. To ensure the event's success, the local authority should support the landscape mediation. The Martigues City Council and the Metropolitan Council were interested in the project because they had ongoing spatial planning documents dealing with the wildfire risk and landscape management (the Metropolian Landscape Plan and the Intercommunal Urban Planning Scheme). The local authorities and the researchers are jointly building the event to ensure that it corresponds to everyone's expectations. In our case, the event takes place in two stages, first a walk with the residents to examine the surrounding landscape and wildfire risk context in their neighbourhood, and then a workshop where the residents report on their landscape analysis and discuss it with a group of professionals responsible for the spatial planning and the wildfire risk (Figure 1).

To conduct the walk and the workshop, we have developed tools for analysing landscape atmospheres and for sharing opinions on landscape objects characterising wildfire risk management in the WUI. The tour walk first passes behind the houses to study the direct line of contact with the forest, then returns by the main road to study the landscape in the neighbourhood. It goes through different depths of view to investigate the context of the risk and its management at several spatial scales (e.g. the plot, the street, the neighbourhood). For the workshop, we set up inclusive communication medium (e.g. A0 map of the study site, video with a local goatherd, photos of the walk).

Figure 1- Concept of Landscape Mediation on wildfire risk in Martigues. A two-step process, a walk and a workshop.

3. Analysis of the results: many ideas are waiting to be realised

3.1. Using sociology to describe landscapes

The walk itinerary was close to a fire that had covered almost 1000 ha in 2020 and had caused the evacuation of 2,700 people and the destruction of two campsites. The recent memory of a fire with significant damage seemed to be a reason enough to mobilise the population to attend the event. Still we went door-to-door to distribute flyers and explain the approach to the inhabitants and to some shop owners, relatively few people

came to the landscape mediation event. One reason for the limited involvement is the location of the study area, which was in an attractive urban municipality (48,500 inhabitants) but in its rural part. It is middle-class neighbourhoods and the locals are mainly families who have lived there for a long time. There is not much traffic except from the local residents and they appreciate this privacy.

Consequently, the residents who took part were in their sixties and older, and had been living in the area for decades, or even had family members in the community of more than two generations. For example, one resident had experienced two wildfires on her lot, in 1989 and 2020. This resident profile provided an ideal opportunity to discuss landscape dynamics over time. Participants had already been involved in wildfire crisis with their neighbours, thus they were in a way the voice of the other locals. They proposed several actions, including having goats graze near the residential fringes and supporting original agricultural initiatives that could be established in abandoned agricultural lands. The residents' opinion was a fine expertise on local vulnerability issues (Figure 2).

The inhabitants appreciated to express to the local authorities their thoughts on wildfire treat and their ideas for actions to improve the situation in their neighbourhoods. All parties involved in the workshop shared the difficulty of identifying the different regulations on risk prevention and the complexity of the stakeholder network involved. We found the inhabitant's knowledge had equal legitimacy with the expertise of professionals in spatial planning and wildfire risk management.

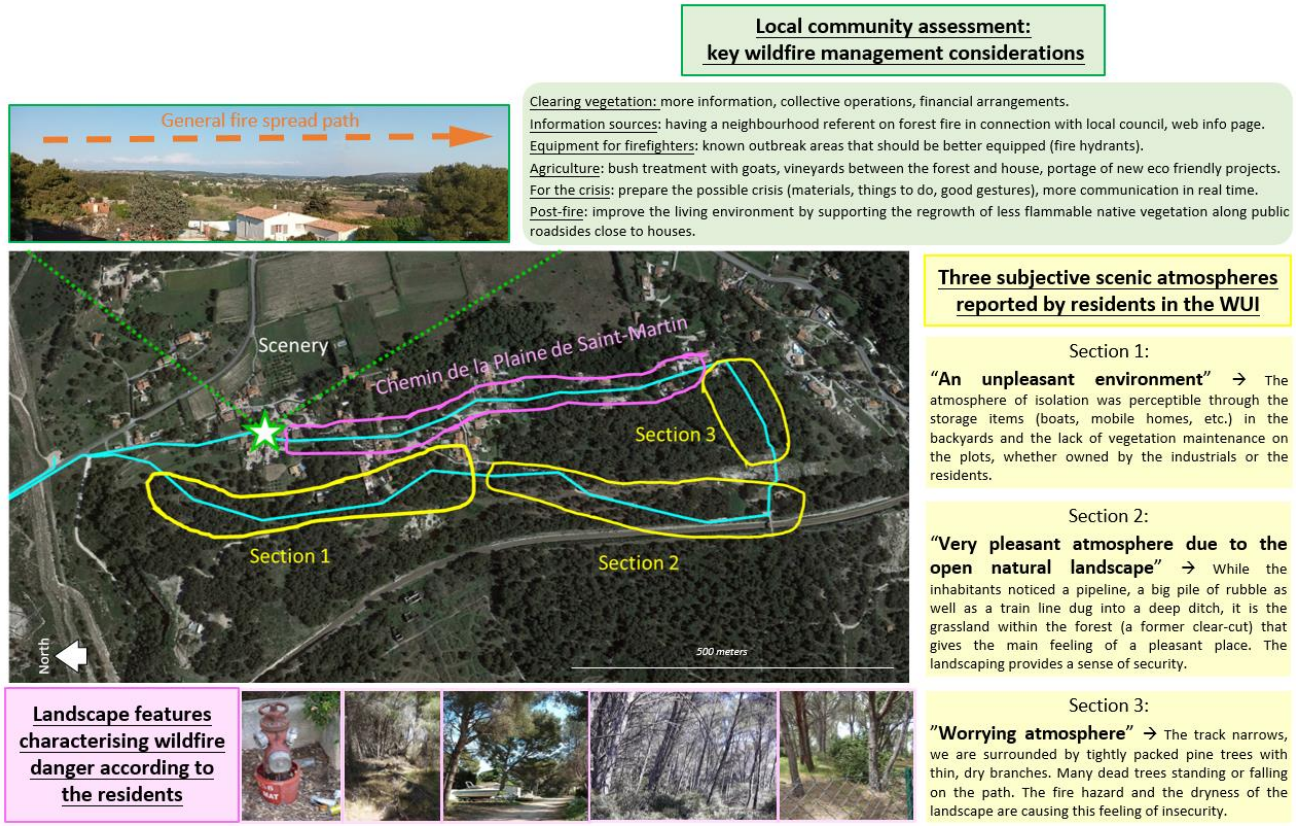

Figure 2- Analysis of WUI vulnerability produced during the walk with the residents. The walk itinerary is blue (3km).

3.2. The event is part of the ongoing process of wildfire risk culture

This exploratory research study shows the means for mobilizing stakeholders in a context where public services have limited capacities to take part in original wildfire risk management approach. Some of the essential spatial planners and wildfire risk managers were not represented in the workshop (e.g. the firefighters). They are brought back into the process afterwards by distributing the report and conducting an interview with them. Also, the strong involvement of the partners present and the quality of the experience sharing, opinions and initiative proposals are guarantees of the success of the mediation tools mobilized. A path has already been found in the Metropolitan Landscape Plan to conduct an action in Martigues with inhabitants. The landscape mediation could

be multiplied over several vulnerable districts and repeated each year, as an annual appointment for a walk and a workshop to discuss wildfire risk and its prevention management. The study case has proved its worth, and the perpetuation of landscape mediation is possible if the communities decide to take up the concept (Figure 3).

The suggested landscape mediation is punctual, whereas the risk culture is a permanent information to share over time. Therefore, organizing such an event around wildfire risk is an opportunity that only makes sense if the participants value together the ideas shared during this time. This communication (article in a local media, reports to stakeholders) contributes to the risk culture by marking the meeting between the local agencies and the population and disseminating the ideas exchanged to other potential interested parties.

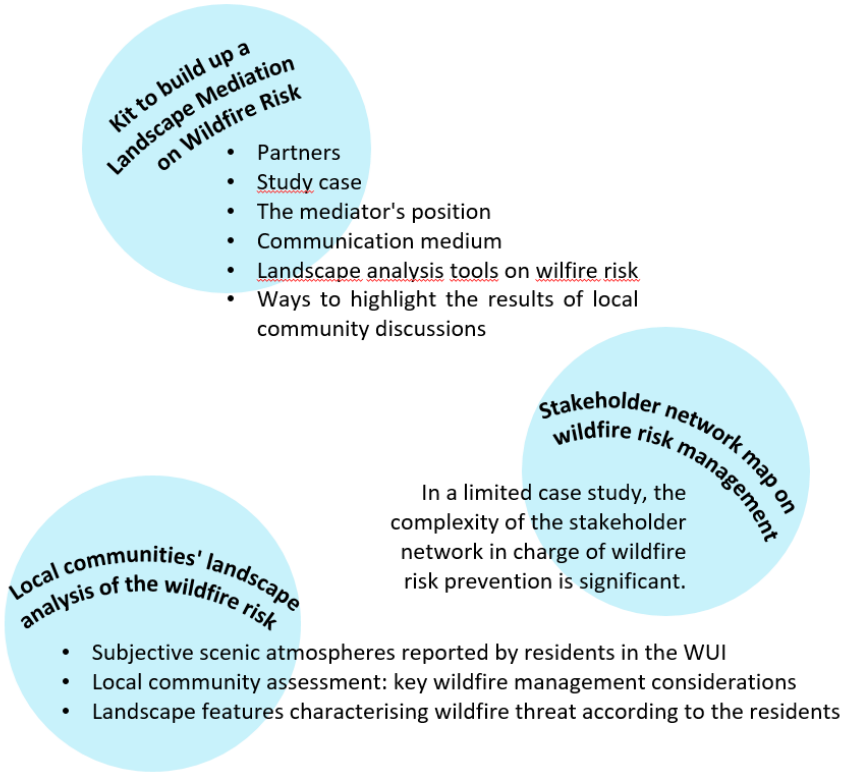

Figure 3- Outcomes from the exploratory research project on Landscape Mediation

4. Conclusion

We have described the benefits of landscape mediation on developing local wildfire risk culture. The landscape mediation event we assessed in the city of Martigues is a study case in line with participatory research actions. For local jurisdictions, it helps to share the risk perception in a collaborative approach, through constructive dialogues with the locals. Furthermore, while the stakeholder system for wildfire risk management is complex, the legislation and responsibilities are evolving, and parties directly in charge are sometimes struggling to define their own role. The landscape mediation clarify the comprehension of this set of functions and then favour the emergence of local and original initiatives. It encourages local authorities to consider residents' perspectives in their spatial planning strategies.

Abstract

Fire Dynamic Simulator (FDS), a fire simulation program, applies Message Passing Interface (MPI) and Open Multi Processing (OpenMP) libraries for large-scale simulation. FDS can be executed by dividing simulation problems in a computing cluster using MPI. The main point is to divide the entire domain to be interpreted into several sub-domains and allow each sub-domain to be calculated by an individual computer with an individual processor. When performing parallel computation, FDS first decomposes each sub-domain, then supports two-step parallelization in which multi-threading is applied within each sub-domain, and uses the OpenMP library to implement multi-threading. In this study, OpenACC, a parallelization technique capable of using heterogeneous hardware architectures, was partially applied to FDS. As an application problem, the calculation performance is evaluated through CSIRO Grassland Fires, a verification case of FDS. The hardware for evaluation was a personal computer consisting of dual Xeon 2678-V3 and GeForce GTX 1070. The FDS source code applies OpenACC using PGI Fortran as a compiler in Linux environments. In calculation performance, calculations using CPU and GPU together show 1.89 times faster performance than calculations using a single CPU. In case of using 1 GPU and 16 CPUs (MPP + OpenACC), the analysis result is 21 times faster. In this regard, analysis of grassland fire of WFDS was performed.

1. Introduction

Central Process Unit (CPU), the brain that performs calculations, has been increasing exponentially in unit performance in accordance with Moore's law over the past half century, but the improvement trend has been saturated by the 21st century. Since then, performance has been increased by increasing the number of cores, and now it is trying to overcome the scaling limitations of systems composed only of CPU by accelerators. Therefore, heterogeneous hardware architectures are widely used, and the well-known AlphaGo has 280 Graphic Process Units (GPU) of Tesla accelerators for deep learning. The adaptive parallel technique in heterogeneous hardware architecture proposed in this study is a new technique using the Kokkos library, in which the practical version was released by 2014, and is a very experimental and innovative technology. Therefore, few literatures have been published so far, and its application has recently been introduced by conferences in the field of high-performance supercomputing and international combustion conferences. There is currently the only alternative called Open Computing Language (OpenCL) in a way that does not use Kokkos while pursuing the same goal of adapting to heterogeneous hardware architectures, but this is a new programming language. Compilers that support this must develop together, but there have been no cases applied to the engineering or computational fluid fields yet. On the other hand, because Kokkos uses templates, which are existing features of general-purpose C++ languages, it has the advantage of being able to use dedicated high-performance compilers that are optimized according to architectures such as GNU, PGI, Intel, Cray, and CUDA.

Fire Dynamics Simulator (FDS) is a dedicated fire simulation program written in the Fortran programming language by introducing computational fluid dynamics techniques to analyze the fluid flow phenomenon driven by fire. FDS numerically solves the Navier-Stokes equation for low-velocity heat-driven flows focusing on smoke and heat transfer from fire.Therefore, FDS provides a model that can analyze basic fire dynamics and combustion. FDS has been developed by the National Institute of Standards and Technology in the United States with the goal of interpreting real fire problems. However, the computational cost increases to analyze very

detailed physical phenomena. To overcome this, FDS is written so that the central processing unit (hereinafter referred to as CPU) is executed on various hardware platforms and operating systems sequentially or in parallel. FDS uses a Message Passing Interface (MPI) to divide and execute analysis problems in a computing cluster. This is a method in which the entire area to be analyzed is divided into multiple meshes and each mesh is computed by a separate processor on a separate computer. FDS supports two-step parallelization by first decomposing each computational domain into a mesh of distributed memory and then applying multi-threading within each mesh in performing parallel analysis, and uses the OpenMP (Open Multi Processing) library to implement multi-threading.In this study, Open ACCelerator (OpenACC), a parallelization technique that can use heterogeneous hardware architectures, was partially applied to FDS to speed up FDS operation. The speed verification application case was conducted on Grassland fire tested in Australia in 2010. The computational performance is evaluated through the verification case of FDS, CSIRO Grassland Fires. The hardware for evaluation was configured in parallel with a personal computer consisting of dual Xeon 2678-V3 and GeForce GTX 1070. FDS source code applies OpenACC using PGI Fortran as a compiler in Linux environment.

2. Parallel Computing Method

MPI and OpenMP are standard methods for performing parallel computation in distributed memory system and shared memory system environment. Parallel computation has been supported since FDS version 5.4, and two parallel processing methods are provided, OpenMP and MPI. These two methods can be simultaneously applied to FDS according to the hardware configuration. In section 3.1.2 of the FDS User's Guide, it was reported that the maximum speed improvement of OpenMP is approximately doubled, and that when MPI and OpenMP are used together, most of the reduction in analysis time is achieved by MPI.

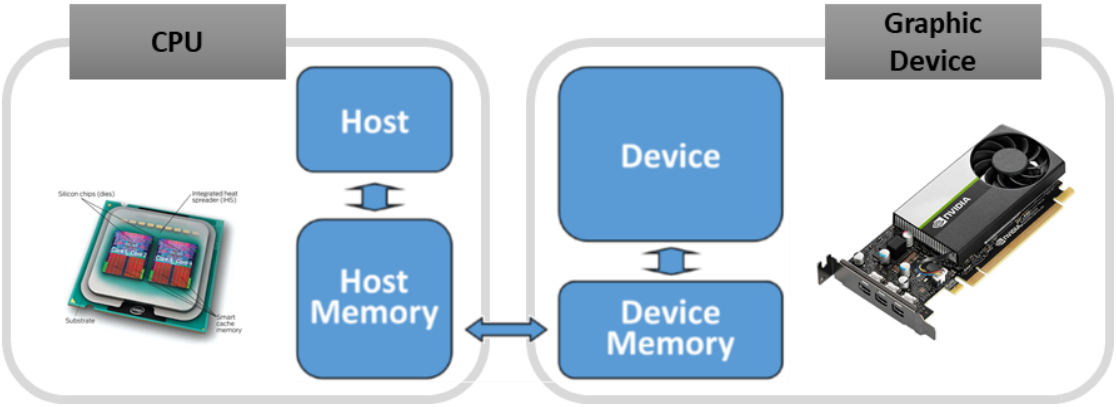

Figure 1- OpenACC's Abstract Accelerator Model

2.1. MPI

MPI is a standard that describes information exchange in distributed and parallel processing. The Message Passing method is an operation model in which data to be exchanged between processors is exchanged using a message passing function. MPI defines the standard of the Message Passing Library, which is a collection of these functions, and several MPI libraries have been developed accordingly. Subroutines that require parallelization in sequence code are constructed in parallel through appropriate parallelization techniques.

2.2. OpenMP

OpenMP is an application programming interface that supports shared memory multi processing of programs in programming languages such as C, C++, and Fortran on various computer platforms. OpenMP provides users with a simple and flexible interface for developing a variety of parallel applications from desktops to supercomputers, and is easily extensible. And by using OpenMP and MPI, the application program can also be built as a Hybrid OpenMP/MPI model.

2.3. OpenACC

OpenACC is a data parallel programming model designed to provide portability between CPU/GPU hardware architectures. Like OpenMP, OpenACC is directive-based, so there are fewer changes to the original code

compared to CUDA or OpenCL. Also, compilers such as PGI and GCC support OpenACC. OpenACC is a method in which the compiler detects directives in a program and determines how to parallelize loops.

3. Computing Performance

The computational performance is evaluated through the verification case of FDS, CSIRO Grassland Fires. As hardware for evaluation, a personal computer composed of dual Xeon 2678-V3 and GeForce GTX 1070 was used. FDS source code applies OpenACC using PGI Fortran as a compiler in Linux environment. In the FDS source code, '!$ACC PARALLEL LOOP' of OpenACC was partially applied to 'PRESSURE_ITERATION_LOOP', the part that determines convergence during calculation.

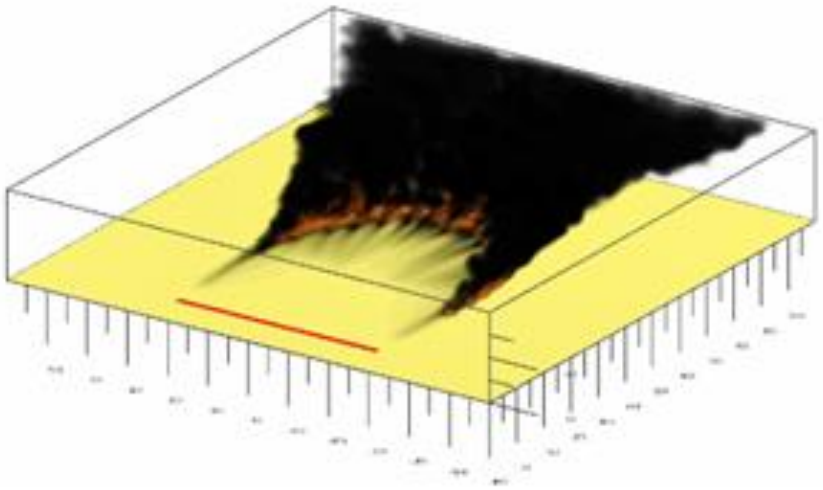

Figure 2- WFDS result of Grassland Fires in CSIRO Austrailia

Table 1- Computing Performance

MPI	Analysis time [hr]	OpenACC with MPI	Analysis time [hr]
1 CPU	109	1 CPU + 1 GPU	57
2 CPU	59	2 CPU + 1 GPU	32
4 CPU	31	4 CPU + 1 GPU	16
8 CPU	17	8 CPU + 1 GPU	9
16 CPU	9	16 CPU + 1 GPU	5

In the case of MPI, when 16 CPUs are used compared to one CPU, the analysis time is 12 times faster from 109 hours to 9 hours. On the other hand, when one CPU and one GPU are used together by applying OpenACC, the calculation time is 1.89 times faster than the result using one CPU. In the case of using 1 GPU and 16 CPUs (MPP + OpenACC), the analysis time is 5 hours, which is about 21 times faster.

Table 2 shows the results of measuring the parallel performance of MPI+OpenACC according to the increase in the size of the computation area. When parallelization was performed with MPI, the performance improvement was evident as the number of CPUs and the size of the problem increased. On the other hand, in the case of MPI+OpenACC, the performance of MPI+OpenACC with 2 CPUs or more is lower than that of MPI. It can be seen that the amount of CPU allocated during MPI parallelization is also allocated to the GPU as much as the number of CPUs, which increases the load and decreases performance. In addition, if the size of the calculation area is about 100 million and 8 CPUs are used, the memory performance of the GPU, GTX 1070, is exceeded, and calculation cannot be performed. However, when one or two CPUs are used, it can be seen that the performance of MPI+OpenACC is significantly superior to that of MPI depending on the size of the calculation area.

Table 2- 2D Heat Conduction SpeedUp with Problem Size and Parallel Method

Problem Size	1024x1024 (@1 million)		2048x2048 (@4 million)		10240x10240 (@100 million)	
Parallel Method	MPI	MPI + OpenACC	MPI	MPI + OpenACC	MPI	MPI + OpenACC
1 CPU	1	1.48	1	2.93	1	4.96
2 CPU	1.96	1.41	1.99	2.82	2.63	4.69
4 CPU	3.70	0.85	4.15	1.70	4.06	2.88
8 CPU	7.21	0.59	6.46	1.08	8.02	Out of GPU memory
16 CPU	15.12	0.31	16.84	0.74	16.71	

4. Conclusion

In this study, OpenACC, a parallelization technique that can use heterogeneous hardware architectures, was partially applied to FDS. As an application problem, computational performance was evaluated through CSIRO Grassland Fires, a verification case of FDS. As hardware for evaluation, a personal computer composed of dual Xeon 2678-V3 and GeForce GTX 1070 was used. In computational performance, the computation using the CPU and GPU is 1.89 times faster than the computation using one CPU. In the case of using 1 GPU and 16 CPUs (MPP + OpenACC), the analysis time is 5 hours, which is about 21 times faster. In the future, it is expected that the hardware parallelization technology can be used to shorten the calculation time for forest fire spread fire analysis using a personal computer.

A Study of the Ignition Mechanism for Dead Pinus Palustris Needles

Abstract

Combinations of cumulative impacts of drought, invasive species, climate variability, and ever-expanding wildland-urban interface make landscapes more susceptible to devastating wildland fires. To treat the increasing risks of wildland fires, one of the ways is to mitigate the risk of ignition, which requires a solid understanding of the ignition mechanism of vegetation fuels. This can be achieved mainly through discerning the degradation stage and the ignition criteria. Scaling up the experiments for the degradation stage and evaluating the suitability of existing ignition criteria are two of the primary challenges for ignition studies on vegetation fuels.

Motivated by the challenges, two series of experiments were conducted using a modified Cone Calorimeter to understand the mechanisms driving the ignition of dead Pinus palustris needles. In the first set of experiments, the ignition of pine needles was studied for varied incident heat fluxes (20-35 kW/m2) and air flow rates (buoyancy-induced - 100 l/min forced flow). In the second set of experiments, Fourier transform infrared spectroscopy (FTIR) was used to characterize the composition of the pyrolysis gases generated from the thermal degradation of pine needles when exposed to various incident heat fluxes (20 and 30 kW/m2) under an inert atmosphere obtained using a flow of pure nitrogen.

The results for the first series of experiments show that the critical mass loss rate at ignition increase with both flow rates and heat flux. From the second set of experiments, it was found that methane (CH4), carbon monoxide (CO), carbon dioxide (CO2), and water vapor (H2O) are the main constituents of the pyrolysis gases. The predominance of these compounds was found to be independent of the external heat flux while their concentrations are sensitive to it. The flammability of pyrolysis gas was found to increase with external heat flux.

1. Introduction

There is an urgent need to advance wildland fire management due to the increasing risk of wildfires (Richer et al., 2006). One of the ways to reduce the risk of wildfires is to avoid ignition, which requires a solid understanding of the occurrence of the flaming combustion of the vegetation fuels.

Characterizing the pyrolyzing process and the ignition moment are the two primary challenges of understanding the ignition of wildland fuels. Mass-loss kinetics and pyrolysis gas characterization are the focuses of pyrolyzing process research. Although the mass loss kinetics has been well studied on a micro-scale experimental basis (Leroy et al., 2010; Liu et al., 2002), it is necessary to scale up the experiments while maintaining fuel properties. For the pyrolysis gas aspect, the technology for identifying the components is advanced (Nunes et al., 2018), while there is a gap in quantifying the dynamics of each component over time.To characterize the occurrence of ignition, the condensed-phase criteria, including ignition temperature, critical mass loss rate, and heat release rate at ignition are widely accepted. However, the suitability of these criteria needs to be checked and verified because of the broad ranges of these values reported by the literature.(Delichatsios, 2020; Lyon & Quintiere, 2007)

Motivated by the challenges, the objectives of this work are dual. The first is to explore the influence of external heat flux on the pyrolysis process of dead Pinus palustris needles. The evolution of pyrolysis gas is expected to be characterized and quantified by FTIR spectroscopy. The second one is to investigate the relationships between a solid-phase ignition criterion and different experimental conditions.

2. Materials and Experimental Design

2.1. Experimental Design

A modified cone calorimeter, shown in Figure 1, was used to study the pyrolysis and ignition mechanisms of pine needles.

Two series of experiments were conducted to understand the mechanisms driving the ignition of dead Pinus palustris needles. In the first set of experiments, FTIR spectroscopy was used to characterize the composition of the pyrolysis gases generated from the thermal degradation of pine needles when the fuel bed was exposed to incident heat fluxes of 20 and 30 kW/m^2, and a nitrogen inflow of 50 l/min being fed from the bottom of the combustion chamber. The main constituents of the pyrolysis gas were identified by the characteristic bands shown in FTIR scans and were quantified by applying Beer-Lambert's law (Plummer, Reagen & Logan, 2003).

In the second set of experiments, the ignition of pine needles was studied for incident heat fluxes ranging from 20 to 35 kW/m^2 and air inflows of 0 l/min to 100 l/min. In these tests, the time-to-ignition (t_{ig}), and the critical mass-loss rate at ignition ($\dot{m}''_{cr}$) were evaluated.

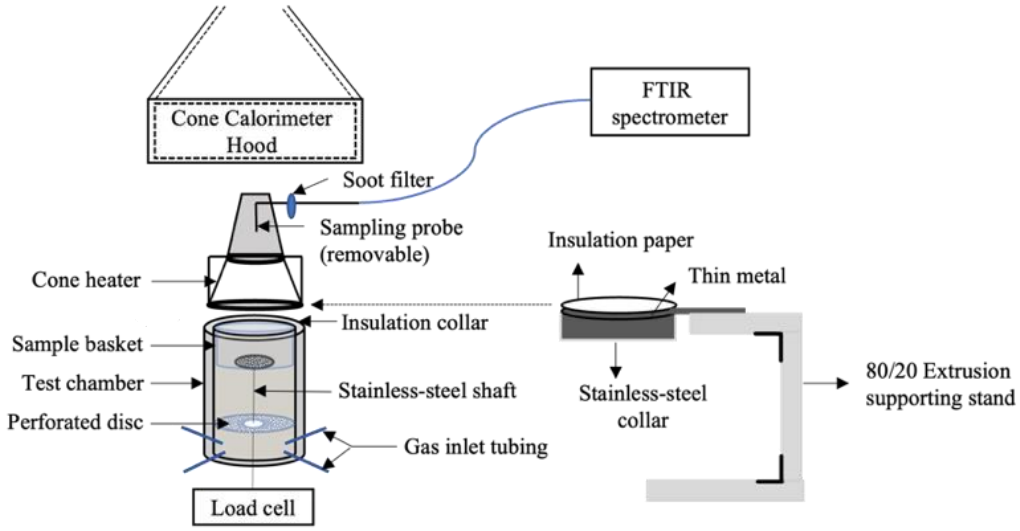

Figure 1 – Experimental apparatus: modified cone calorimeter allowing the inflow with desired flow rates

2.2. Materials

The fuel samples were oven-dried at 60°C for 24 h for conditioning and measuring their residual moisture content. After this, the conditioned pine needles were stored in sealed containers until testing. All the samples had an average fuel moisture content of 4.6 % on a dry weight basis.

For the experiments, 20 g of conditioned pine needles were placed in a cylindrical sample holder 12.6 cm in diameter and 3 cm in depth. Two different types of sample holders, shown in Figure 2, were used; for the experiments with no inflow of oxidizer being fed through the bottom of the combustion chamber (buoyancy-induced flow), a sample holder with 0% porosity was used. For experiments with a forced inflow being supplied, a sample holder with 63% porosity was used.

(a) (b)

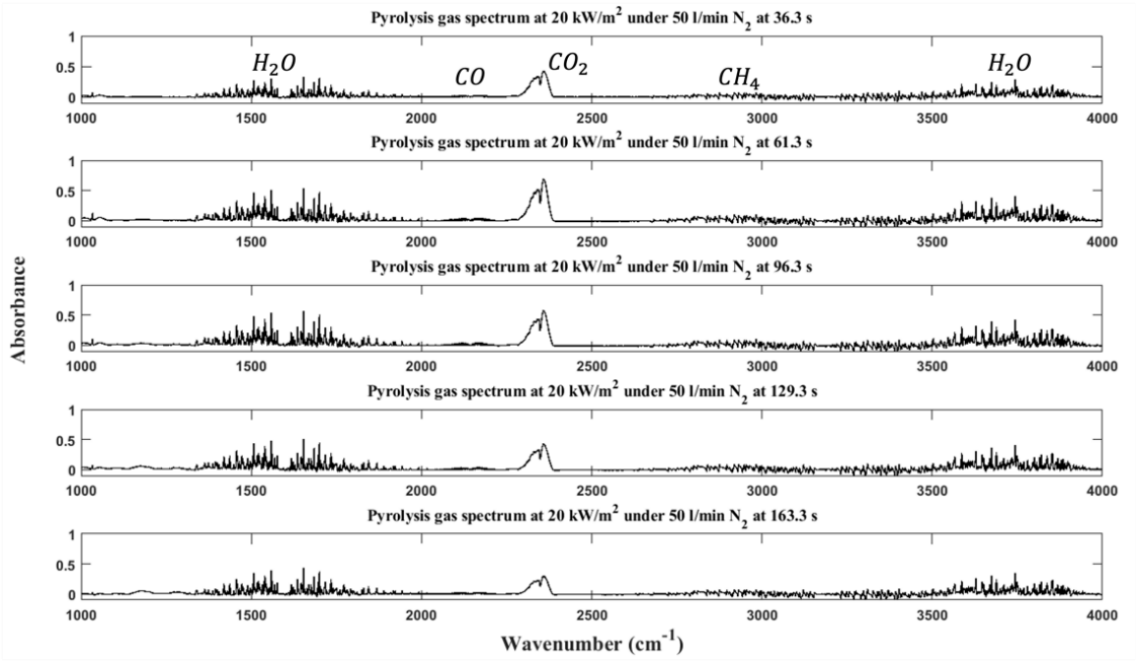
Figure 2 - Fuel samples for the tests with (a) buoyancy-induced flow using the basket of 0% opening and (b) forced flow using the basket of 63% opening.

3. Results and Discussion

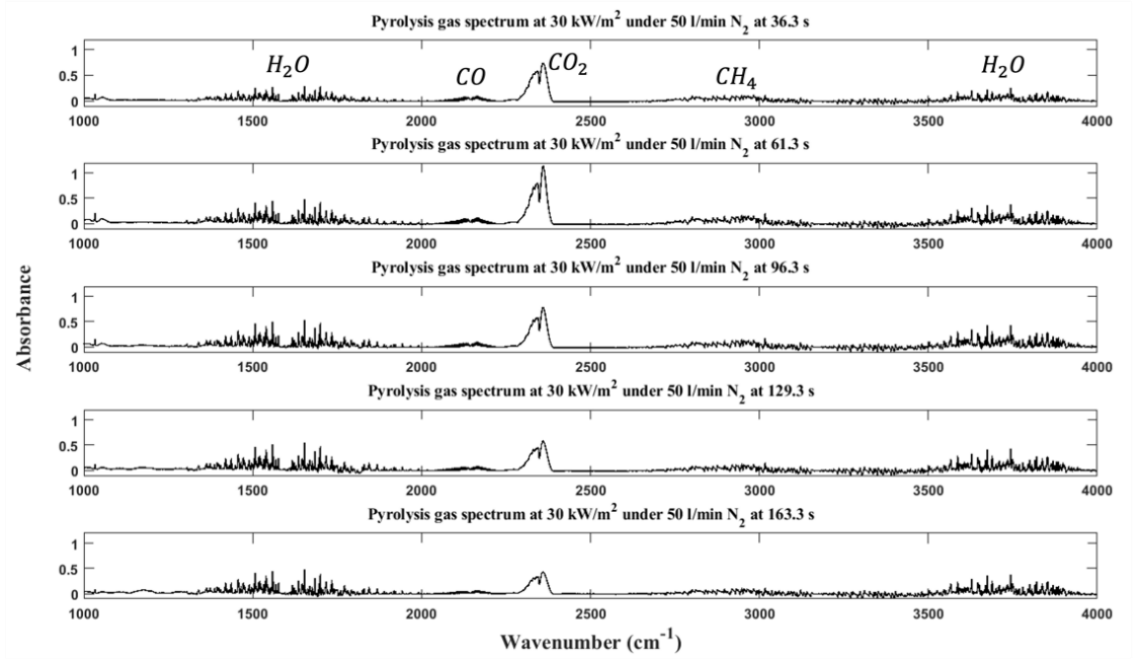
3.1. FTIR analysis of pyrolysis gas

3.1.1. Pyrolysis gas component identification

Figure 3 presents the FTIR spectra of the pyrolysis gas samples collected during the experiments conducted at 20 kW/m^2 and 30 kW/m^2, respectively. The main constituents of the pyrolysis gas determined by the characteristic bands shown in FTIR scans include CH_4, CO, CO_2, and H_2O. The characteristic bands at 2880-3180 cm^{-1}, 2010-2250 cm^{-1}, and 2290-2390 cm^{-1} indicate the formation of CH_4, CO, and CO_2. The characteristic bands at 1390-2020 cm^{-1} and 3500-3998 cm^{-1} represent the occurrence of H_2O. Similar pyrolysis gas components of plant species are also found in other literature (Granada et al., 2012).



(a)

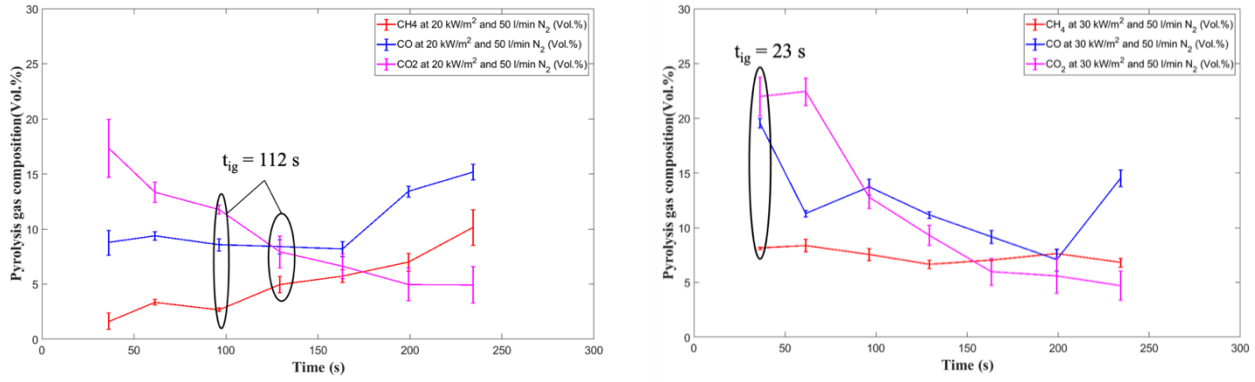


(b)

Figure 3 - Pyrolysis gas FTIR spectra at 50 l/min N_2 and (a) 20 kW/m^2, 50 l/min N_2 and (b) 30 kW/m^2.

3.1.2. Quantification of the pyrolysis gas constituents

Figure 4 shows the evolution of the concentration of the different gas species identified in the pyrolysis gas samples collected at both heat flux levels. All the results are averaged from three repetitions. It is essential to highlight that the calculated concentration of each component at each moment is not the instantaneous concentration at that moment, but the average concentration over time of the data collection (26.3 s).



(a) ***(b)***

Figure 4 - Pyrolysis gas concentration evolution at 50 l/min N2 and (a) 20 kW/m2, 50 l/min N2 and (b) 30 kW/m2.

Combining these results with the time-to-ignition under the same conditions (see Section 3.2), it is possible to evaluate the composition of the pyrolysis gases at ignition. For an incident heat flux of 20 kW/m^2, the concentration of CH_4, CO, CO_2, and H_2O at ignition are found to be 3.8, 8.5, 9.9, and 77.8 vol.%. For an incident heat flux of 30 kW/m^2, the concentrations of CH_4, CO, CO_2, and H_2O at ignition are 8.1, 19.6, 22.0, and 44.1 vol.%.

Thus, the effective heat of combustion of the pyrolysis gases (H_{c_py}) can be evaluated as the weighted sum of the heat of combustion of each species, defined by Eqs. (1) and (2).

$$H_{c\_py} = Y_{CO} \cdot H_{c\_CO} + Y_{CH_4} \cdot H_{c\_CH_4} \quad \text{Eq (1)}$$

$$Y_i = \frac{X_i M_i}{\sum X_i M_i} \quad \text{Eq (2)}$$

where X_i, M_i, Y_i, and H_{c_i} are the mole fraction, molecular weight, mass fraction, and heat of combustion of a given gas species. The reference values of the heat of combustion of CH_4 and CO are 50.1 and 10.1 kJ/g, respectively (Quintiere, 2006).

The resulting effective heat of combustion of the pyrolysis gases was evaluated to be 2.6 kJ/g and 6.4 kJ/g for 20 and 30 kW/m^2, respectively. This result is in general agreement with the range of values (from 4.62 to 5.38 kJ/g) reported by (Cancellieri et al., 2005). The variation of the heat of combustion on different heat fluxes indicates that the pyrolysis gas obtained at a higher heat flux is of greater flammability.

3.2. Ignition tests(tig)

3.2.1. Time-to-ignition (tig)

Table 1 presents the mean ignition time (t_{ig}), mean thermal penetration depth (δ), and dimensionless thermal depth (x) measured at external heat fluxes ranging from 20 to 35 kW/m^2, and airflow rates of 0, 50, and 100 l/min air.

Table 1: Mean time-to-ignition, thermal penetration depth, and dimensionless thermal depth for a 30 mm fuel bed under different external heat fluxes and flow rates.

Flow rate (l/min)	Heat flux (kW/m^2)	t_{ig} (s)	δ (mm)	x (-)
0	20	66.67 (3.54)	9.16 (0.25)	3.28 (0.09)
	25	19.33 (3.76)	4.88 (0.43)	6.28 (0.50)
	30	13.00 (0.82)	4.04 (0.12)	7.44 (0.22)
	35	5.67 (0.27)	2.67 (0.07)	11.26 (0.28)
50	20	124.33 (18.47)	12.39 (1.04)	2.48 (0.23)
	25	35.67 (9.06)	6.51 (0.92)	4.95 (0.81)
	30	22.67 (2.37)	5.32 (0.28)	5.68 (0.29)
	35	12.33 (2.76)	3.87 (0.43)	8.01 (0.80)
100	20	No ignition	-	-
	25	88.67 (5.18)	10.56 (0.27)	2.85 (0.07)
	30	38.33 (3.17)	6.92 (0.34)	4.36 (0.21)
	35	20.00 (2.41)	4.98 (0.35)	6.10 (0.39)

The thermal penetration depth, defined in Eq. (3), represents the depth pyrolysis layer (Delichatsios, 2020). The dimensionless thermal depth is defined as the ratio of the fuel sample thickness to the thermal penetration depth (Delichatsios, 2020), and it is used to discriminate whether the fuel bed shows thermally-thick or thermally-thin behavior at ignition based on the criterion presented in Eq. (4) (M. Delichatsios, 2020).

$$\delta = \sqrt{\alpha t_{ig}} \qquad \text{Eq (3)}$$

$$x = \frac{\tau}{\delta} = \begin{cases} < 0.8 & thermally\ thin \\ 0.8 < x < 2 & thermally\ intermediate \\ 2 < & thermally\ thick \end{cases} \qquad \text{Eq (4)}$$

For a thermal diffusivity of pine needles (α) of 1.26 × 10-6 m^2/s (Korobeinichev et al., 2018), it appears that the 30 mm-thick pine needle bed behaves thermally thick for all testing conditions.

From the table, it can be seen that t_{ig} and δ increase when increasing the airflow rate and decrease when increasing the magnitude of the external incident heat flux over the fuel bed. When increasing airflow rates, the net heat delivered to the fuel bed decreases due to an enhanced convective cooling through the fuel bed, which reduces the pyrolysis reaction rate of the fuel bed and the quantity of the released fuel vapor. Meanwhile, the generated fuel vapor through the pyrolysis is diluted by the incoming airflow.

On the other hand, the decrease of t_{ig} and δ when increasing the external incident heat flux over the fuel bed is due to the steepness of the temperature profile developed inside the fuel bed; higher incident heat fluxes will increase the amount of energy available to promote the pyrolysis reaction, increasing its rate. Thus, less time is required until a sufficient fuel rate for ignition is achieved. Furthermore, higher incident heat fluxes will produce steeper temperature profiles, causing a decrease in the relative distance between the thermal propagation depth and the pyrolysis front depth. Thus, as the time-to-ignition decreases with the magnitude of the external heat flux, the thermal wave can only propagate into depths closer to the surface of the fuel bed.

3.3. Critical mass loss rate ($\dot{m}''_{cr}$)

The results of the critical mass-loss rate **($\dot{m}''_{cr}$)** are shown in Figure 5. The uncertainties of the results are determined by one standard deviation of three repetitions for each test.

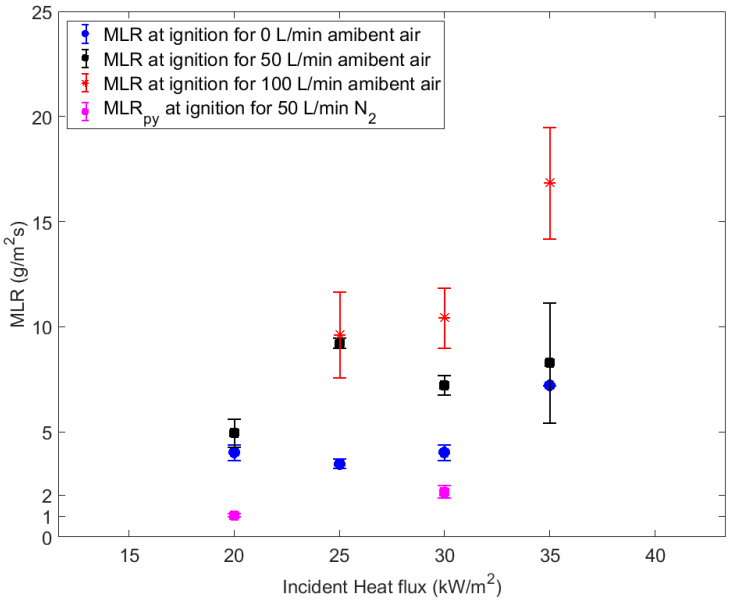


Figure 5 – Critical mass loss rate (MLR) for sustained flaming ignition

The critical mass-loss rate at ignition was found to increase when increasing the external incident heat flux and the airflow rate. Two mechanisms mainly drive the mass loss of the fuel bed. One part of the mass loss is due to pyrolysis, while the other one is due to the smoldering combustion of the fuel bed. Both reactions have been found to increase their rate when provided more energy (Bartlett & Bisby, 2015). Thus, increasing the magnitude of the external incident heat flux over the fuel bed increases the pyrolysis rate, smoldering combustion, and consequently, the mass-loss rate of the fuel bed. The reason for the increase of $\dot{m}''_{cr}$ when increasing the airflow rate is due to the dilution of the flammable mixture. As the chemical reaction at flaming ignition is near stoichiometric (Lyon & Quintiere, 2007), the fuel vapor concentration needs to increase with the airflow rates so that the equivalence ratio meets the requirements for ignition. Therefore, to obtain sufficient fuel, as shown in Eq (5), the thermal depth or the pyrolysis reaction rate needs to be increased. The increase in thermal depth with airflow rates has been shown in the analysis in 3.2.1. The pyrolysis reaction rate can also be locally increased by the appearance of smoldering spots, which is consistent with the observation that smoldering was detected before ignition for all tests conducted under forced flow conditions.

4. Conclusion

The work presented herein attempted to enhance our understanding of the conditions that lead to the ignition of Pinus palustris pine needles through a series of experiments aimed at characterizing the pyrolysis gases and the conditions under which piloted ignition occurs.

In pyrolysis tests, the influence of different heat fluxes on pyrolysis gas yields was investigated. The yield, generation rate, and flammability of pyrolysis gas were all found to increase with increasing heat fluxes.

In ignition tests, the influences of external heat fluxes and airflow rates on the time to ignition and mass loss rate at ignition were analyzed. The analysis of time-to-ignition results indicated that the thermal behavior of the fuel bed at ignition was influenced by both heat fluxes and airflow rates. The analysis of mass loss rate suggested significant contributions of smoldering combustion to the flaming ignition under low heat fluxes and high airflow rate conditions.

WUI (Wildland Urban Interface), Urban Forest Fire Management, Fire Risk Analysis, Fire Policy, Fire Management

Abstract

The risk of fire in urban forests is high due to housing and living infrastructure adjacent to the forest, resulting in large human and property damage and high frequency of occurrence. It is very important to identify the forest fire environment and potential risk factors for each city in order to manage the forest fire risk in the cities adjacent to the forest. In this study, urban forest fire management measures were suggested by conducting a survey on the causes of forest fires and the entire adjacent forests in Nowon-gu, which has the most urban-forest adjacent areas in terms of administrative districts among Seoul, which has the highest population density in Korea. The forest fire investigation has been conducted for the last 5 years, and in addition to analyzing the forest, topography, and meteorological environment, an analysis of fire-vulnerable areas in the event of a forest fire in downtown Seoul was conducted. Eight action plans were presented by dividing the actionable forest fire management into prevention, preparation, and response stages for areas adjacent to forests and areas vulnerable to forest fire risk. First, in prevention, fuel management that can reduce the risk of forest fires, map production and risk reduction management for temples in the forest, and selection of appropriate locations to install forest fire long-distance around monitoring cameras and drone autonomous monitoring stations were suggested. Second, in the preparation stage, a fuel blocking method was presented to establish a safe zone for hiking trails, prepare a mountaineering safety map for forest fire evacuation, and prevent the spread of residential fires in forest interface area. Third, in the response stage, the installation of a multi-purpose outdoor fire hydrant for suppression of forest fires and house fires adjacent to the forest, the activities of forest fire extinguishing vehicles and marking of the entry area, and the establishment of an urban forest disaster integrated control system were suggested.

1. Introduction

As forests and adjacent forests are developed as residential or commercial areas due to urban expansion, the number of cases in which forest fires become urban fires and building fires spread into forest fires is increasing. In the case of WUI forest fires, due to spatial characteristics, not only forest fires, but also complex fire-fighting activities such as the evacuation of people, extinguishing fires in buildings, and protection of dangerous facilities are required, and organic cooperation between the forestry department and the urban fire-fighting department is more necessary. In the case of the United States and Canada, community-based forest fire management is implemented according to the FireWise and FireSmart programs, respectively. In Korea, the risk of forest fires is high due to the continuous increase in urban expansion and use of urban forests, but there are no forest fire management activities and programs in the local community. Therefore, this study intends to propose a forest fire management plan for the forest adjacent to the Nowon-gu of Seoul, which has the highest population density in Korea. In Nowon-gu, the forest area occupies 1,546ha, which is 44% of the total administrative district, and a total of 18 forest fires have occurred since 2015 in forest. In Nowon-gu, 7 cultural assets including the royal tombs of the Joseon Dynasty, designated as UNESCO cultural assets, and 26 temples are distributed in the adjacent forest area.

2. Methods

2.1. Forest fire risk analysis to Nowon-gu WUI

Forest fire risk analysis was conducted on the forests of Bulam Mt. and Surak Mt. of 1,456 ha in Nowon-gu, WUI houses and buildings, temples and facilities in the forest, and shelters on hiking trails. The following four items were investigated.

① Forest fuel density and forest fuel type

② Risk of fire spread due to forest fires in WUI houses and structures

③ Possibility of casualties during forest fire spread

④ Ease of firefighting environment

WUI forest fire risk analysis was conducted by analyzing correlations with topography, weather, and forests along with past forest fire cases to select areas vulnerable to forest fires. was classified, and predictive factors such as topography, forest, and weather were quantified using a spatial analysis program.

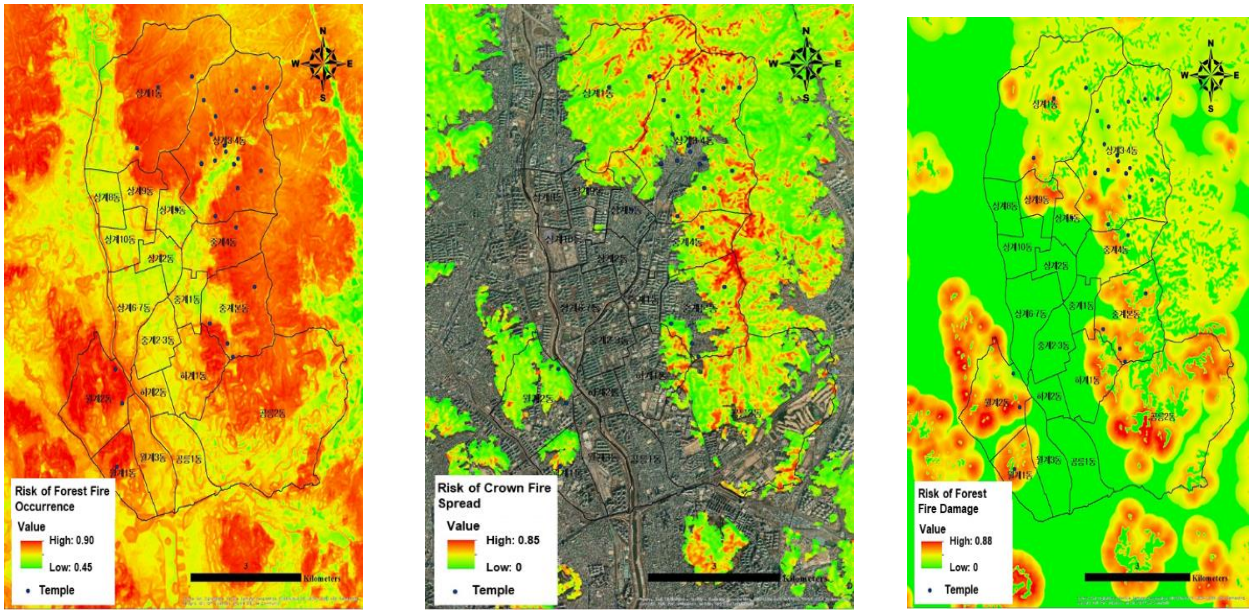
2.2. Forest Fire Management Plans to Nowon-gu WUI

Nowon-gu WUI forest fire management measures were divided into three stages: prevention, preparation, and response, and the existing countermeasures and activities of local administrative agencies were analyzed and methods to reduce and prevent risks were suggested based on the results of analysis of areas vulnerable to forest fire risk. The risk felt by residents was investigated through the on-site residents briefing session, and WUI risk environment improvements were heard to manage the risk of forest fires.

3. Study Results

3.1. Standard scenario

As shown in Figure 1, the risk of release of forest fires in the forest adjacent to Nowon-gu was classified on a scale of 0 to 1, and the maximum risk of forest fire occurred within a radius of 300m of the WUI. As for the risk of spreading of crown fire, the area with the highest risk was found to be around 20 m in the lower radius of the ridge. The risk of damage from forest fires was analyzed as high risk 9, high risk 6, moderate 5, and low 6.



(a) Risk Map Forest Fire Occurrence ***(b) Risk Map of Crown Fire*** ***(c) Temple fire damage risk map***

Figure 1- Results of forest fire risk analysis in Nowon-gu, Seoul

3.2. WUI Forest fire management measures

For the project to strengthen the capacity for forest fire management in Nowon-gu, 8 projects were presented in the areas of prevention, preparation, and response. In the field of prevention, ① fuel reduction project to lower the risk of forest fire, ② the risk rating mapping and risk reduction project for temples, ③ selection of appropriate locations to install forest fire long-distance around monitoring cameras and drone autonomous monitoring stations were presented. In the field of preparation, ① project to establish a safe zone on hiking trail and prepare a mountaineering safety

map for forest fire evacuation, ② a fuel continuity blocking project to prevent house fires in WUI were presented. In response fields, ① a multi-purpose outdoor fire hydrant installation project for suppressing forest fires and house fires to WUI, ② forest fire extinguishing vehicle entry and activity area indication project, ③ urban forest disaster integrated control system construction project were presented. Including the preparation of detailed implementation plans and required budgets for a total of 8 projects in 3 areas, it suggested a method to strengthen forest fire management capabilities in stages by year with the utilization of public workers and public relations for residents from 2021. Figure 2 is a schematic diagram for a total of 8 projects, and is a conceptual diagram of fuel reduction in the prevention field and the construction of a safety zone for hiking trails in the preparedness field.

(b)

(c)

Figure 2- Nowon-gu WUI Forest Fire Management Measures Conceptual Map; (a) Prevention field: Measures to reduce fuel, (b) staging area: WUI fuel continuity cut off, (c) Response field: Fire engine access road marking

A total of 14 evaluation items for each scenario are as follows.

①Whether or not information on forest fire situation is collected and confirmed, ②Establishment and feasibility of firefighting strategy, ③Selection of location for firefighting work, ④Construction of fire line, ⑤Effect of ground firefighting work, ⑥Preparation and use of ground firefighting equipment, ⑦Sudden situation (Spotting fires, Fire Storm, Rolling Stone or wood etc) check and response, ⑧Use of evacuation equipment, ⑨Secure an evacuation route and a safe place, ⑩Feasibility of evacuation judgment and method, ⑪Arrangement of remaining balance, ⑫Communication by team, ⑬Report the situation to the command center and make an emergency request, ⑭Protection object protection.

In the survey of firefighters on the training evaluation tool, the suitability evaluation was found to be 97.5±2.5%.

4. Conclusions

The results of the WUI forest fire risk analysis and risk management measures suitable for the region in Nowon-gu, which has the largest forest area in Seoul, which has the highest population density in Korea, are as follows.

First, a forest fire risk map for the Nowon-gu, a temple fire risk map in the forest, and a tree crown fire occurrence risk map were produced.

Second, for temples with a high risk of forest fires, a risk mitigation method was suggested so that they could be maintained below normal.

Third, a total of 8 countermeasures were presented in the field of prevention (3 items), preparedness (2 items), and response (3 items) as Nowon-gu forest fire management plan.

Based on the method of promoting this research and preparing countermeasures, it is intended to be used in preparing various forest fire prevention measures through application to other regions, thereby contributing to forest fire management in WUI.

An Equivalent Fuel Model for Wildland Urban Interface – Application to Risk Management

Wildland urban interface, equivalent fuel, thermal equivalency

Abstract

Wildfires are imposing increasingly greater risk to people and insured properties. The frequency and intensity of destructive wildfires has increased significantly in past decades. Most wildfire damage to properties occurs in the wildland-urban interface (WUI), where properties are either exposed to wildfire directly and burn or are ignited by firebrands. Many wildfire models are focused on modelling the spread of fires in wildland; however, the studies of the spread of wildfires into urban areas is limited. This paper presents a new model for fuel load in urban area using an equivalent fuel load as wildland fuel to simulate wildfire spread when they approach wildland and urban interface/intermix. The model is to estimate the heat release rate from a typical single house and determine the combination of different fuel sizes. Then, according to the density of structures based on satellite imagery the fuel from LANDFIRE fuel is updated with the model urban fuel. A similar method of equivalent fuel load for agriculture area is developed and the LANDFIRE fuel is updated with the agriculture fuel. Using the updated landscape fuel and terrain, Rothermel-based simulation of wildfire is performed in FARSITE. This simulation is helpful in determining the risk of wildfires for properties and communities.

1. Introduction

In recent decades the frequency and significance of wildfires have increased significantly in many parts of the world including the United States (Manzello *et al.* (2018)). Recent fire seasons in the western United States are some of the most damaging and costly on record. Data from California's fire department shows that in 2021 alone, there have been 8,835 wildfires in California which have burned 2,568,948 acres and damaged 3,629 structures. A United Nations report warns that the risk of highly devastating fires may increase by more than 50 percent by the end of the current century, Sullivan (2022). A better understanding of the spatial distribution of wildfire risk will help to mitigate the catastrophic loss of life and properties. This can help by ignition prevention, fuel and vegetation management, enhancing preparedness, and suppression response in high-risk areas as well as reducing human development and increasing home resistance to ignition in fire-prone areas, Calkin *et al.* (2014). This will also help property- and casualty-related industries, such as (re-)insurance industries, to mitigate their financial losses, by designing policies such that the risk of wildfire is considered more accurately (Hazra and Gallagher (2022)).

To estimate the threat of wildfires a stochastic simulation of probabilistic fire scenario is needed (Finney *et al* (2011)[a,b]). This simulation process requires the prediction of occurrence of probabilistic wildfires and simulation of fire growth based on the physical properties of the fuel and terrain and the associated simulated weather. Many models have been developed by researchers including FARSITE and Prometheus, which are simulating the growth of wildland fires (Finney (2004) and Tymstra (2010)). These models simulate the spread of wildfires based on Rothermel (1972)'s Fire Spread in wildland area. A model for the probabilistic simulation of fires in wildland has been developed and a probabilistic risk component of wildland fires has been calculated for the continental United States (Finney *et al* 2011[a,b]). The required wildland fuel models in United States can be acquired from the LANDFIRE website. Landfire data provides a model environment in the form of eight bands raster that includes fuel properties as well as terrain specifications for wildland. But the model environment is limited to wildland and many other applications including urban areas and agriculture lands are considered non-burnable. This work presents a model based on the energy release properties of burning houses and assigns an equivalent fuel model for urban and WUI area as well as agricultural lands. The LANDFIRE fuel is updated with urban and agriculture fuel models for the urban area. The new model can be uploaded to FARSITE or other

wildfire simulator that uses LANDFIRE data which enables wildfire simulator to simulate the spread of the wildfires in WUI.

2. Model description

2.1. The heat release of a single house

A model fuel load for houses is designed such that it can produce the same amount of thermal energy as reported in earlier works of Trelles and Pagni (1997) and Rehm *et al.* (2001). The estimated energy release process can be divided in three stages, first the fire grows exponentially and burns at maximum heat release rate for about an hour, and then burning dies down slowly within two steps. At the peak of burning of the involved house, the vegetation around the structure burns and releases thermal energy simultaneously (Trelles and Pagni (1997)). Summation of the heat release rate yields a total energy release for combustion of an involved house, which includes heat release from the structure and its contents. The energy release from burning of the contents is obtained from experimental studies by Blais *et al.* (2020) of burning the contents of a typical U.S. living room. Assuming fuel load of the typical house is distributed uniformly throughout the entire house and considering the footprint of the house, the total fuel load of the content of a typical house is calculated. The model fuel is designed based on the equivalent amount of thermal energy release from structure and content.

2.2. Estimating the fuel load for WUI

The potential fuel loading of urban areas also depends on the number of the houses in each raster cell of LANDFIRE data. The ratio of vegetation fuel load to structure fuel load decreases once we move from the wildland to urban area as the areal density of structures increases (Rehm *et al.* (2001)). To account for the change in fuel type due to the structure density, the structure density in the simulation area is calculated from the US Building Footprint datasets developed by Microsoft (2022). Considering the density of the buildings, the LANDFIRE fuel in urban areas is updated from non-burnable to the new urban fuel.

2.3. Equivalent fuel for agricultural land

Similar to WUI and urban areas, LANDFIRE considers agricultural lands as non-burnable areas. An estimate of the fuel load for agriculture fields is provided by South Carolina's Forestry Commission, which we used for updating LANDFIRE fuel model

Wildland- urban interface (WUI), observation plot, combustible fuel, wildfire statistic, integrating housing density.

Abstract

The Wildland- urban interface (WUI) is an area, where houses meet or intermingle with undeveloped wildland vegetation. The identification of these areas is not yet present in all countries. Although scientific research on this topic is still incomplete in Hungary, there are already initiatives and some results to identify WUI areas and analyse their risks. Authors approach the WUI fire risk from two directions. On the one hand, wildland is a combustible biomass, so wildfires pose a direct threat to the built environment. The reason for this threat is that residential buildings are located along the forest, which, as a flammable material, provides an opportunity for the spread of fire. This allows fire to spread from wildland vegetation to the populated area, endangering human life and property. Authors examine the characteristics of WUI fires in Hungary through analysis of observation plots. In the short paper Authors present the direct and indirect interface WUI and analyse the risk of WUI fires by using GIS spatial analyses. Authors also analyse the combustible fuel, the number of fires, and the integrating housing density in the observation plot.

1. Introduction

The Wildland- urban interface (WUI) is an area, where houses meet or intermingle with undeveloped wildland vegetation (Cohen, 2003), (Radeloff, 2005). The concept of WUI is still less known in some part of Europe (also in Hungary), but in the Mediterranean region it is the biggest challenge of fires caused by human negligence. Fires at the WUI are a huge challenge in many countries. One example is the United States, where millions of people and homes on both west and east coasts are at risk from these fires (Radeloff, 2018). In Canada, such areas cover more than 30 million hectares (Johnston 2018). Australia has also WUI fire danger, therefore, a study on fire prevention has been carried out, focusing on priorities and perceptions of wildfire risk (Koksal, 2019). In Europe, countries of the Mediterranean region are especially high vulnerable. In Spain, there are emergency plans against the wildfires (Caballero 2007). In Portugal, the emphasis is also on the prevention, as the risk of wildfires is one of the highest in Europe almost every year (Viegas, 2012). France is also a good example, where a topological matrix has been established to identify WUI areas (Lampin-Maillet, 2009). In Hungary, the national literatures on wildfires focuses less on the prevention of WUI fires and more on the effectiveness of firefighting (Restás, 2018) and the detection (Bodnár, 2018).

2. Methods

During our research we have examined and analysed the relevant literatures in the topic as well as findings of other authors. We present each findings, and in some cases, we discuss or agree with them. In addition, we conducted discussions with international experts on the subject. In order to present the WUI areas developed in Hungary, we made image analyses in an observation plot. Our main observation plot is in South Hungary, in Bacs- Kiskun County nearby the town Kiskőrös. On this observation plot we have made fuel analyses, examined the wildfire statistics from the last 10 years, and examined the integrating housing density along the wildland area. For each risk, we determined the risk of fire hazard. In addition, spatial analyses allowed us to quantify

patterns and relationships in data and display the results as maps, tables, and charts. So we performed GIS Spatial analyses with topoXmap, developed by Hungarian GIS experts. TopoXmap is an efficient, powerful GIS (Geographic Information System) data collection, visualization and processing software which includes GIS tools. It can use and process raster and vector datasets. It possesses powerful GIS visualization tools and supports to build database and to analyse GIS datasets.

3. Results

On the first observation plot (not the above mentioned territory nearby Kiskőrös) we show that in Hungary direct and also indirect interfaces developed. So Figure 1 is a WUI area and the location is part of the village of Nagykovácsi in Hungary (Pest County), but the area belongs to the **urban agglomeration** of Budapest. During the image analysis, we performed a graphical delimitation, where the direct interface of WUI was marked with a red and the indirect interface with yellow. We considered as a **direct interface**, where the areas of wildland and urban environment are adjacent to each other and the distance between them is minimal. **Indirect interface** is where the distance between wildland and residential area is significantly longer, but there are agricultural lands or other combustible materials between the two areas.

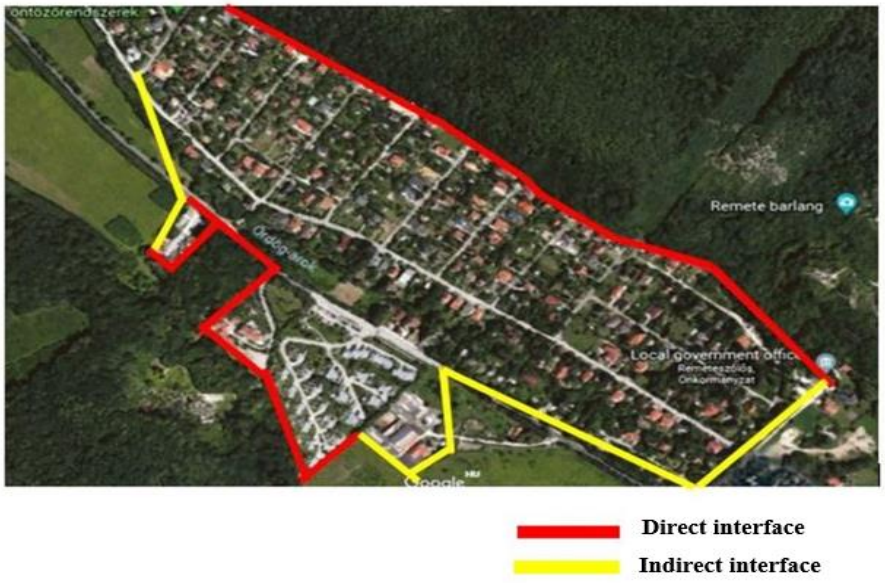

Figure 1- Direct and indirect interface at the WUI.

After that we examined another observation plot for fires at the WUI in 3 steps. We analyse the combustible fuel (first step), the number of fires (second step) and the integrating housing density (third step) in our second observation plot.

In the first step, we **analyzed the combustible fuel** in the observation plot (Bacs-Kiskun County-Kiskőrös) and we distinguished three main groups such as *low dangered forest lands*, *medium dangered forest lands* and *high dangered forest lands* (Figure 2). Pine and juniper vegetation are classified as high endangered forestland (red). Mixed forest and oak forest stands higher than 5 meters are classified as moderately endangered vegetation (yellow). Other native and planted tree species (for example poplar, ash, beech, maple, acacia,) are classified as low endangered forest land (green).

In the second step we **examined the wildfire statistics** in the observation plot from the last 10 years. We distinguished the fires according to their distance from the settlement. We put fires in WUI-1 zone that occurred 500 metres from the residential area. The additional zones were as follows: WUI-2 zone – 1 000 m; WUI-3 zone 1 500 m – WUI-4 zone 2 000 m and WUI-5 zone 2 500 m. In Figure 2, fires in WUI-1 and WUI-2 zones (red and orange hoops) are important for the analysis.

Table 1- Number of wildfires in the WUI zones in the observation plot.

Year	Number of wildfires	WUI-1	WUI-2	WUI-3	WUI-4	WUI-5
2011	103	42	17	9	9	26
2012	278	114	42	25	21	76
2013	66	23	11	8	6	18
2014	78	35	5	5	9	24
2015	50	18	6	2	5	19
2016	69	24	10	12	4	19
2017	145	32	30	21	22	40
2018	45	8	9	10	5	13
2019	180	41	25	22	34	58
2020	85	26	11	8	15	25
2021	123	29	23	20	16	35

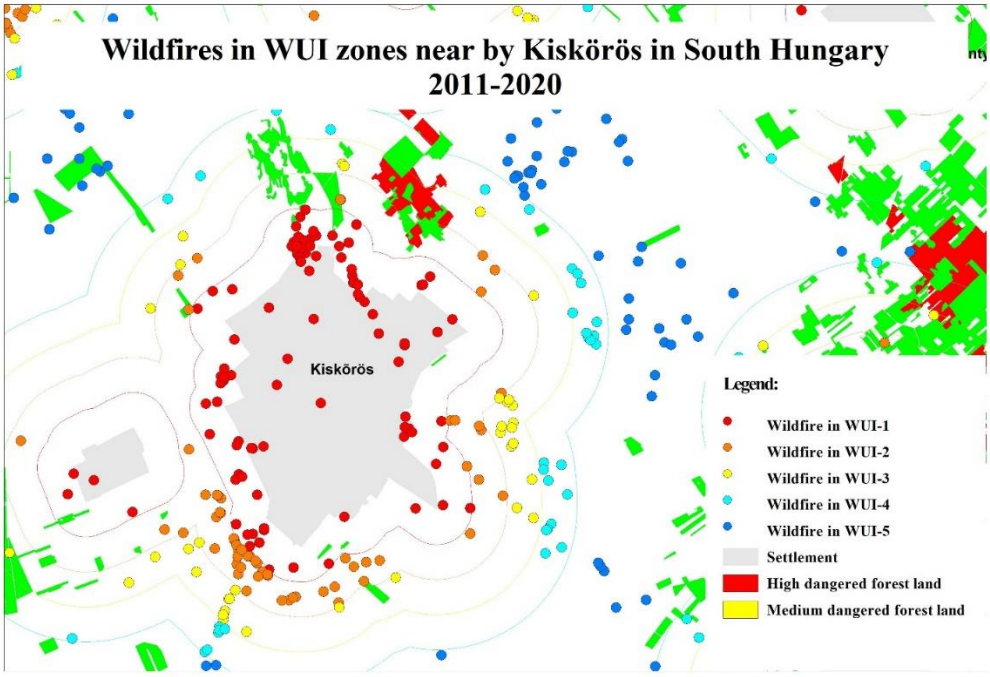

Figure 2 - The distance of fires from the residential area in the observation plot.

We performed GIS Spatial analyses with topoXmap on Figure 2, which presents the fires that occurred in the wildland areas of the settlements in the observation plot. The red colour indicates fires that occur within 500 metres from the residential area (WUI 1 zone) and the yellow those that occur within 1 km (WUI 2 zone). It is clear that a significant part of wildfires occurred close to the residential areas (marked in red and orange). Because of this, buildings were endangered from wildfires. The cause of fires is primarily the human factors.

In the third step of our three-step analysis, we examined the **housing density** along the wildland area at the WUI. Our observation plot is small, so in this case we have examined the integrating housing density of the entire county (Bacs-Kiskun Coutnty). We used Google Earth (open access) for this purpose, where we made an image analysis. We classified the integrating housing densities in three categories. In the first category (green) there are only farms nearby the forest. The second category is where the residential buildings are scattered relative to each other along the forest edge (10 m < >30 m, yellow). We classified the areas into the third category, where residential building very close to each other (<10 m, red).

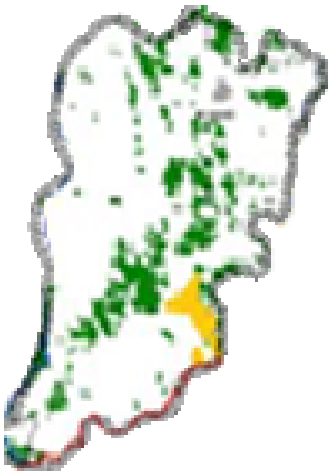

Figure 3- Integrating housing densities at the WUI in Hungary.

After the analysis we determine that there are many farms in the county. So the integrating housing density is low, mainly due to farmlands, and therefore it results in a low fire risk.

4. Conclusion

As a result of our analysis, we prove that WUI areas have developed also in Hungary. As WUI areas endangers human life and and property, these areas must also be identified in Hungary. To summarize our research above, we state that the preventive fire protection of Wildland-urban interface areas is a complex nature, which is still a research gap in Hungary, regardless of the research and guidelines already available in the international references. Taking into account international trends, we examined the risk of WUI fires of a national observation plot. The risk was determined as a result of a three-step analysis. As a result of the analysis, we consider the observation plot, as a high vulnerable WUI area. WUI risk is primarily due to the risk of fuel and fire occurrence. To sum up our results we determined that WUI fires can develop primary due to combustible fuel and number of fires in the observation plot we have analysed. However, they mainly endanger residential buildings and farms at the forest edge, and there is less chance of further residential buildings being damaged from fires.

WUI fires, Chile, FWI, Earth Observation satellites, spectral indices

Abstract

The Las Máquinas wildfire took place in central Chile in the austral summer season of 2017 and became the most severe event in Chilean history, causing loss of life, property and the destruction of native forest, crops, large areas of commercial plantations and biodiverse habitats. Since this event has no precedent in Chilean wildfire history, it was used as an example to carry out a detailed analysis of the conditions before (pre-), during (per-) and after (post-) the fire from a remote sensing perspective. The goal of this work is to develop a framework to carry out detailed analyses of catastrophic fires for forensic and public policy purposes, making use of the advantages posed by Earth Observation satellites, including the simultaneous imaging of large areas with a good spatial resolution, and an ever-increasing temporal resolution, coupled with a sophisticated suite of instruments which allow measuring many parameters simultaneously. This study examines the biophysical, meteorological and physical variables like the evolution of the Normalized Difference Vegetation Index (NDVI), weather conditions, maximum temperature evolution, the Canadian Fire Weather Index (FWI), the burned area, the maximum fire radiative power, among others, for the five municipalities that were affected by the fire: Cauquenes, Chanco, Empedrado, Constitución and San Javier, all of which are located in the Maule Region. The results indicate that Las Máquinas wildfire took place under exceptional meteorological conditions. In particular, the conditions before the night when Santa Olga was destroyed were characterized by extreme values of the FWI, which caused a significant increase in the burned area and overwhelmed any response by the fire brigades.

1. Introduction

Central Chile experienced tragic wildfire events in the 2016-2017 season, which killed 11 people, destroyed over 1000 structures, including the complete destruction of the village of Santa Olga, burned down approximately one half of the protected forests of *Nothofagus alessandrii*, an endangered southern beech species endemic to Chile. The total burned area for the fires was of about 575,000 ha, with the damage occurring especially in the Maule Region (CONAF 2017, ONEMI 2017), which saw the destruction of ~10% of its total area. The *Las Máquinas* fire consumed 190,000 ha in a few days, becoming the most devastating event in Chilean history. This wildfire is analyzed in this paper solely relying on Earth Observation (EO) tools. The goal of this work is to develop a framework to carry out detailed analyses of catastrophic fires for forensic and public policy purposes, making use of the advantages given by EO satellites, including the observation of large tracts of landscapes with a good spatial resolution, and an ever-increasing temporal resolution, coupled with a sophisticated suite of instruments which allow measuring many parameters simultaneously. For this purpose, we analyzed the landscape conditions before the fire (*pre*-fire), the propagation of the fire front (*per*-fire) and the evolution of the vegetation in the years after the event (*post*-fire), using open-access satellite imagery obtained from multiple remote sensing instruments, giving a new perspective to the description of this event. Additionally, the *pre*- and *per*-fire Canadian Fire Weather Index (FWI) was calculated for the entire Region of Interest on a daily basis, based on remotely sensed data and physical simulations.

2. Methods & materials

2.1. Study area

The Maule region is located in Central Chile (35° 25' 36'' S, 71° 39' 79'' W), with an area of 30,296 km^2 (see Figure 1). The climate is prototypical Mediterranean. Forestry is one of the main economic activities, with large continuous *Pinus radiata* and *Eucalyptus globulus* plantations. The Region of Interest (ROI) corresponds to five municipalities within the Maule region, where the wildfire took place. These municipalities are: Cauquenes, Empedrado, San Javier, Chanco and Constitución, which correspond to the five zones shown in Figure 1 that are delimited by a thick black line filled with a gray hatched fill.

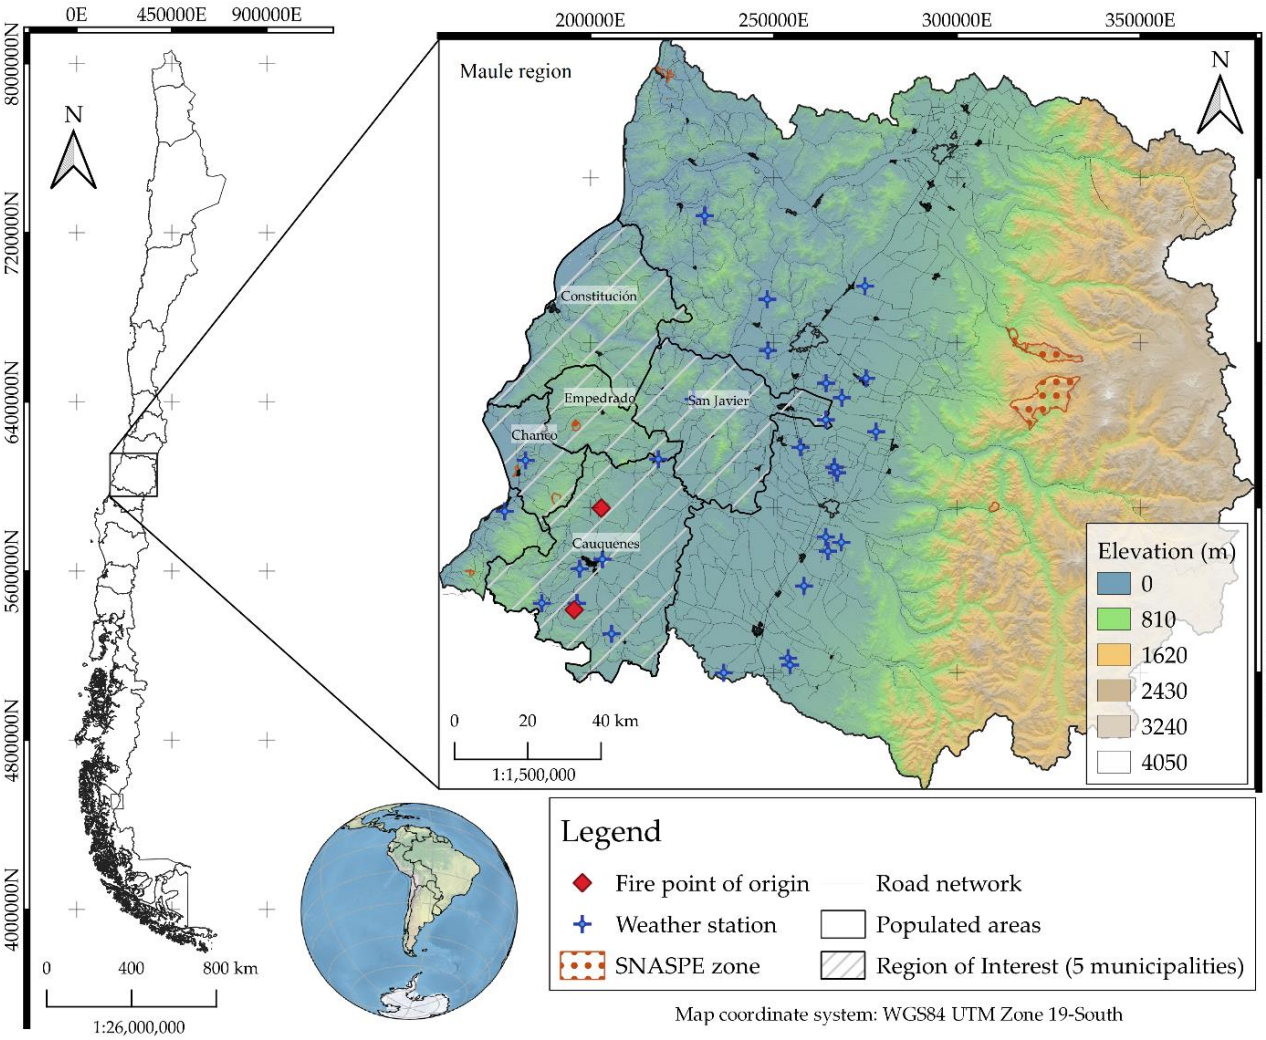

Figure 1. ROI with topography, weather stations, points of fire origins, and populated areas. SNASPE zones correspond to protected wilderness areas.

2.2. Burned area

Three different satellite products were used to calculate the burned area of the event: MODIS (product MCD64A1 v006 Burned Area (Giglio et al., 2015a), Landsat-8 pre- and post-fire images at Level-2 (surface reflectance with atmospheric correction), and Sentinel-2 pre- and post-fire images at Level-1C. The "sen2r" package (Ranghetti et al., 2020) was used in R to perform atmospheric, terrain and cirrus correction at the Top-Of-Atmosphere (TOA) for Sentinel-2 data, delivering Bottom-Of-Atmosphere (BOA) reflectance images. Landsat-8 and Sentinel-2 images were obtained from NASA's EarthExplorer. All images had < 0.5% cloud pixels within the ROI. Three images of Landsat-8 and Sentinel-2 were assembled to build the ROI, while only one MODIS Tile was required. The images were cropped and masked to the extent of the ROI. For Landsat-8 and Sentinel-2 BOA data, the following spectral indices were computed: Normalized Difference Vegetation Index (NDVI) (Rouse 1973), Normalized Difference Water Index (NDWI) (McFeeters 1996), Normalized Burn

Ratio (NBR) (Key & Benson 2006) and its temporal difference between pre, and post fire, i.e. the delta Normalized Burn Ratio (dNBR), which can represent the optimal separation of burned pixels from unburned ones and provide an scaled index representing the burn severity (Van Wagtendonk 2004). The two following filters were applied to the data: (i) NDVI pre-fire must be greater than 0.25, and (ii) NDWI must be lower than zero, meaning that only vegetation (El-Gammal et al., 2014) and non-water pixels can burn. Several threshold values for the dNBR were studied.

2.3. Vegetation evolution

Using MODIS product MOD13A1 (Vegetation indices 16-Day) (Didan 2015), the NDVI (Rouse 1973) was calculated. The average NDVI value for each municipality was computed from January 2010 to January 2022.

2.4. Fire weather

2.4.1. Standardized precipitation index

The Standardized Precipitation Index (SPI) (McKee et al., 1993) is based on the deviation of rainfall from normal data, and is computed by summing precipitations over k months, and fitting these accumulated precipitation values to a parametric statistical distribution from which probabilities are transformed to the standard normal distribution ($\mu = 0$, $\sigma = 1$). The precipitation data corresponded to the Integrated Multi-satellitE Retrievals for Global Precipitation Measurements (IMERG-GPM) monthly accumulated precipitation data product (GPM 3IMERGM.06) at a 0.1 degree × 0.1 degree spatial resolution (Huffman et al., 2019a), acquiring monthly accumulated precipitations from January 2001 to January 2016. SPI was computed using the "SPEI" package (Beguería & Vicente-Serrano 2017) in R, based on the Pearson Type III distribution, i.e. 3-parameter Gamma distribution function (Guttman 1999). In addition, the area under the curve (AUC) of the SPI was also studied.

2.4.2. Temperature evolution

Temperature evolution was carried out using the maximum monthly temperature from 1979 to 2019 grid product of Chile's CR^2. The product was built using statistical regionalization of the ERA-Interim atmospheric reanalysis data, while adding local information (such as topography and temperature observations) and surface temperature estimates by MODIS Land Surface Temperature product (M*D11A1) (Wan et al., 2015). The raster pixel-data was extracted for the whole ROI and then the average value was computed and stored.

2.4.3. FWI

The FWI was calculated using remote sensing products and physical simulations. $FWI = f(T_a, U_r, PP, RH)$, where T_a is the ambient temperature or NSAT (near-surface air temperature, in °C), U_r is the wind speed at 10 m height (km/h), PP is the precipitation (mm), and RH is the relative humidity (%). Wind speed was simulated using WindNinja V3.6.0 (Forthofer et al., 2014), with a landscape file for the ROI built by using primarily the information of the National Land Use Inventory (LUI) (CONAF 2016). NSAT was calculated using multiple linear regression models and machine learning random forests regression algorithms. The variables used are those proposed by Zhang et al., 2014. The regression training dataset was built by using daily images of NDVI, PW (precipitable water vapor, cm) and T_s (land surface temperature) from 2010 to 2016 for the month of January only. The pixels at the location of the weather stations within the ROI were extracted, as well as the air temperature measured by the weather station at the closest acquisition time of the satellite-product.

Precipitation was obtained from the IMERG-GPM (Huffman et al., 2019b), where the product GPM IMERG Final Precipitation L3 Daily at a 0.1 degree × 0.1 degree spatial resolution was used. Relative humidity was obtained by calculating the quotient of the actual vapor pressure, e_a, and the saturation vapor pressure, $e°(T_a)$. The only variables required are the near-surface air temperature (NSAT) and the dew-point temperature (T_{dew}) (Allen et al., 1998; Lawrence 2005). The latter was obtained from MODIS M*D07 product (atmospheric profiles) (Borbas et al., 2016). Finally, the FWI was computed in R using the "cffdrs" package (Wang et al., 2017) with adjusted latitude and initial conditions of the Fine Fuel Moisture Code (FFMC), Duff Moisture Code (DMC) and Drought Code (DC) derived from the fire danger indices historical data from the Copernicus Emergency Management Service (Vitolo et al., 2019).

3. Results

3.1. Burned area

Landsat-8 and Sentinel-2 burned area for several dNBR threshold values is shown in Figure 2. The upper bound of the red rectangle corresponds to the burned area reported by the authorities (218,076 ha), while the lower bound corresponds to the burned area calculated by means of the MODIS MCD64A1 product. Figure 3 shows the burned area obtained from MODIS, and both Landsat-8 and Sentinel-2 for certain dNBR threshold values. Figure 4 exhibit the evolution of the daily burned area.

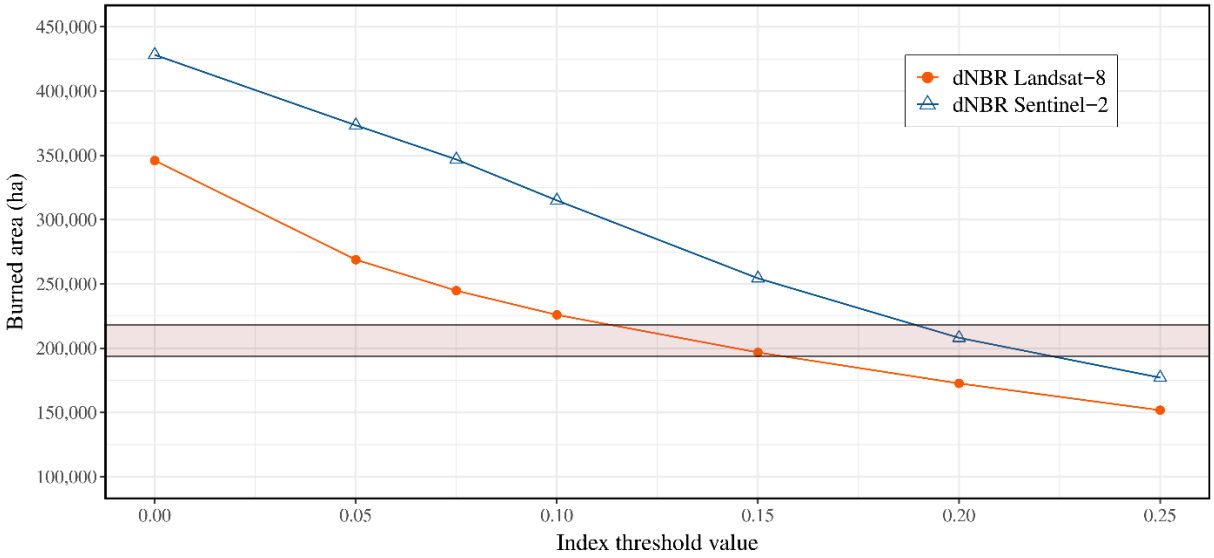

Figure 2. Burned area versus dNBR threshold values for Landsat-8 and Sentinel-2 images.

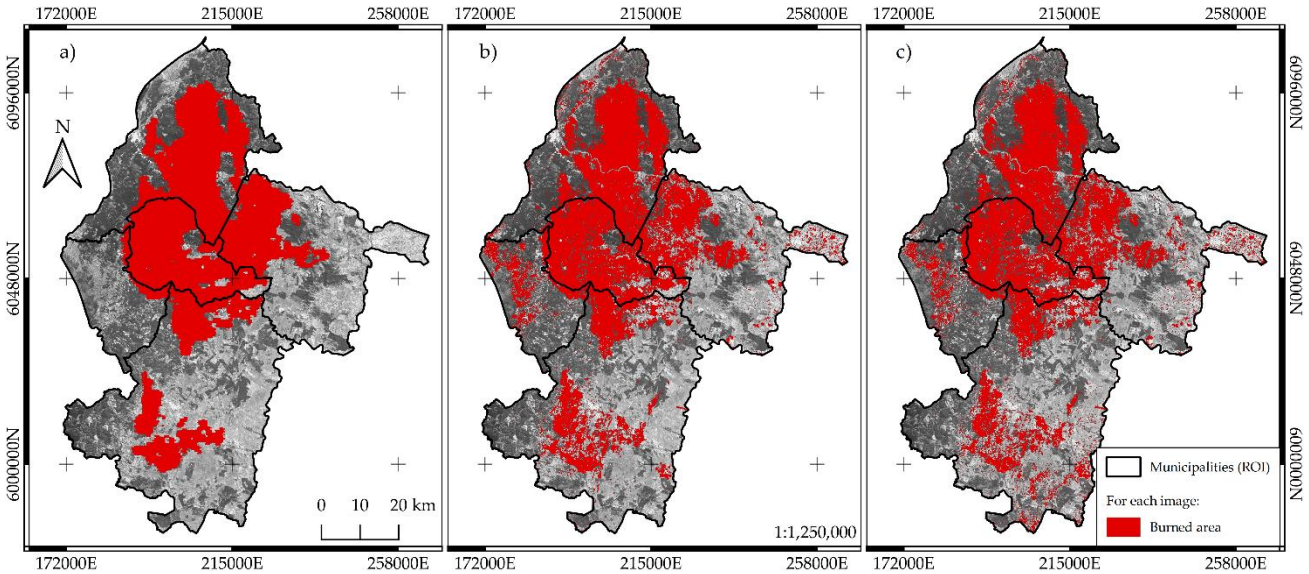

Figure 3. Burned area for a) MODIS MCD64A1 product, b) Landsat-8 with dNBR=0.135, and c) Sentinel-2 with dNBR=0.205. Considering the dNBR threshold values mentioned before, the Landsat-8 and Sentinel-2 burned area results were 204,440 ha and 204,450 ha, respectively. While the affected surface with MODIS MCD64A1 was 193,804 ha. Map coordinate system is WGS84 UTM Zone 19-South.

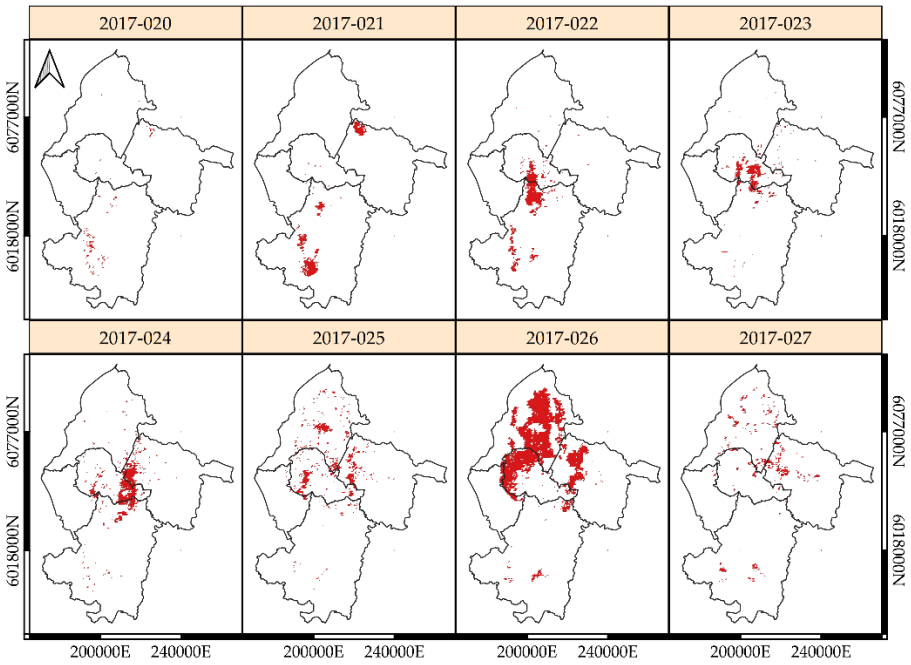

Figure 4. Burned area evolution (MODIS MCD64A1 product) between Julian days 020 – 027 (January 20th to January 27th, 2017) within the ROI. Each image corresponds to daily data.

3.2. Vegetation evolution

The results in Figure 5 shows that the most affected municipality within the ROI in terms of its flora was Empedrado. Note that around 89% of Empedrado surface-area was burned.

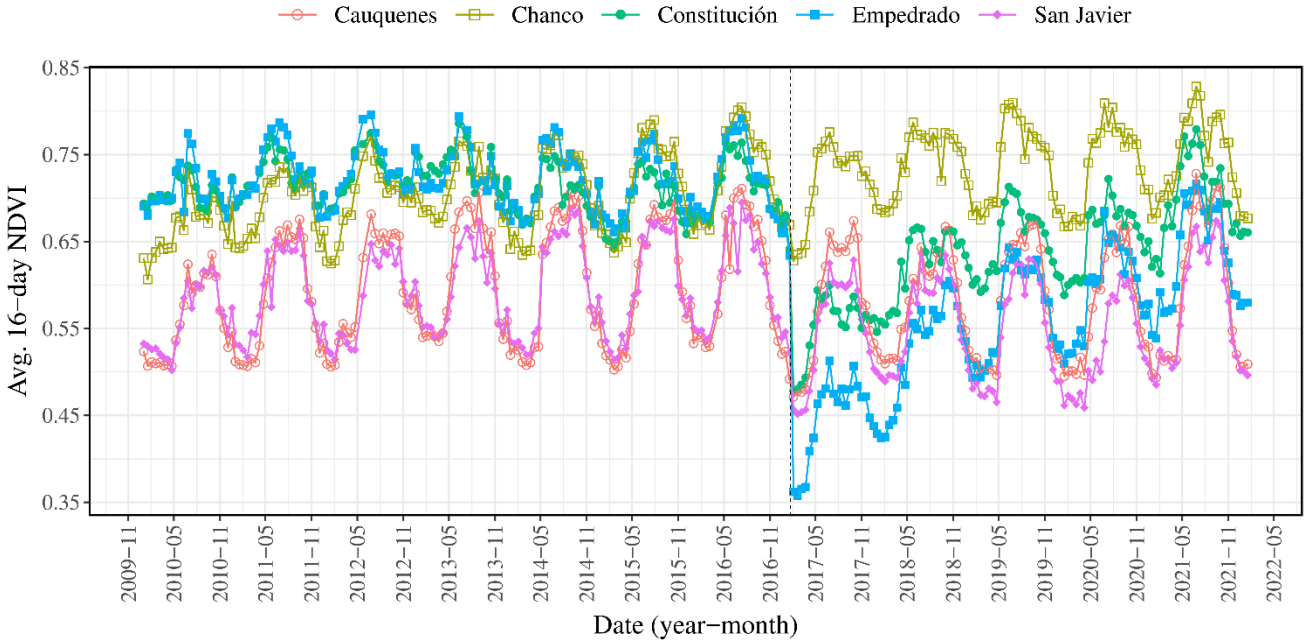

Figure 5. Average NDVI evolution from January 2010 to January 2022 for each municipality within the ROI. The vertical dashed line corresponds to the fire start date (January 20, 2017).

3.3. Standardized precipitation index

Severe drought values were found the year prior to the event (see Figure 6a). Furthermore, the downward trend displayed by the cumulative SPI AUC in Figure 6b corresponds to a persistent drought from 2009 onwards.

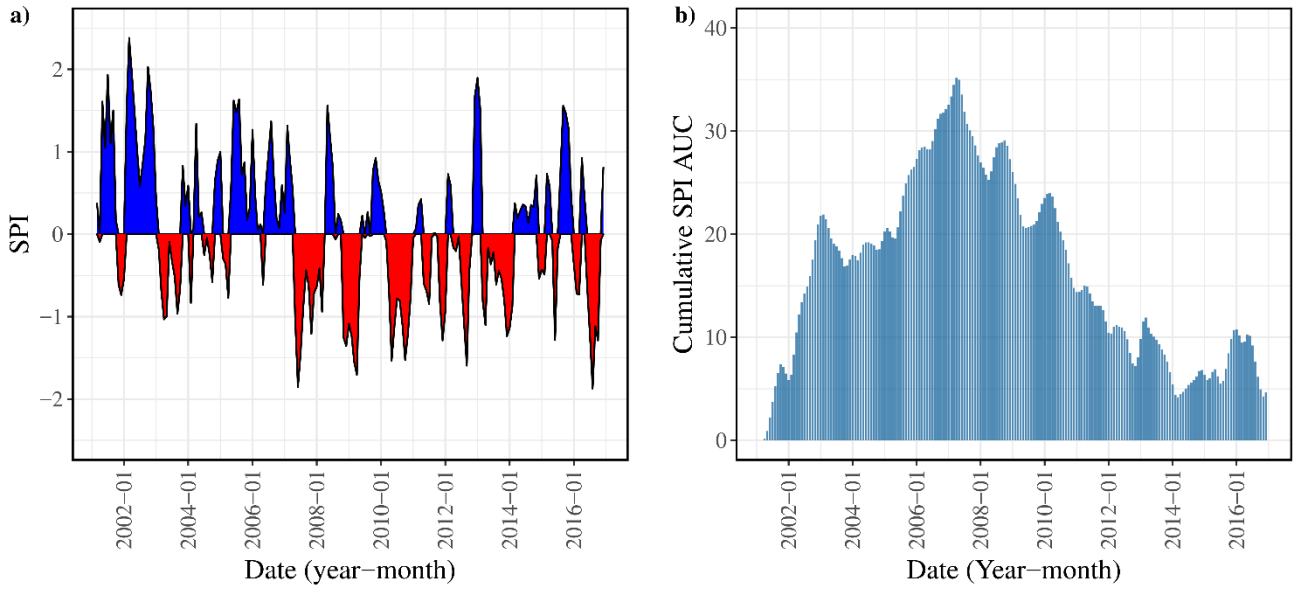

Figure 6. Standardized precipitation index (SPI) a) evolution and b) AUC analysis within the ROI from 2001 to 2016.

3.4. Temperature evolution

Record temperature of around 29°C were found on December 2016, the month prior to the event and the highest since 1979 within the ROI.

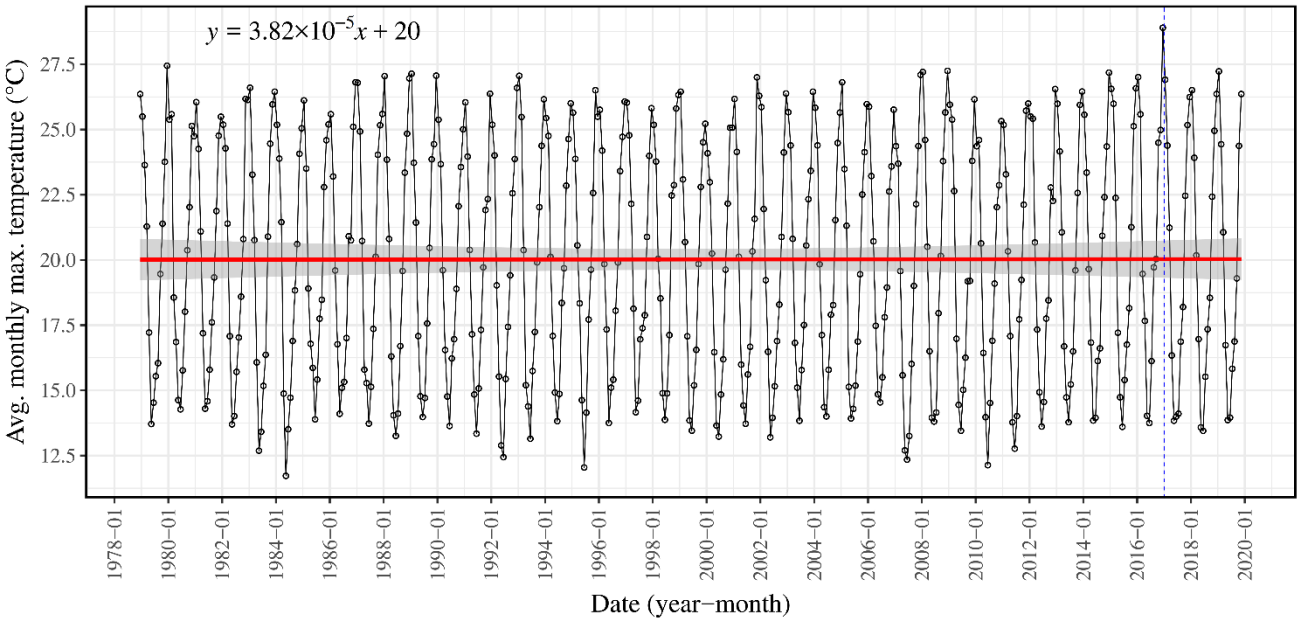

Figure 7. Average maximum temperature within the ROI from January 1979 to December 2019. Red line corresponds to the data trendline, the gray zone is the confidence interval, and the vertical dashed line is the fire start date.

3.5. Canadian FWI

FWI evolution and validation are shown in Figure 8. All datasets exhibit an increase in the FWI during the event (Figure 8a, 8c and 8e). On the other hand, a FWI map is shown in Figure 9. As it is possible to observe, on January 24th, Aqua FWI values at the north of the ROI exhibit extreme FWI values of 52.4±5.5, which is a day prior to the catastrophic events that destroyed the village of Santa Olga.

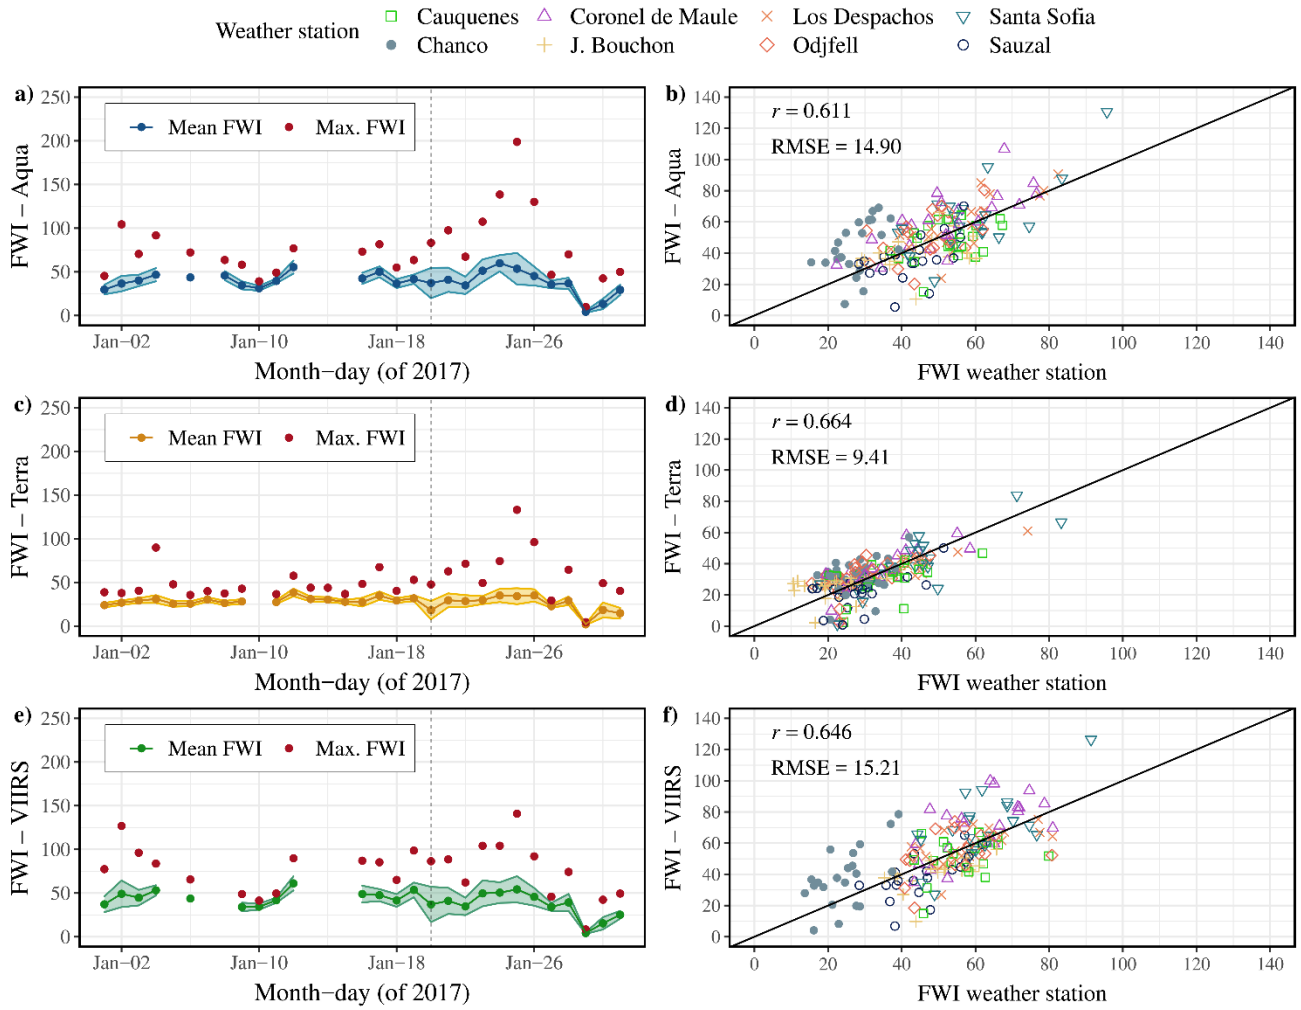

Figure 8. Canadian FWI evolution for a) Aqua, c) Terra and e) VIIRS-SNPP, and validation for b) Aqua, d) Terra, and f) VIIRS-SNPP. The colored areas in a), c) and e) represent the standard deviation of the FWI. The vertical dashed line corresponds to the fire start date.

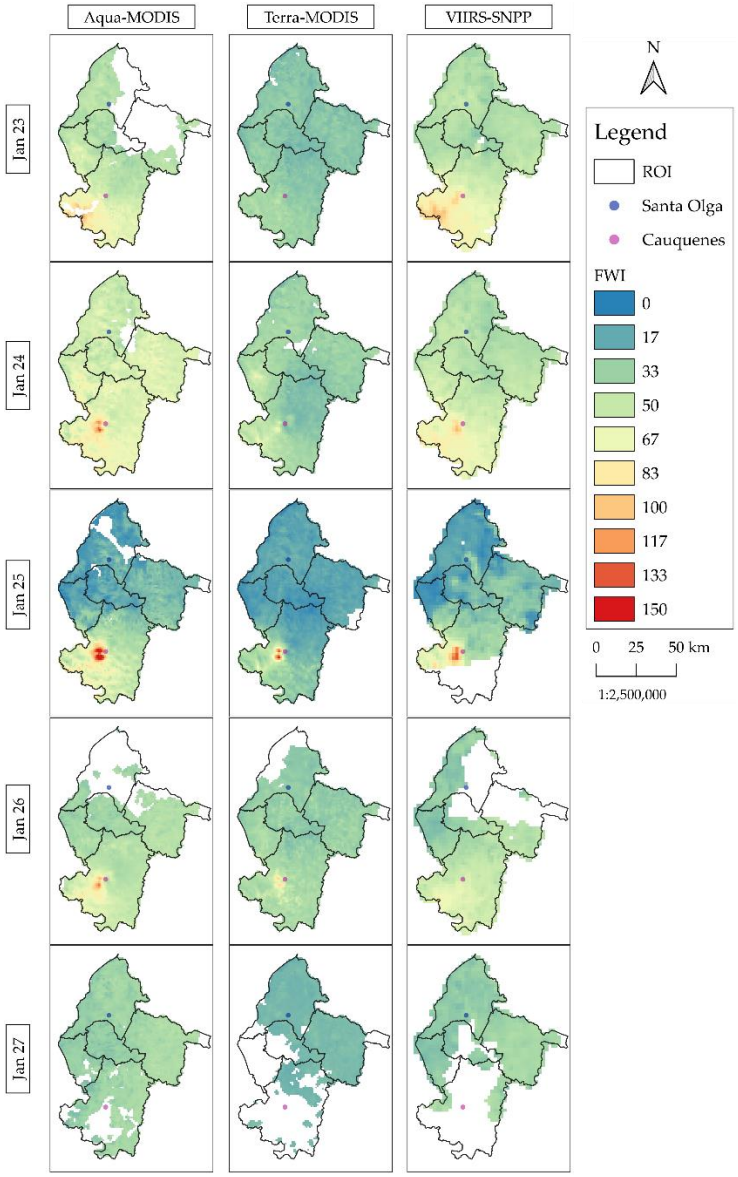

Figure 9. Canadian FWI estimated with Aqua-MODIS, Terra-MODIS, and VIIRS-SNPP, from January 23 to 27, 2017.

4. Conclusion

The *Las Máquinas* wildfire took place under exceptional meteorological conditions. The lowest NDVI values were registered for Empedrado during the event. On the night of January 25, the wildfire propagated at a peak rate, particularly among Empedrado (center), Constitución (north) and San Javier (east) (Fig. 4). The SPI data shows a consistent moderate-to-severe drought in the ROI, in agreement with the mega-drought observed in central Chile (Garreaud et al., 2020). The fire also occurred in a period with a record averaged maximum temperature (Fig. 7).

FWI results show that the index can be calculated on a daily basis from remotely sensed data (and wind-speed simulations), and that a day prior to the catastrophic events in Santa Olga, extreme FWI values were observed within the Constitución municipality. Moreover, the pre-fire FWI trend analysis (from January 1 to 19) showed positive slope values, which might be an indicator of wildfire risk.

From the FWI validation results, it is possible to conclude that the use and application of a remote sensing methodology to calculate the FWI is feasible, since the results were neither strongly overestimated nor underestimated.

Through remote sensing, we were able to compile a large amount of open-access satellite-based information with a good spatial and temporal resolution. This detailed information, and the reported framework for retrieving and processing the data, can contribute to the forensic study of large wildfires, particularly those occurring in remote areas or countries without a sophisticated wildfire safety and response infrastructure.

Land Use Land Cover Change, Wildland-Urban Interface, Dynamic Modelling, Simulation, Risk Mapping

Abstract

We propose a modelling framework aimed at representing change in fire risk level due to land cover change, and more specifically to change in the map of Wildland Urban Interface (WUI). The framework is composed of one module that simulates transitions between classes of the land cover matrix using a "state-transition" model, while a gravity-like model is used to represent discontinuous urban spread in relation to the land cover matrix dynamic. The WUI map is calculated using the WUIMap model at each step of time: this later method crosses some fuel types and classes of scattered buildings spatial distribution. A risk level is associated to each interface type based on a rules based assessment of hazard and vulnerability components.

The methodology was applied to the French sub-mediterranean Baronnies Provençales Regional Natural Parc. This area was up to now few prone to forest fire, mainly due to its elevation, but climate change scenarios let anticipate the average climate fire risk level will drastically increase in this area during the next decades. The objective was to assess the increase part of risk level originated by land cover change, and provide a spatial representation of this change. Results show that although spread of scattered buildings will remain low in terms of number of buildings, its impact on risk components, and specifically on territorial vulnerability, is considerable, as a low number of buildings may impact very large portion of the territory in terms of risk. In a further step of this research, new multicriteria models will be used to refine risk assessment.

1. Introduction

Drivers of wildfire risk change are numerous, including climate change and land cover change (FUME 2013). Because of climate change, wildfire risk will raise in both latitude (toward the North) and altitude. However, in many situations, climate change may be considered uniform at the scale of local territories. On the other hand, land cover change affects the spatial distribution of the risk within local territories, especially if the global risk, associating hazard, vulnerability and exposure components (IPCC 2014), is considered. Together with change in vegetation fuel, dynamic of wildland urban interfaces is a key factor of change in such global risk.

Anticipating future fire risk at local scale is a key element for land management and planning activities in wild fire prone areas. We propose a method of evaluation of risk change in relation to WUI dynamic. It is applied to one backside French South-Eastern supra-Mediterranean protected area: the Baronnies Provençales Regional Natural Parc area (Parc Naturel Régional des Baronnies Provençales). It gathers some 116 Eurostats Local Administrative Units (LAU, formerly NUTS 5), ie. "communes". Due to its elevation (from 300m up to 1500m), and the attenuation of the Mediterranean influences, this area was up to now relatively little prone to forest fires. Different works (Chatry et al., 2010, Galizia et al. 2021, Romero and Ganteaume, 2020) show that this situation will change in the next few decades due to climate change and land cover change.

2. Objectives

The objective is to provide an assessment of future change in risk spatial distribution related to change in WUI extend in a low mountain protected area. The risk to be assessed is the global risk, integrating hazard, vulnerability and exposure (Birkmann et al, 2014). The temporal perspective, ie. the simulation time period of the modelling exercise, is the next two to three decades (2050-2060).

3. Method

3.1. Risk assessment at WUI

WUI typologies, which characterizes the relationship between fuel areas and areas of vulnerabilities, are used as estimators of global risk level. Change in risk spatial distribution is assessed based on change in WUI map. The WUI typology used is the WUIMap (Lampin-Maillet and Bouillon, 2011) model one. A scale of risk associated to WUI types is proposed, combining a hazard component and a vulnerability component to calculate a global risk index for each WUI type (figure 3).

3.2. Future WUI change

Future WUI change are simulated based on a couple of Land Use/Land Cover Change (LULCC) change models (Maillé and Espinasse, 2012). This approach separates two main types of Land Cover Change (LULCC): i) scattered buildings diffusion-densification simulated by a gravity-like model and ii) the change in land cover "matrix" simulated by a "state-transitions" model. It also separates and articulates land cover change processes (physical) and some land uses change processes (symbolic).

On a conceptual level, the model considers land cover classes, representing land cover types. However, land cover classes are endowed with attributes (similarly to computer sciences "classes") and have their own behavior (dynamic). We call legend (or nomenclature) the list of the land cover classes. Patches are spatial instances of a class (polygon, pixel, continuous set of pixels…). The model then represents two types of dynamic: semantic transitions (change of classes) and state change (change in attribute values).

The model is based on a very simple legend (nomenclature) of 4 (plus 1) land uses/land cover dynamic classes: i) F: Forest lands, ii) W: non-forest wildlands (opened and half-opened, including some pastoral lands), iii) A: agriculture (cultivated, excluding pastoral lands), and iv) U: urban and other artificialized lands (including roads and infrastructures). One last land cover class gathers land covers supposed static (water areas and some mountain mineral areas). WUI land cover classes are not part of the legend (nomenclature), but are derived from the model outputs.

The state of land cover classes is represented by attributes, depending on the LC class. 3 main state attributes are represented: fuel load (concerns the only W land cover class), potential of building density (all non-urban dynamic land cover classes) and anthropogenic pressure (only W land cover class). Attributes values are normalized between 0 and 1:

- for fuel load, 0 is the minimum load (herbaceous stratum only), 1 is the forest state ;
- for potential of building density, 0 is a non-buildable area, 1 is an area that can evolve up to continuous urban, according to the land planning document ;
- for anthropogenic pressure, 1 represents "fully" used area (no free ecological dynamic possible: urban and periurban lands, cultivated areas, high pressure pastoral area), 0 represents area with free (or quasi-free) ecological dynamics (totally abandoned areas).

Among the land use change processes represented by the model, the buildable state of land patches is a key factor of WUI dynamics, linked to land planning activity. However, our approach is purely geographic, as the only variables that drive the dynamic are than land cover and topography. The underlying anthropogenic and/or natural processes determining land cover changes are not explicitly represented. For example, change of one given land patch from not buildable (0) to fully buildable (1) (symbolic state) only depends on initial land cover class of the patch, continuity with other buildable areas, local initial building density and some other topographical variables defining an "urban potential" (average altitude, slope and aspect of the patch). A stochastic residual comes to modulate the results of the deterministic calculation, in order to propose a normal representation of the spatial distribution of the unknown information (typically, personal human decisions).

Finally, an interface map is calculated at each step of time using the WUIMap model. This one cross some specific classes of building density and classes of vegetation aggregation. This model was demonstrated to provide good indicators of the global (hazard/vulnerability) risk (Lampin-Maillet & Bouillon, 2011). The different classes of WUI stemming from the WUIMap model are provided in the legend of fig 3.

The following table proposes a synoptic view of the model and its relationship with the WUIMap risk model.

Table 1: Synoptic view of the WUI change model and its relationship with the WUIMap risk model. *Note that W->F semantic transition results from two possible dynamics: forest spread or afforestation, for which the W->F transition automatically occurs when the fuel load of a W patch reaches 1. **Also the Non-U -> U transition automatically occurs when building density overcomes the WUI very high-density threshold.

	Buildings overlay	**Land use/land cover "matrix"**							
		Physical land cover				**Symbolic land use**			
Class of spatial dynamic	Diffusion	Semantic transitions (change in LULC class)			Attribute change	Semantic transitions		Attribute change	
Dynamic	Scattered buildings diffusion/densification	Forest advance (W -> F)*	Afforestation (W->F)*	Urbanization** (NonU→U)	Natural fuel load increase of W FL ∈ [0-1]	Not buildable -> buildable	Land abandonment (A->W)	Potential of building density pBD ∈ [0, 1]	Antropogenic pressure AP ∈ [0, 1]
Concerned classes	A,F,W	W	W	A,F,W	W	A,F,W	A	A,F,W	W
Spatial representation	Point	Pixel	Polygon	Polygon	Polygon	Polygon	Polygon	Polygon	Polygon
Main dynamic factors of the change	- Local building density - Potential building density	Anthropogenic pressure (AP) -Forest neighborhood	-Fuel load (FL=1)	-local building density (lBD)	-Anthro-pogenic pressure (AP)	-Urban neighborhood -Local building density lBD -Urban potential	-Urban neighborhood -Local building density lBD -Agriculture potential	-Urban neighborhood (UNB) -Local building density lBD	-Building density (lBD) -urban neighborhood
Main static factors of the dynamic	- Urban potential	-Forest potential			-Forest potential			-Urban potential	-Pastoral potential
Derived outputs	Local building density lBD ∈ [0,1]	Forest land and neighborhood		Urban neighborhood (UNB)	Fuel load and structural index			Wildlands state and neighborhood	
⇩	⇩	⇩		⇩	⇩		⇩		
WUIMap inputs	Buildings density (low-high)	High fuel aggregation WUI types		Very high building density WUI type	Intermediate fuel aggregation WUI types		Low fuel aggregation WUI types		

3.3. Data for calibration (diachronic mapping), validation and scenarios

Parameters of the model are calibrated based on diachronic mapping. Three main data sources are used:

- French cadastral database ("DGI Majic 3") allowed assessing the "scattered building dynamic", for each of the commune. This database contains the buildings, georeferenced, with their date of construction, unless for ancient one (before 1930). It is so possible to assess an historical rate of spread of scattered buildings for each commune.
- Land cover database, including Corine Land Cover 1988/1990, 2000, 2006, 2012, 2018, and *Crige* regional land cover database 2006, 2014, 2018. These database are jointly used:
- Satellite images for date older than 1988 as well as downscaling the oldest land cover database, CLC1988 notably, in order to improve inter-date consistency.

These data allowed calculating different parameters for different contexts (for each of the communes (LAU) – for instance) of the model including notably:

- rate of spread of scattered building, in relation to topography and urban environment (urban potential)
- rate of spread of forest land on opened and semi-opened wildlands, in relation to topography (forest potential)
- speed of closure of wildlands in relation to the forest potential
- etc.

More complex "atomic models", ie elementary models that are not modules of other higher lever models, are also calculated. Typically, an atomic model is specified, based on GLM analysis of past data, for assessing the

rate of land use transitions such as land abandonment probability, in relation to agriculture potential (topography, shape of the patch, urban neighborhood…). A GLM model of change from not buildable to buildable classes (potential of building density different from 0) in relation to the contextual building density and urban neighborhood is also specified. To do so, sample of patches are drawn at random and transition model are calculated by logistic modelling. Sub-samples of the patches are kept for validation.

Based on these parameters assessments, different scenarios are defined, which are specified by tuning the values of some of the parameters: protection of the environment, conservation of agriculture and forest, economic development, and one projective scenario (simple projection of the current dynamics):

- ***Scenario "protection of the environment":*** Preservation of natural spaces is favored without strong demographic impetus, which retains its trends (lower rate of discontinuous urban spread than measured in the past). On the other hand, the scenario promotes livestock farming to maintain open natural spaces (low rate of wildland closure).
- **Scenario "*conservation of agriculture and forest*"**: it promotes the maintenance of agricultural activity and production (low rate of agriculture land abandonment), as well as livestock farming to maintain open relict natural spaces (low rate of wildland closure). It also promotes logging.
- ***Scenario "*economic development*"***: it promotes "urban" economic activities as well as tourism that may have an impact on space: this is reflected in particular by a possible extension, even local, of high-stakes areas within or in contact with little artificialized areas (high rate of spread of discontinuous urban areas).

3.4. Periods and step of time

The past period for model calibration is 1974-2018. The step of time of simulations is annual.

4. Results

Examples of results showing the map of scattered urban spread and land cover matrix change simulations using the projected scenario are proposed in the following figures.

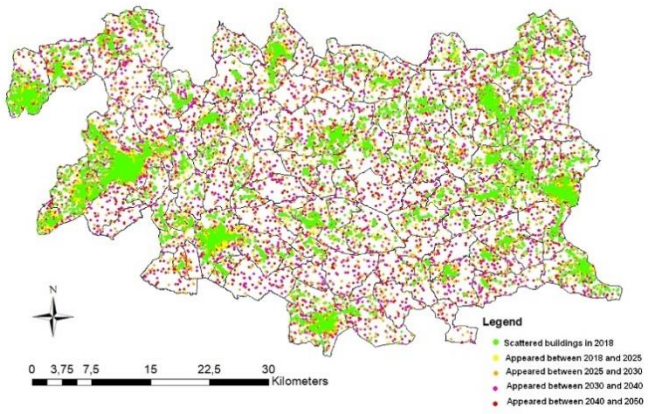

Fig 1. simulation of future scattered urban spread between 2018 and 2050 (projective scenario)

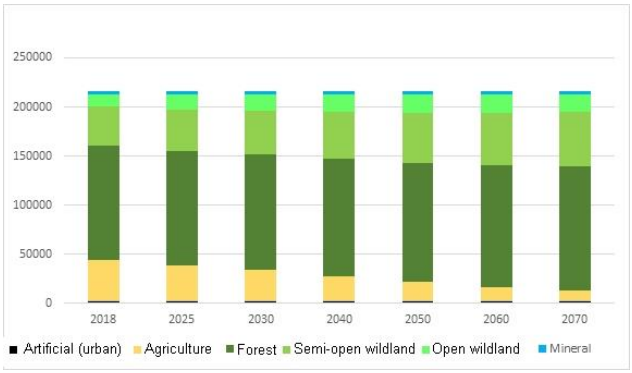

Fig 2. Quantitative change of the land cover matrix 2018 and 2050 (projective scenario)

A WUI maps are calculated based on these land cover map simulations. These maps are indicators of the global risk at local scale.

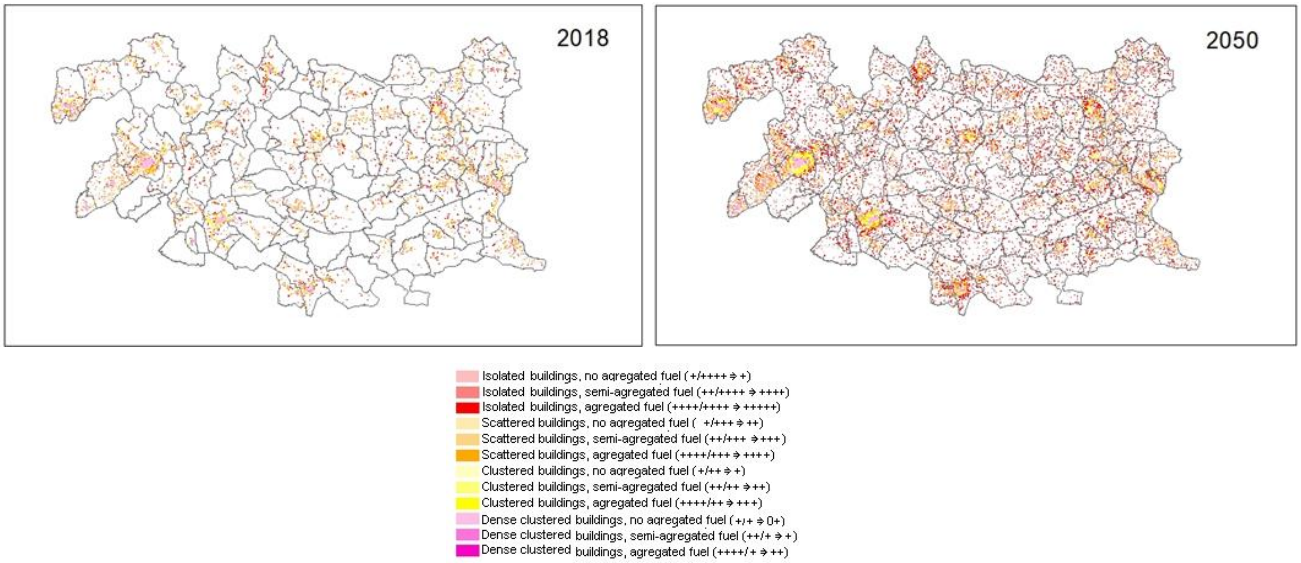

Fig 3. Simulated change in WUIMap interface types spatial distribution between 2018 and 2050, as indicator of risk. The legend mention the risk indicator associated to each WUI type in the form of:

hazard indicator / vulnerability indicator => global risk indicator

The vulnerability here considered is an "intensive" vulnerability, assessing the vulnerability of each building related to the type of interface it belongs to. The extensive vulnerability has also to be calculated, taking into account the number of buildings within the interface patches.

5. Conclusion

Anticipation of future wildfire risk in areas up to now little prone to that risk, is a key decision support for land management and planning. We propose a model for WUI spread simulation as the result of several land cover change, including scattered buildings and urban spread, as well as fuel spread on abandoned agriculture and pastoral areas. The objective of the model is not to preview the future risk absolute value, but rather to assess the possible effect of different land management scenarios on the future spatial distribution of wildfire risk. It is a support for today decisions. The risk model is simply based on WUI types. Results shows spectacular future increase of risk levels on most of the territories, while land cover change remain relatively modest: the spread of low density scattered built area results in some large areas risk increase, as low density built areas have the highest risk as soon as a significant fuel biomass is present. As a perspective, one other more complex analytical risk model (Chai-Allah & Maillé, 2020) is also used allowing better assessing the different components of the risk, including hazard, vulnerability and exposure. This later model is an expert-opinion based multicriteria one, where the interface type is one of the criteria for some of the components calculation. A panel of experts assessed the weight of this criterion for each of the relevant components. Up to now purely static, such a multicriteria risk model will be used in the future to assess change in risk level because of land cover change at territorial scale.

Abstract

Realistic modeling of the vegetation fires based on reliable data from laboratory experiments is a key factor in the prediction of the fire dynamics behavior and its spread rate in wildlands. A robust understating of the fire behavior in different species can provide a pragmatic insight to take precautionary steps to mitigate the fire risks in Wildland-urban interfaces. Computational Fluid Dynamics (CFD) modeling of wildland fires offers a considerably high load of information needed for engineers and policymakers. This paper addresses the numerical modeling of the Ivy (Hedera helix) and grapevine (Vitis) plants using the fire dynamics simulation for the fire behavior analysis. Other species which authors have conducted experiments are Acacia, Apple tree, Arizona cypress, Bay laurel (Laurus nobilis), Blueberry tree (Prunus Spinosa), Cherry Tree, Fig tree, Gum rockrose (Cistus ladanifer), Hydrangea, Kiwi tree, Leyland cypress, Lindens (Tilia), Loquat (Eriobotrya japonica), Nerium oleander, Olive tree, Pacific madrone (Arbutus menziesii), Rhus typhina (Anacardiaceae), The Holly (Ilex Aquifolium), Thuja occidentalis (white cedar), and Wild Blackberry (Rubus Ulmifolius) shrub, in alphabetical order. The corresponding mathematical modelings of these experiments are being carried out by the authors.

The current numerical study was performed using the NIST open-source FDS code, developed by the National Institute of Standards and Technology with specific emphasis on the heat release rate from fires in different types of indigenous plants common in the Mediterranean climate, especially in Portugal. The validations of the numerical results are realized based on the observations from the experiments conducted at the Laboratório de Estudos Sobre Incêndios Florestais (LEIF) by the authors. The large-eddy simulation (LES) is used in these sets of simulations to close the turbulence equations in the low-Mach regime. The 2nd order accurate finite difference approximation scheme is used to discretize the governing equations on uniformly spaced three-dimensional staggered grids. The flow obstructions are treated using the simple immersed boundary method. Comparing the results of the FDS with those from the practical experiments, it is concluded that mathematical modeling of the vegetation fires can provide reasonably accurate results based on the fuel's physical and chemical characteristics along with operating boundary conditions.

1. Introduction

Forest fires as uncontrolled and non-prescribed combustion or burning of plants are considered a serious threat not only to the forests by jeopardizing the fauna and flora, mistuning the biodiversity in forest ecosystems but also in severe cases of extended fires, the residential areas. During drought seasons, especially in summers, with escalating effects imposed by global warming, the forests become more vulnerable caused by scattered litters of dry senescent leaves, twinges, and twigs as potent fuel types to make forests susceptible to lethal fires with colossal loss of the vegetation cover. Wildfires can become more intensified based on the environmental conditions (e.g., meteorological conditions, and terrain topography) which in turn can lead to irreparable casualties for the residential sites nearby or even farther. A forest fire may exist as surface, underground, ground, crown fires, and in severe cases as firestorms with natural or man-made causes. According to the European Commission report on forest fires, in 2020, southern European countries, e.g., Spain, France, Portugal, Italy, and Greece were the most affected regions losing thousands of acres of forest lands, including Romania, which is an expanding threat to the central and northern Europe. Based on the recent forest fires in Portugal, especially in 2017, the concept of WUI fires becomes more important than ever, which necessitates more laboratory experiments as the basic requirement for theoretical investigations. Since performing tests on different

vegetation fuels is limited due to the dimensions of the species with complex arrangements and diversities in nature, FDS can be an efficient tool to simulate the fire behavior based on the data gathered from laboratory-sized burnings. The FDS results can be subsequently applied to the diverse species in size and arrangements to have a realistic vision to define precautionary measures and policies. This paper intends to address the computational fluid dynamics modeling (CFD) of the fire behavior in Ivy and grapevine plants, using the FDS based on the experimental data conducted by the authors at LEIF located in Lousã, Coimbra (Portugal). This methodology is an efficient way to broaden the vision of engineers and down the road the policymakers in urban planning sectors.

2. Solution Methodology in FDS

The current FDS formulation applies the low Mach number assumption which yields in filtering out the acoustics from the equations and allowing the variations both in temperature and density, Rehm and Baum (1978). This approximation converts the governing equations into the elliptic format in the LES turbulence model. The FDS code utilizes Deardorff's turbulent eddy viscosity sub-grid closure model by default, Deardorff (1980). Turbulent Schmidt and Prandtl numbers are set to the constant values. The fast chemistry eddy dissipation concept by Magnussen and Hjertager (1977) is used for the formulations of the turbulence-chemistry interaction with the single-step reaction for the fuel and oxidizer combustion using the lumped species method, Fox (2003), discussed in McGrattan et al. (2013).

The Runge-Kutta discretization with high stability-preserving (SSP) is used over time for flow variables. This scheme is second order in both space and time. The Poisson equation is solved using the direct fast Fourier transform (FFT) solver. The mesh is uniform and staggered. The immersed boundary method is applied to treat the flow obstructions in the computational domain.

3. Experimental Tests

Five samples of each type of vegetation fuel were used for the experiments. Tables 1 and 2 contain the characteristics of the samples of the Ivy and the Grapevine in detail:

Table 1 – Details of case studies for the Ivy.

Case Nº	Initial Mass (kg)	Final Mass (kg)	FMC_w (%)	Length (cm)	Height (cm)	Depth (cm)
1	13.73	11.35	49.00	70	80	25
2	5.40	4.30	47.00	65	70	20
3	8.40	7.20	46.30	75	80	25
4	13.26	12.00	36.70	80	80	25
5	17.96	16.70	52.40	75	80	28

Table 2 – Details of the samples of the Grapevine.

Case Nº	Initial Mass (kg)	Final Mass (kg)	FMC_w (%)	Length (cm)	Width (cm)	Depth (cm)
1	1.12	0.14	60.40	124	68	14
2	1.12	0.05	61.20	130	67	16
3	1.10	0.08	51.50	130	68	14
4	1.16	0.12	56.67	133	69	15
5	1.18	0.12	59.21	127	67	13

In Tables 1 and2, the initial and final masses refer to the mass of the plants before and after the burning process in kilograms measured by the instantaneous mass acquisition system. The wet basis moisture content of the species is measured using the digital moisture analyzer.

The first experimental case, the Ivy plant, fixed to a massive vertical plate to mimic the common ivy-green-wall, in which the length in Table 1 refers to the horizontal distance from the point A to B, and the height refers to the distance from B to C, as pointed out in Figure 1. In the case of the Grapevine, the sample has a horizontal configuration on a metal grid, in order to create the scenario of a pergola of vines that is so often seen next to houses. The length in Table 2 is the distance from the point D to E, and width refers to the EF length as illustrated

in Figure 2. Depth (cm) in both cases defines the distance between the opposite sides of each sample. The experiments have been carried out in the environmental conditions with a mean temperature of 26.7 ºC, 23.6 ºC, and relative humidity of 42.4%, and 58.2% for the Ivy and the Grapevine, respectively.

Figure 1. Laboratory tests, Ivy.

Figure 2. Laboratory tests, Grapevine.

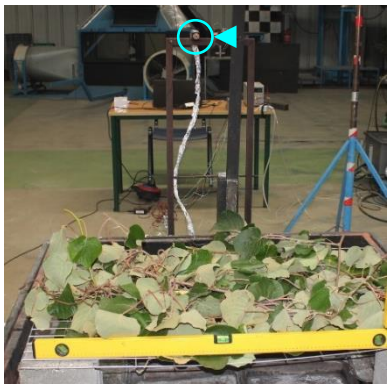

Figure 3. The location of the heat flux sensor.

Figure 4. S-type pitot tube in the experiments.

Fire evolution was recorded by three RGB and two IR cameras. Having the calibration rod at the RHS of Figure 3 (distance between red/white tapes is 20 cm), one can determine the flame dimensions. The thermal behavior of the fire was captured by installing the sets of thermocouples to measure temperatures at different points and the heat release rate was measured using the heat flux sensor installed at a 1.0 m height. The S-type pitot tube is used to detect the uprising convective gas flow velocity from fire installed at a 3.5 m height, as illustrated in Figure 4. The mass-loss rate is measured continuously using the load cells installed at 3 points beneath the test stand with a precision of 10 gr, connected to the summing junction, before connection to the digital indicator.Two trays of denatured alcohol (96% v/v) each containing 200 ml and four trays each containing 250 ml, were used to ignite the Ivy and the Grapevine plants, respectively. The reason for utilizing the trays of alcohol is to imitate the fire in the understory in wildfires and use a sustainable energy source to keep the fire lit in the primitive stages of the experiments.

The dry basis moisture content of each species was measured based on the mass difference between the wet and oven-dry conditions for both pre and post-burn cases as reported in Tables 3 and4**,** as follows

Table 3 – Details of the samples of the Ivy.

	Pre-burn			**Post-burn**		
Plant segment	m_0 (g)	m_f (g)	FMC_d (%)	m_0 (g)	m_f (g)	FMC (%)
Foliage	177.10	63.23	1.80	98.79	54.86	80
0 < Ø < 3 mm	517.60	299.57	0.73	197.84	129.13	53
3 < Ø < 6 mm	300.33	122.44	1.45	281.86	150.64	87
6 < Ø < 10 mm	365.00	166.60	1.19	208.22	93.60	122
Ø > 10 mm	2350.00	973.70	1.41	3202.75	1461.60	119

Table 4 – Details of the samples of the Grapevine.

	Pre-burn			Post-burn		
Plant segment	m_0 (g)	m_f (g)	FMC_d (%)	m_0 (g)	m_f (g)	FMC (%)
Foliage	368.99	137.29	1.69	52.14	31.38	66
0 < Ø < 3 mm	62.32	22.89	1.72	13.22	8.08	64
3 < Ø < 6 mm	147.33	60.82	1.42	93.46	51.90	80
6 < Ø < 10 mm	33.68	17.52	0.92	18.18	13.86	31

In Tables 3 and 4, m_0 is the initial mass, m_f is the final oven-dry mass in grams, and FMC_d is the dry basis moisture content. Different classes of species' segments are divided into 5 categories: i) foliages; ii) parts with a diameter/thickness (Ø) less than 3 mm; iii) from 3 to 6 mm; iv) 6 to 10 mm; and v) larger than 10 mm for both pre and post-burn cases.

4. FDS Modeling

4.1. The Computational Domain

To study the fire behavior and specifically the heat release rate, as an important factor from each species, the structured, staggered grid is generated for two computational domains. For the Ivy case study, the 3D sketch corresponds to Figure 1, and the domain has a dimension of 0.9 m × 1.0 m × 3.7 m in the x, y, and z directions, and contains 3,971,968 grid cells as illustrated in Figure 5, with two trays of alcohol (colored in red). The computational domain for the Grapevine corresponds to Figure 2 and has a dimension of 6.0 m × 6.0 m × 6.0 m in the x, y, and z directions, containing 2,979,200 mesh cells, as depicted in Figure 6. In this case, four trays of alcohol were used to ignite the plant. The details of the samples correspond to the Case Nº 2 of the laboratory tests reported in Tables 1 and 2.

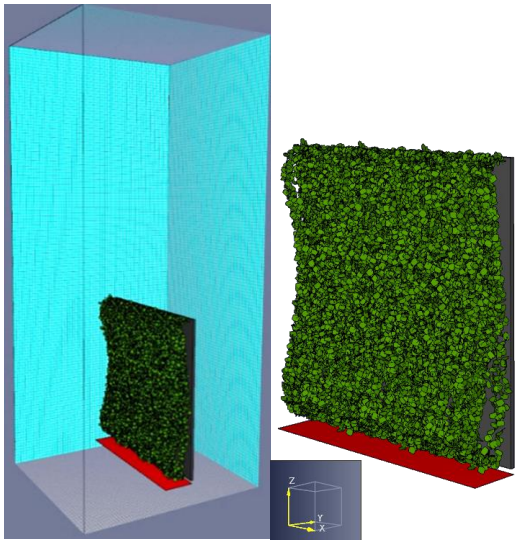

Figure 5. 3D Computational Model, Ivy.

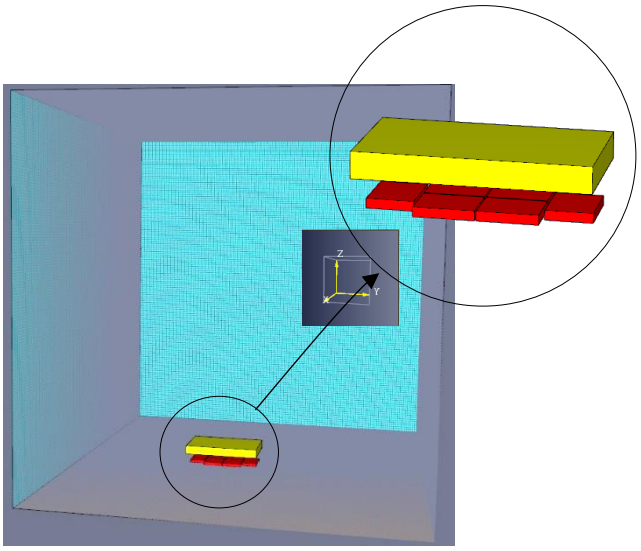

Figure 6. 3D Computational Model, Grapevine.

The boundaries of the CFD of fire in both plants correspond to the details mentioned in Tables 1 to 4. The 3D model for the Ivy is sketched in 3D-CAD SOLIDWORKS software. In the second stage, the geometry is translated into the parallelepiped volume using MATLAB code. In the Grapevine test case, the Lagrangian particle cloud approach is used to model the presence of leaves and twigs along with a possibility for the flow penetration through the cuboid. In both cases, the XY planes beneath the sample are set to be solid and adiabatic, while other boundaries are set as air vents to allow the passage of flows from either side corresponding to the test conditions.

5. Results and Discussion

The FDS simulations of both plants were performed using the equivalent hydrocarbons with CHON contents of 1.0, 1.7, 0.72, 1.0E-3, and 2.0, 3.7, 0.72, 1.0E-3, for the Ivy and the Grapevine, respectively. The Ivy plant is

simulated as a porous obstruction with a 3D configuration inspired by the factual test sample. The Grapevine is modeled using the Lagrangian particle cloud method. The plant is simulated as an ensemble of 4 different classes mentioned inTable 4. The results of the transient LES simulations for both cases are demonstrated in Figures 7 and 8 for the corresponding time-lapse of 0, 5, 15, 20, and 40 seconds in both real-time laboratory experiments and CFD simulations. The heat release rate from FDS for each case study is compared with the corresponding HRR from the laboratory tests conducted at LEIF, in Figures Figure and Figure .

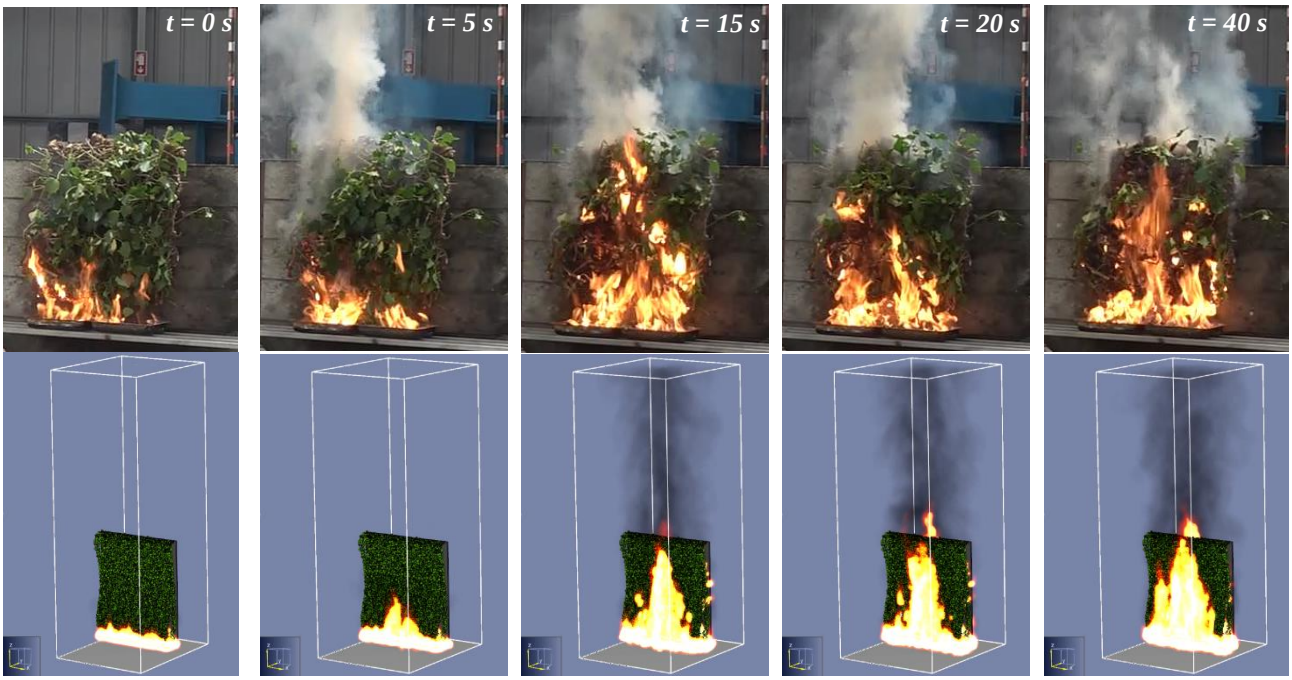

Figure 7. Comparison of the real-time lab experiments with numerical modeling from FDS for the Ivy plant at 0; 5; 15; 20; and 40 s.

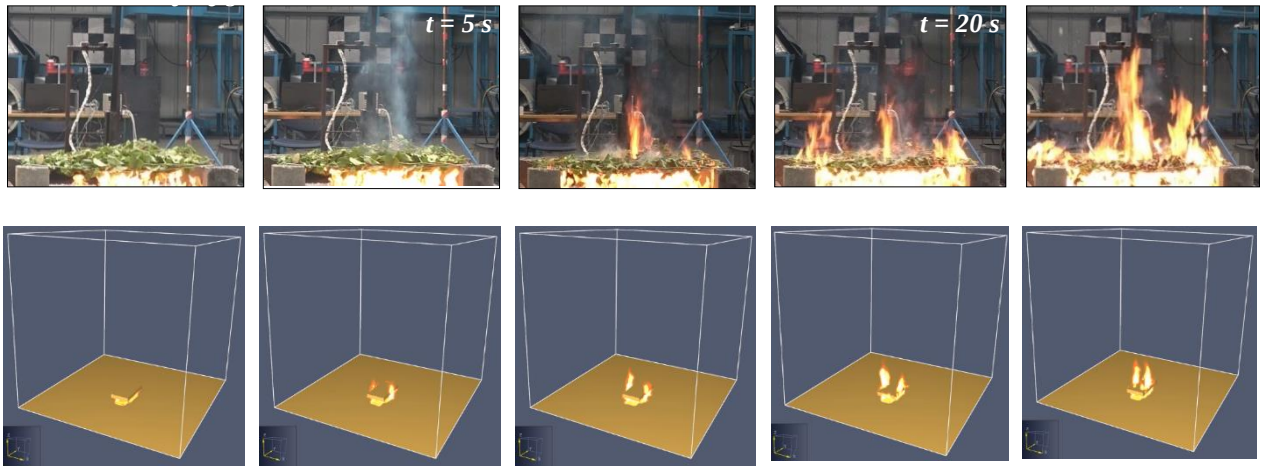

Figure 8. Comparison of the real-time lab experiments with numerical modeling from FDS for the Grapevine plant at 0; 5; 15; 20; and 40 s.

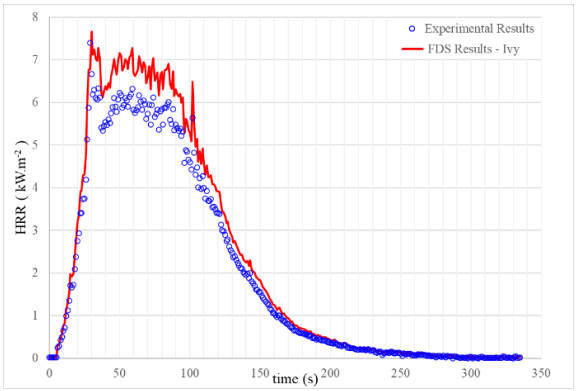

Figure 9. Comparison of HRR for experimental and numerical cases, Ivy.

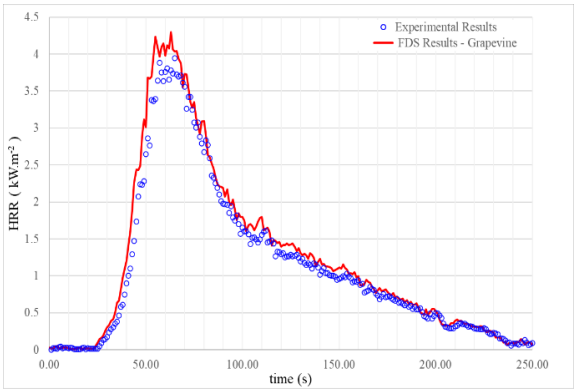

Figure 10. Comparison of HRR for experimental and numerical cases, Grapevine.

6. Conclusion

In this paper, both experimental and numerical modeling of the fire behavior for the Ivy and the Grapevine plants are addressed. Utilizing the capability of FDS in the simulation of fires can be very helpful for fire researchers and experts. The heat release rate from each vegetation species is an important factor that needs to be analyzed for further fire risk analysis and management. Since FDS solely cannot materialize this goal, experimental observations for reliable fire calculations are mandatory. Modeling the fire behavior using the FDS, developed by NIST, the authors could simulate the fire behavior in two forest species with a promising agreement with the experimental data. Moreover, the authors have carried out multiple experiments using different types of plants indigenous to the Mediterranean climate, especially in Portugal. For future work, it is intended to perform FDS modelings based on the available laboratory data to have a complete database for thermal characteristics of the vegetation fuels, their interactions with the surrounding environment, and their contribution to the wildfires. Last but not the least, the final purpose of the ongoing reach is to categorize the forest species as less vulnerable to the hazardous types which can jeopardize lives and residential sites, especially in WUI regions.

Abstract

It is a well-observed phenomenon in developed societies that, in order to return to nature, a part of the society seeks to settle near forests or in the forest creating wildland – urban interface (WUI) areas. It has special features and generates significant risk of fire on the experts try to find responds. In the present study, the authors intend to explore the theoretical foundations of the application of the sprinkler system in forest protecting built environment from fires. Understanding and finding basic rules for the effective sprinkler system application can contribute to reduce the impacts caused by fire. As research methods, the authors based their study mostly on geometric calculation and the physics of evaporation, moreover the basic mathematical formulas as well as logical conclusions were also used. Authors found geometry of circle overlapping generates always problems regarding the effectiveness of sprinkler systems. 50% overlapping in longitudinal axis seems to be acceptable solution. In this case overlapping rate is 78% per circle with 1.6 kg.m-2 water coverage levels and 22% of the circles have 0.8 kg.m-2 water coverage level. As another solution, sequentially used system seems good solution for replacing the evaporated water, where 75% of the coverage level is accepted as lowest threshold of the effective rate.

1. Introduction

It is a well-observed phenomenon in developed societies that, in order to return to nature, the middle class of the society seeks to settle near forests or in the forest (Petrov and Marinov 2020). The extent of the danger and the significance of the risk are shown by the emergence of the concept of WUI (Wildland Urban Interface) in recent decades (Caballero et al. 2007; Johnston 2018), which refers to the mixing of the natural and the built environment. The characteristics of fires in the WUI environment have been examined in a number of studies that suggest that both fire prevention and firefighting face new types of challenges (Radeloff et al. 2018; Koksal et al. 2019). There are a number of answers to the questions generated by the challenges, one of which the authors seek to address in this article. The essence of the question in this article, i.e., the aim of the research, is to examine the possibility that sprinkler systems used in closed areas to extinguish fires could be suitable or not for use in open areas, especially for the forest-related built environment to protect them from the destructive effects of fire. There are many researches focusing on the application of sprinkler system, mostly in closed areas, both residential (Bénichou at al. 1999; Butry at al. 2007; Moinuddin 2019) and industrial environments (Garis et al. 2018; Vishnoi 2017), however the option examination of their effectiveness in open space is missing. Therefore, in the present study, the authors intend to explore the theoretical foundations of the application of the sprinkler system in forest fires, and what principal criteria such a system should meet. Authors believe that this contributes to find basic rules for the effective application.

2. Methods

Authors have examined and analysed the relevant literatures focusing on the sprinkler systems to adapt closed areas experiences to open areas. In addition, they conducted discussions with fire engineers to be expert on this subject. As research methods, the authors based their study mostly on geometric calculation and the physics of evaporation, moreover the basic mathematical formulas as well as logical conclusions were also used. Finding

the basic criteria for the effective application of the sprinkler systems this study uses some simplifications and ideal assumptions.

3. Results

Based on Byram's formula (Byram 1959), 2 m flame length takes about 1.2 MWm^{-1} fire intensity, 1 MWm^{-1} assumed in this study. Based on firefighter practice 2 m flame length requires about 5 m wide watered shrub or vegetation strip to stop fire (Bell 1987). Sprinkler heads create circles footprint; in this study, watered circles are 5 m in diameters. 5 m width is effective at cross axis, but left or right side of this axis watered width is less than 5 m, meaning that it is not effective (it is zero at radius distance at the longitudinal axis in case of a simple circle). Therefore, more than 5 m in diameters circles are required or some parts of the circle footprints accepted as limited effectiveness. In this study, authors count with latter option, that is, some parts of the circle footprints have limited effectiveness.

To raise the effective parts of the footprints, authors use overlapping of the circles to ensure the adequate width of the watered strip. In case of 50% overlapping in longitudinal axis the water amount is double in overlapping areas that is 78% (2 x 39%) of the total circle footprint. In case of 5 m in diameter the maximum overlapping is about 4.33 m in cross lane that is 0.67 m less than 5 m.

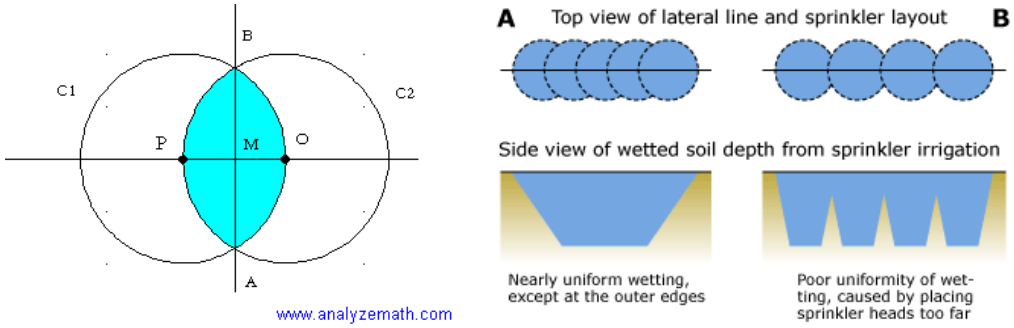

Figure 1. Circle overlapping (left) (Wolfram MathWorld) and footprints of sprinkler systems (right) (Salinity Management Guide 2007)

The 50% overlapping requires more sprinkler head that is 1 head per 2.5 m. Higher position of sprinkler would mean bigger diameter of watered surface however more than 5 m means waste in water use. About 50% overlapping means the optimal water use. It is economical question how many water wasted can balance the higher price of using more sprinkler head. In short time water use is not very important but as a stable, long time existing system can be.

The 1 MWm^{-1} fire intensity, like a shrub or bush fires, requires about 1.2 – 1.8 kgm^{-2} water for stopping fire spread (Murgatroyd 2002; Solarz and Jordan 2010, Delforge 2011). As a thumb rule authors take 1.6 $kg.m^{-2}$ water as effective amount in this study. Each vegetation surface has limited capability of keeping water on its surface. More water than the maximum means that it will flow down the ground and it has no cooling effect. Because of the geometry there is no ideal solution for the effectiveness however it should be optimized or use thumb rules. In this example, 78% (2 x 39%) of overlapping of each circle footprint with 1.6 kgm^{-2} amount of water should be accepted as effective cover rate.

Because of the overlapping of sprinklers' footprint each sprinkler head should produce 0.8 kgm^{-2} water. Top view area of the 5 m in diameter circle is about 20 m^2; it means 1 sprinkler head should produce 16 kg of water (0.8 kgm^{-2} x 20 m^2 = 16 kg). After producing the required amount of water in theoretic and economic view sprinkler heads should stop the water not to waste it.

High temperature as well as low humidity assumed in case of intensive shrub fire; authors count with above 30 ^{0}C degrees. At this temperature thin water layer (or small droplets) on leaves can evaporate quickly. It depends mainly on the temperature, humidity, wind and the surface area of leaves (or the rate of water and surface). Because of the surface tension of the water some additives (e.g., foam agent) is required (ca. 0.1 – 0.5%) to cover the vegetation surface (leaves) with water steadily (or "drops on leaves" is accepted). In case of shrub the leaf area index (LAI) is about 2 that mean a 5 m in diameter circle has 20 m^2 top view area but 40 m^2 of 3D leaf

surfaces. This means that the evaporation surfaces of a 5 m in diameter circle shrub land is about 40 m^2. In ideal case on 31 m^2 leaf surface (78% of 40 m^2) has 0.8 kgm^{-2} water amount, on 9 m^2 (22% of 40 m^2) has 0.4 kgm^{-2} water amount, however it means 1.6 kgm^{-2} and 0.8 kgm^{-2} water amount in top view case.

Rate of water evaporation depends on many factors (Ward and Fang 1999; Marek and Straub 2001), however in this case – sunshine, above 30 ^{0}C degrees, less than 15% humidity, slight wind – as a thumb rule, we can calculate with about 1.5 mmh^{-1}, meaning that overlapping area became totally dry again in 32 minutes, not overlapped area in 16 minutes. After producing the required water – 16 kg per 20 m^2 top view footprint of sprinkler head – because of the evaporation theoretically there are two options:

A) Continuously used sprinklers to compensate the evaporation.

B) Sequentially used sprinklers to replace the evaporated amount of water.

Case A): Because the evaporation is 16 kg per 20 m^2 (40 m^2 leaf surface) per 16 min, the rate is 1 $kg.min^{-1}$ per sprinkler head footprint area (20 m^2); it means requirement for compensate evaporation loss is 1 $kgmin^{-1}$ per sprinkler head. It can be very difficult to find applicable sprinkler head. Moreover, in case of continuously used sprinklers water mist will change the circumstances drastically – cool down the sprayed area and humidity up to 100% – meaning that the evaporation will be reduced even more, as an end point of the function at 100% air humidity actually there is no evaporation.

In case B) the question is that, what is the effective frequency of switching on and off the sprinkler heads. This frequency should depend on the acceptable coverage level of water comparing to the required 16 kg per sprinkler head footprint (20 m^2). Authors think 75% of the coverage level – that is 12 kg per sprinkler head footprint (20 m^2) – is acceptable. It means 22% will be covered by 0.6 kgm^2 (in 3D with LAI: 0.3 kgm^{-2}) while 78% of the head footprint will be covered by 1.4kgm^{-2} (in 3D with LAI: 0.7 kgm^{-2}). Taking into account the evaporation rate that is 1.5 $mm.h^{-1}$ the required switch on frequency is 4 min (0.1 kgm^{-2} evaporated water per 1.5 mmh^{-1} = 1.5 $kgm^{-2}h^{-1}$ evaporation rate). Counting with 4 min sequentially used sprinkler heads the coverage level of non-overlapping area swings between 75-100%, that is 0.6-0.8 $kg.m^{-2}$ on top view footprint, however in case of overlapping area it swings between 87.5-100% that is 1.4-1.6 kgm^{-2}.

Theoretically, on the overlapping area the coverage level should jump up to 1.8 kgm^{-2} that is 112.5% however leaves have limited capability to keep water on its surface[5]. In case of shrubs, it is about 1.2 – 1.8 kgm^{-2}, in this example 1.6 kgm^{-2}. More water than enough means lost as well as the amount above the upper limit of effectiveness. This means that 12.5% as an extra is not effective because it goes down to the ground. Logically each sprinkler head footprint has one overlapping part that is 39% of the total area. In case of 5 m in diameter circle it takes 7.8 m^2 of 20 m^2. The lost water is 0.2 kgm^{-2} x 7.8 m^2 = 1.56 kg. This amount takes 23.4 kg wasted water of the total of 60 kg used water per hour.

The 300 m long wetting zone requires 120 sprinkler heads (2.5 m per head). Total water amount – to reach the protection capability (120 heads x 20 m^2 x 0.8 kgm^{-2}) – takes 1,920 kg water. Water consumption of the system – in case of 4 min sequential use of heads replacing the evaporated water (60 kgh^{-1} per head x 120 heads) – takes about 7,200 kg water per hour. Wasted part of the used water during service is 39% that means 2,808 kg water per hour.

4. Conclusions

There are many studies dealing with the application of sprinkler systems to suppress fires or to stop fire spread in residential settlements or in industrial environments but there is no study focusing on the usage of sprinkler system stopping fire propagation in open spaces or rural area. Du to serious fires happened in the near past all around the world this study try to find some fundamentals to help future studies focusing on similar topics.

Results say that the geometry of circle overlapping generates always problems regarding the effectiveness of sprinkler systems. 50% overlapping in longitudinal axis seems to be acceptable solution (2.5 m per head). In this case overlapping rate is 78% per circle with 1.6 $kg.m^{-2}$ water coverage levels and 22% of the circles have

[5] In case of aged forest crown it is about 5 kgm^{-2}.

0.8 kgm^{-2} water coverage level. Sequentially used system seems good solution for replacing the evaporated water, where 75% of the coverage level is accepted as lowest threshold of the effective rate. As an example, 300 m long protection zone requires 120 sprinkler heads. Building up this zone it requires 1,920 kg water for wetting up, then keeping it in service it requires 7,200 kgh^{-1} water. In this case 39% of the service water is lost because it is above the upper limit of effectiveness.

As a final conclusion, sprinkler system can be an effective solution against fire creating a barrier or for stopping it in a professional point of view however both the issue of economic and the technical optimization require further study.

Burnover; Camp Fire; entrapment; evacuation; wildland-urban interface

Abstract

The most destructive and deadly wildland-urban interface (WUI) fire in California history burned through communities in Butte County, California on November 8, 2018. Characterized by strong winds, dry fuel conditions, and steep terrain, the fire spread more than 12 km in the first 2 hours after ignition, triggering mass evacuations. The fire destroyed over 18 000 structures and caused 85 fatalities, mostly within the first 12 hours of the incident. Extensive data collection was conducted after the fire, gathering detailed first-hand account information from technical discussions with 157 first responders, photos and videos, emergency call recordings, and first responder radio logs, among other data to support an in-depth case study of the incident. Subsequent analysis and data integration yielded a complete timeline reconstruction of the first 24 hours of the event, as well as additional observations of the fire behavior. This report presents novel findings related to 23 identified life-threatening entrapment/burnover events, in which fire trapped or overtook people and compromised escape routes. These events affected the safety of hundreds of civilians and dozens of first responders, and occurred throughout the fire area. Many entrapments/burnovers impacted civilians evacuating in heavy traffic on major artery roadways or otherwise blocked evacuation routes and first responder access. Some resulted in injuries and fatalities. As the frequency of fast-moving fires requiring last-minute large-scale evacuations increases, the risk of similar events is high, particularly in intermix communities where the presence of primarily wildland vegetation along evacuation routes and some secondary roadways, likely amplified by local topography and wind, can result in significant entrapments/burnovers.

1. Introduction

1.1. The 2018 Camp Fire

The Camp Fire, which occurred in Butte County in northern California in 2018, was the most destructive and deadly fire in California history (CAL FIRE 2022). The fire first ignited shortly before dawn on November 8, 2018 near Camp Creek Road (for which the fire is named), in the community of Pulga, located in the Feather River Canyon (CAL FIRE 2019a). Dry fuel conditions, a strong wind event, and steep wind-aligned topography presented conditions conducive to rapid fire spread. By 07:30, just over one hour after ignition, high winds up to 22 m/s had driven the fire from the origin, over a ridge, and into the community of Concow 6.4 km to the southwest. By 08:00, numerous spot fires were igniting throughout the eastern portion of the town of Paradise an additional 6 km southwest of Concow. Structures in Paradise were burning by 08:30 as thousands of civilians began evacuating. The rapid fire spread led to 85 fatalities (Butte County Sheriff 2019; CAL FIRE 2019b; Butte County District Attorney 2020), and within 12 hours a majority of the structures in Paradise had burned. Ultimately, over 18 000 structures were destroyed and over 700 structures were damaged by the fire (Wallingford 2018; CAL FIRE 2022). Figure 1 depicts the location of Butte County within the state of California with the final fire perimeter shown in red.

After a preliminary reconnaissance (Maranghides *et al.* 2020a; Maranghides *et al.* 2020b), it was determined that an in-depth case study of the incident was feasible due to the data available and would provide scientific merit. Subsequent data collection and data integration were conducted to reconstruct a detailed timeline of the fire to provide a foundation for additional data analysis (Maranghides *et al.* 2021). The results presented here constitute findings related to the numerous life-threatening burnover events that were identified during the case study (Maranghides *et al.* 2021; Maranghides *et al.* 2022). The interested reader is encouraged to study (Maranghides *et al.* 2021) for the most detailed fire progression data available. While over 2200 data points

were included, the spatial resolution and detail required to provide accurate temporal contours is incredibly high and is not possible at this scale without consistent widespread aerial measurement. An animation of the analyzed fire observation data showing the fire progression is available from (National Institute of Standards and Technology 2021) which provides a non-interpolated view of fire progression.

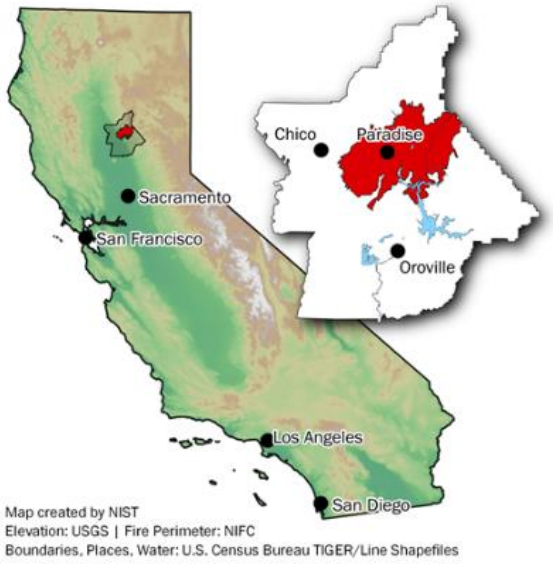

Figure 1 – Location of Butte County in California and the Camp Fire (red).

1.2. Entrapments and Burnovers

Entrapments in wildland fires are defined by the National Wildfire Coordinating Group (NWCG) as "a situation where personnel are unexpectedly caught in a fire behavior-related, life-threatening position where planned escape routes or safety zones are absent, inadequate, or compromised. An entrapment may or may not include deployment of a fire shelter for its intended purpose. These situations may or may not result in injury. They include 'near misses.'" (Page and Freeborn 2019; National Wildfire Coordinating Group n.d.-a). A burnover is further defined as an entrapment in which "fire moves through a location or overtakes personnel or equipment…often resulting in personal injury or equipment" (Page and Freeborn 2019; National Wildfire Coordinating Group n.d.-b). A recent report by Page et al. (Page *et al.* 2019), considering a comprehensive database of firefighter entrapments in the US, indicates entrapment rates have been steady at about 9 incidents per year.

In the US, most entrapment documentation is related to firefighters during operations, rather than civilians. Internationally, there are few studies about burnover events involving civilians unless they are focused on fatalities (Blanchi *et al.* 2014; Diakakis *et al.* 2016; Haynes *et al.* 2019; Molina-Terrén *et al.* 2019). In general, the number of entrapments or burnover events involving civilians is likely undercounted because they are not widely publicized, reported, or studied. As more fires burn rapidly into WUI areas with little time to evacuate, the potential for burnovers is increasing. Recent events with civilian fatalities while attempting evacuation have been documented in Portugal (Viegas *et al.* 2017; Viegas *et al.* 2019) and Greece (Horowitz 2018; Xanthopoulos and Athanasiou 2019).

During the Camp Fire, numerous events occurred where fire temporarily restricted through-access on a major traffic artery or a secondary road, or trapped civilians or first responders amid dangerous conditions. The events varied in intensity and duration. Some impacted civilian evacuation while others impacted first responders only. Some burnovers resulted in civilian fatalities, civilian and first responder injuries, and destruction and damage of civilian and first responder vehicles. In many cases, burnovers did not result in fatalities, injuries, or damage. These were instances in which fire blocked the road and civilians caught in traffic and/or first responders attempting to access the scene either waited for conditions to improve or opted to take another route, if available. These events could be interpreted as entrapments or "near misses" with respect to the NWCG definitions but are included in this report as they have significant impact on civilian and first responder life safety. All identified

events were grouped and labeled as burnovers in this report for simplicity, acknowledging the uncertainty in the data regarding exact extent and accounting for all potential people in the event.

Specifically understanding the fire development and progression associated with individual burnover events will require in-depth spatial and temporal (pre-, during, and post-fire) data collection of local fuels, weather, and topography. This detailed data was beyond the scope of the current work, which identified the prevalence of these types of events during the Camp Fire.

2. Identified Burnovers

The fire progression timeline report (Maranghides *et al.* 2021) includes 23 technical findings related to fire progression and fire behavior. Four of the findings relate to the burnover events that were identified during the case study data analysis. The findings were:

F15. Multiple burnovers occurred during the Camp Fire.

F16. Burnovers adversely affected pre-planned evacuation routes and led to use of Temporary Refuge Areas (TRAs).

F17. Intense vegetation and structure fires occurred along roadways and resulted in multiple road closures which adversely impacted response and evacuation activities.

F18. Fire resulted in downed utility poles along roadways and throughout the communities. The downed poles, along with the associated electrical and utility lines, blocked multiple streets and impaired access for response and evacuation.

Nearly two dozen entrapment/burnover events were identified in the analysis and compilation of data collected from 157 individual first responder accounts as well as numerous photos and videos. Additional detail about the data collection and data integration processes can be found in (Maranghides *et al.* 2021). The detailed narrative of each event is beyond the scope of this paper, but is documented in (Maranghides *et al.* 2021; Maranghides *et al.* 2022), and conveys the range of different scenarios under which burnovers occurred. The presented list does not include an analysis of the local conditions associated with the 85 documented fatalities. Additional burnovers may have occurred that were not captured during the data collection process; however, there is high confidence that nearly all of the large burnover events are accounted for based on the total combined dataset of fire observations (Maranghides *et al.* 2021), traffic conditions, burned vehicles, and TRAs (Maranghides *et al.* 2022).

The 23 documented burnover events occurred throughout the fire area within the first 26 hours of the incident, beginning almost immediately as fire impacted the community of Concow. The location of each event is marked in Fig. 2 with their corresponding ID number, with additional details listed in Table 1. These events affected civilian and/or first responder evacuation and movement, with 12 occurring on major egress arteries (identified by bold type in Table 1).

Many of the entrapments/burnovers significantly impacted evacuation (n=17) and required the formation/utilization of TRAs (n=9) to maintain life safety for residents and firefighters. In at least two cases, fire shelters were deployed by firefighters to reduce radiative exposures to civilians and first responders. Several entrapments/burnovers resulted in civilian or first responder injuries and civilian fatalities.

The burnovers were divided into two categories with respect to risk of injury or death. Fourteen burnovers were identified as “Category 1,” representing the highest potential of death/injury (highlighted red in Table 1), and nine as less-hazardous “Category 2” events. Of the 11 burnovers that occurred before 10:00 on November 8, nine were listed as Category 1, and two as Category 2. All but one of the Category 1 burnovers on the morning of November 8 significantly impacted civilian evacuations. Seven of the 14 Category 1 burnovers resulted in the formation of Temporary Refuge Areas (TRAs). Significant civilian evacuation traffic played a major role in the population exposed to these burnover events.

Local conditions dictated the spatial and temporal extent of each burnover. Burnover durations averaged nearly two hours and were influenced by the type and quantity of vegetative and other fuels in the area, as well as the spatial extent of the event. Overall, vegetation setbacks from the roadway (estimated using photos, video, and imagery) ranged from 0 m to 10 m; however, in most instances the setbacks were 3 m or less. Many events

affected significant lengths of roadway, on average estimated over 800 m per burnover, and ranged from 150 m up to 3 km. Road widths ranged from 3 m on narrow tertiary local roads to 23 m wide multi-lane primary arteries.

[c] The roadway segment affected by each burnover was estimated from the technical discussions.
[d] First time of observation. Burnover conditions existed prior to the first recorded observation.
[e] No data.

3. Discussion / Implications of Findings

One may first notice the large number of identified events. The mission focus of the fire service, the relatively specific definition of burnovers versus entrapments, as well as the potential negative stigma of burnovers (Strohmeyer *et al.* 2018), may all combine to a general under-reporting of such events (Jolly *et al.* 2019). Additionally, the majority of reported entrapments are likely reported in wildland fire settings opposed to WUI fire settings in more developed infrastructure with additional urban fire service mutual aid. The fact that 23 individual instances were identified within one incident suggests that this may be a more frequent issue, specifically in the context of WUI fires. Fourteen incidents were labeled “Category 1,” indicative of higher severity and significant threat to life.

It is important to note that these events also had a significant impact on civilians. Overall, these events have a different narrative compared to many firefighter-only burnovers experienced during suppression efforts. Of the 23 events, only 2 include officially documented firefighter injuries sustained during fire suppression efforts.

Those events, #15 and #18, injured 5 firefighters and were reported in an after action "Green Sheet" report (CAL FIRE 2018). The rest of the identified events were dominated by civilian presence, often with the assistance or guidance of first responders to locate a safer TRA. In very few cases was active suppression used or available to protect civilians from fire exposures.

Half of the events occurred in Paradise during overlapping time windows (IDs 4, 6, 7, 8, 21, 9, 10, 11, 12, 22, 23) early in the incident, stressing emergency resources. Simultaneous events, particularly across large spatial areas, significantly stretch the resources available to respond to each event to protect evacuating civilians. Early evacuation is key; however, this may not always be feasible. In rapidly developing events, a well-planned and efficient evacuation plan will need to be tailored to local conditions. The need to protect civilian evacuations may significantly change the operations of the fire service, resulting in additional fire spread and structure/infrastructure loss.

While 14 of the 23 incidents occurred before 11:00 on Day 1 (when more civilians were involved), several did occur the following day on November 9, impacting first responder operations. The potential for such events must be considered throughout the entire incident, not only for first responders but also for situations where fire continues to progress and impact additional populated areas. There are also significant long-lasting effects of burnovers in WUI areas, particularly as abandoned/burned vehicles and burned and downed power poles and lines can block passage for hours, impacting evacuation and first responder operations.

4. Conclusions

This portion of a greater case study into the 2018 Camp Fire in Butte County, California presents a unique dataset of burnover events that impacted mass evacuations during a WUI fire. Twenty-three burnover events threatening the safety and trapping or restricting movement of first responders and hundreds of evacuating civilians, were identified through in-depth analysis of data collected from technical discussions with first responders. Seventeen burnovers directly impacted the evacuation of civilians, 12 of which occurred on major evacuation roadways. Most burnover events lasted between 1 and 2 hours in duration and impacted an average roadway length of 800 m. Two events injured firefighters and were documented by the incident in official "Green Sheet" reports.

This is an important area of study as the frequency of fast-moving fires requiring last-minute large-scale evacuations increases. In intermix communities, the presence of primarily wildland vegetation along evacuation routes and some secondary roadways, likely amplified by local topography and wind, can result in significant entrapments/burnovers. There is limited technical information to provide reliable guidance on the relationship among vegetative fuel type, density, and setback from the roadway, along with topography and exposures, that can be used to develop reliable guidance for the protection of egress arteries against burnovers. Additional research is needed to characterize fire behavior that leads to burnovers and to quantify burnover severity. Such a study would need to capture the necessary fuels, weather, and fire behavior information. This work must be undertaken immediately following the event, as much of the data will originate from first-hand observations and perishable field data, such as post-fire fuel consumption measurements. This information would inform fuel setback guidance for primary egress arteries and provide technical input to evacuation plans.

5. Acknowledgements

The authors would like to acknowledge Ruddy Mell, Steven Hawks, Mike Wilson, Will Brewer, Chris Brown, Bob Vihnaneck, and Doug Walton for their contributions to the overall case study effort. The authors would also like to acknowledge the many first responders and community officials who contributed their time and information to the case study, as well as the data collection teams who participated in the technical discussions to collect much of the data used to compile the information in this report.

Wildland-urban interface; WUI fires; risk assessment; wildfires

Abstract

This study presents a risk analysis for structures in the wildland-urban interface (WUI) using fragility curves. Reconstruction modelling using the model ELMFIRE is conducted to reproduce exposure conditions for the 2017 Northern California Tubbs Fire as a case study. The reconstruction simulates the distribution of embers, expanding the ability of fire reconstruction to represent conditions during the fire event which are not represented by the flaming fire front. Results from the Tubbs Fire simulation are used to provide exposure conditions to investigate the relationship between exposure conditions, structure and community characteristics, and the damage sustained by a structure in the fire event. A methodology using fragility curves to estimate the probability of destruction, used for risk analysis in other disaster fields, is modified and developed here for application to wildland-urban interface fires. Results of the fragility analysis find that increased ember exposure increases the likelihood of damage or destruction. Relatively low levels of ember exposure still result in relatively high likelihoods of destruction, highlighting the importance of ember spread. Current models cannot simulate structure-to-structure fire spread; additional limitations are highlighted for future work.

1. Introduction

In the last decade, large wildland fires threatening communities, called wildland-urban interface (WUI) fires, have become increasingly frequent and severe, causing increasing damage and destruction to structures. For example, fifteen of California's twenty most destructive wildland fires (measured in terms of homes destroyed) have occurred from September 2015 onward (CAL FIRE, 2022), with the most destructive, the 2018 Camp Fire, destroying over 18,000 structures. Globally, in the last five years alone, major destructive fires have occurred in Australia (2020), Chile (2019), Greece (2021), and Portugal (2017), to name a few. The increase in destructive WUI fires is anticipated to continue, due to the combined effects of climate change and increasing development in the WUI, the area where structures and wildland fuels interface or intermix.

Current mitigation strategies to protect homes from wildfire vary extensively and, for the most part, have little quantitative data supporting their effectiveness. One approach to addressing effectiveness of mitigation efforts is to investigate the risk to structures from wildfire. Risk can be defined, generally, as the product of hazard and vulnerability (Scott et al., 2013). Hazard consists of the probability of a given exposure level being achieved, and vulnerability consists of the susceptibility of a structure to a given exposure level. Current hazard and risk assessment of wildland fires focuses primarily on fire risk at a landscape scale, used for land and resource management (Scott et al., 2013). Despite the importance of fire exposure from the wildland, risk assessment at

the community scale has neglected to include the conditions to which a structure was or may have been exposed (Alexandre et al., 2016; Syphard & Keely, 2019), primarily because such information has been out of reach.

An objective of the present work is to develop a quantitative wildfire risk assessment framework, applicable to structures and communities in the WUI that can inform pre-disaster community design and emergency planning and support strategic operations that ensure fire and life safety during a wildfire. The methods detailed herein include leveraging reconstruction wildland fire modelling and statistical analysis to connect hazard exposure conditions and urban vulnerability characteristics to the amount of damage a structure or community experiences. As a preliminary case study, we investigate the 2017 Tubbs Fire in California, the second most destructive fire in California history. This fire directly exposed over 8,000 structures in a period of under six hours, thus providing a large database of structure information. This work addresses a major gap in current WUI risk assessment which has, to-date, not included ember exposure, a key cause of fire ignition in WUI fires.

2. Methods

2.1. Fire Hazard Modelling

The Tubbs Fire ignited at 9:45 PM local time on 8 October 2017 (CAL FIRE, 2017). The area of the fire is characterized by a combination of grass, shrubs, understory, and timber litter fuels, such as herbaceous grasses and shrubs, and live oaks (Coen et al., 2018). Due to severe south-westerly foehn winds, the fire spread over 19 km in the 5 hrs following ignition, reaching the city of Santa Rosa in the early morning of 9 October 2017. Before containment, the fire burned 36,807 acres, destroyed 5,636 structures, and caused 22 fatalities (CAL FIRE, 2022).

An operational fire model that could be used in real time during a fire event, ELMFIRE (Eulerian Level Set Method of Fire Spread) (Lautenberger, 2013, 2019a, 2019b), was chosen to model the Tubbs fire. While it has many of the same limitations as other semi-empirical models, it is used here for its relatively fast computational run time, its ability to simulate ember deposition of multiple embers (a feature not available in other models), and its implementation of Monte Carlo analysis techniques (Lautenberger, 2017) to address the stochasticity and uncertainty of physical phenomena inherent in simulating wildland fires.

2.1.1. Model Inputs

ELMFIRE requires geospatial inputs which describe the vegetation in the simulation domain (represented as a fuel model (Scott & Burgan, 2005)), environmental conditions (i.e., fuel moisture content, weather, winds), and topographical information. Fuel and topographical data were downloaded from LANDFIRE at a resolution of 30 m (Rollins, 2009). One of the difficulties of applying wildland fire modelling methods to WUI areas is that there are differing physical scales and processes involved in fire ignition and spread across wildland fuels versus structural or urban fuels. Fuel models used in wildland fire modelling assume that urban areas are non-burnable. Despite the problems inherent in this assumption, there are no current operational models available to describe the spread of fire in WUI areas.

Weather and winds were modelled using the Weather Research and Forecasting (WRF) model, a mesoscale numerical weather prediction model. The WRF model for the Tubbs fire was initialized based on meteorological conditions at the start of the fire. The computational resolution of the WRF model was down-sampled in the fire model domain to match the limiting resolution of the fuels (30 m). In total, the model simulated 7 hours of the fire with a temporal resolution ranging from 1-15 s.

2.1.2. Model Outputs

Fire spreads into the WUI via radiation, direct flame contact, and ember exposure. Thus, key quantitative outputs from fire modelling that are subsequently used as hazard intensity metrics for risk analysis include flame length and ember count. Flame length is linearly related to fireline intensity (kW/m) by Byram's Equation (Byram, 1959), and, while the fire model does not directly output radiation, flame length is used to represent the impact of the main fire front on ignition and fire spread. Ember count is the number of embers ignited per grid cell over the course of the fire simulation.

2.2. Structure Dataset

2.2.1. Vulnerability Characteristics

Data on pre- and post-fire structure characteristics and post-fire structure damage is available for the Tubbs Fire (and many other fires) through damage inspection (DINS) reports produced by California's Department of Forestry and Fire Protection. The DINS data is obtained as a geospatial vector file with point geometry representing the location of structures. Since the defensible space around a structure is known to heavily influence its vulnerability to fire (Valachovic et al., 2021), the dataset geometry is converted so that structures are represented by polygons using a building footprints database published by Microsoft (2018). This allows for calculation of additional attributes such as minimum structure-to-structure distance and vegetation-to-structure distance (or defensible space), the latter using LiDAR data for vegetation. These two characteristics of structural vulnerability were included in the risk analysis to understand the impact of community layout on structure ignition, as structure-to-structure spread is known to be a driver of fire spread in the WUI. Year built of the structure was also included, as it influences the materials and methods of construction due to changes in building code requirements.

2.2.2. Damage States

Each structure in the DINS dataset is assigned one of six damage states ranging from "No Damage", to some percentage indicating the level of partial damage, to "Destroyed". These damage states are a key component to the risk analysis described below. Although a small selection of undamaged structures is recorded, the DINS reports preferentially include damaged and destroyed structures. Yet to draw conclusions about the relationship between structure damage level and fire exposure, it is necessary to include structures that survived the fire, as well as those that were destroyed. Therefore, this dataset has been supplemented to include structures that were likely to have been exposed to fire or embers, as assumed by their location compared against fire modelling outputs. These structures are assumed to have incurred no damage, given their omission from the DINS report. Finally, since a low number of partially damaged structures were recorded, the analysis considers only three overall damage levels (as shown in Figure 1): no damage (DS0), some damage (DS1); and destroyed (DS2). This combination is consistent with previous work that has looked at home destruction (Penman et al., 2015).

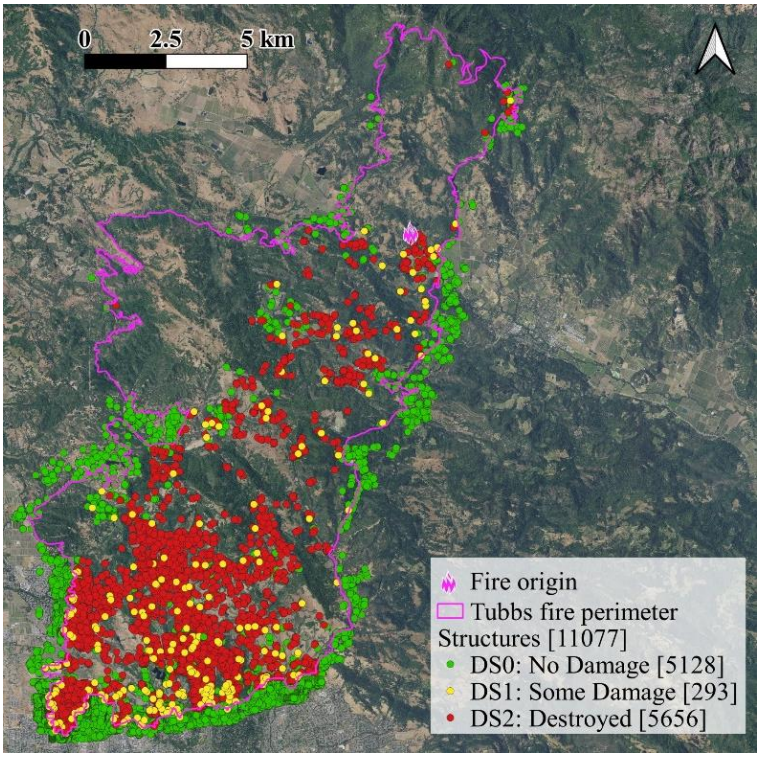

Figure 1- Tubbs fire perimeter outlined in pink with the ignition location indicated by a yellow star. The red dots indicate the location of structures that were destroyed in the Tubbs fire, the yellow dots indicated those that incurred partial damage, and the green dots are structures that were undamaged.

2.3. Risk Analysis Framework

We explore a risk analysis framework, following Rossetto et al. (2014), that incorporates fire hazard intensity metrics, structure vulnerability data, and structure loss inventory. Fragility curves, which are used in damage and loss models for flood and hurricane events, such as HAZUS (FEMA, 2001), represent a probability of exceeding a certain damage state given a level of intensity. The fragility curves are fitted using a generalized linear model with the explanatory variable considered to be the intensity measure (ember density) as well as the year built, defensible space, and the distance to the nearest structure. Other measures of intensity such as the flame length and additional structure and community characteristics can be incorporated and will be presented in future work. The response variable is modelled using a binomial probability density function.

The analysis of probability can be applied on a general level to all structures or by splitting the structures into different building classes. These building classes may be characterized by certain structure features (such as the presence/absence of combustible roofing) that could cause a structure to react differently from another structure under identical exposure conditions. The goodness-of-fit of the model is assessed using the *p*-value and the confidence interval. These metrics are used to determine the appropriate explanatory variables to include, the best link function, and to develop the building classes for significance. Initial results using all structures are presented here. The effect of building classes will be explored in further work.

3. Results and Discussion

To understand the relationship between exposure and damage, fragility curves with all structures for each intensity measure were produced. Figure 2 shows the fragility curve for all structures as a function of the number of embers ignited in a given cell. The probability shown in Figure 2 also incorporates the correlated influence of structure year built, defensible space as measured by vegetation distance via LiDAR, and the distance to the nearest structure. Here DS1 includes both partially damaged and destroyed structures, as the fragility curve represents an exceedance rather than an equivalence. In other words, the line representing DS1 indicates the probability that a structure surpasses the no-damage threshold at a given intensity level. The probability of both damage and destruction increases as the intensity measure increases. Structures require only low ember exposure to reach damaged and destroyed states (i.e., a single ember per cell is often sufficient). For high ember loads, probability of destruction of nearly all structures increases steeply.

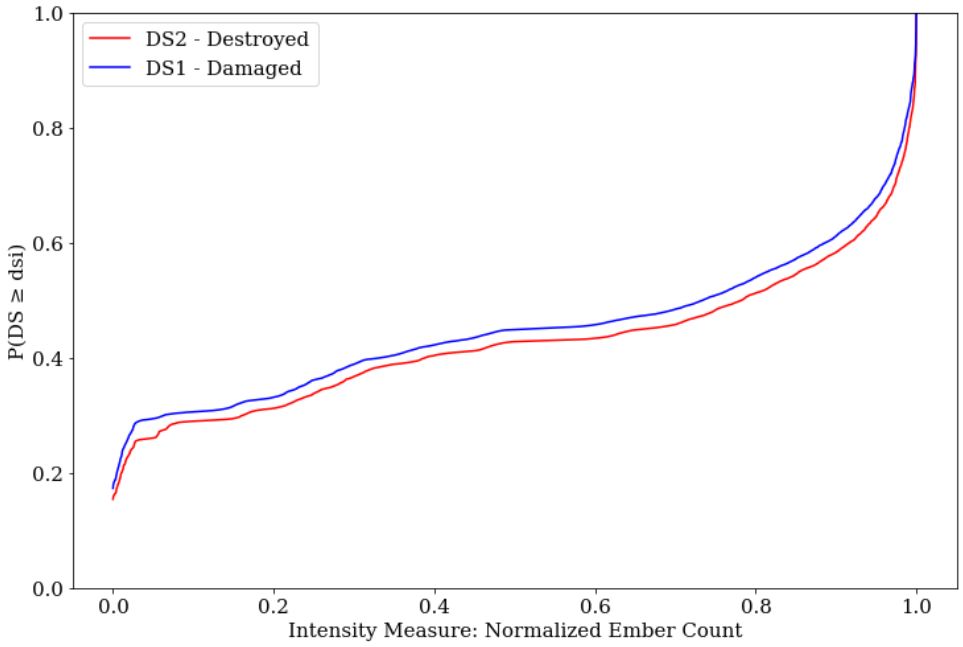

Figure 2- Fragility curve representing probability that the damage state of a structure exceeds either DS1 or DS2 as a function of a normalized ember count, which represents higher or lower numbers of embers ignited in a given cell. Ember count, year built of the structure, defensible space, and structure-to-structure distance are considered as explanatory variables.

The initial results of the fragility curve analysis show a clear relationship between exposure and destruction. Similar trends, not shown here, are found when considering flame length in the explanatory variables, though flame length is found to have a weaker correlation than embers with probability of damage or destruction. Overall, far fewer structures are exposed to flames than to embers, highlighting how critical it is to include embers in our models and in our risk analyses. While previous work (Duff & Penman, 2021) highlights that ember and fire exposure are both important in determining structure damage, the present work elucidates the relationship between ember exposure and destruction across a range of intensity conditions.

4. Conclusions and Future Work

This work shows a strong correlation between ember exposure and destruction, consistent with reports that embers are responsible for the majority of home ignitions (Mell et al., 2010). Future work will assess how local features, such as topography and fuels, compare to using embers for risk assessment. Further work should consider additional mechanisms of exposure, such as structure-to-structure spread (and the best way to capture that information). Similarly, this study focused on specific fire and structure characteristics expected to have an impact on risk, based on the literature; however, additional features may be relevant. Structure and community characteristics (defensible space, distance to nearest structure, year built of a structure) were considered individually here; however, another study has found that some characteristics are only significant when combined with others (Duff & Penman, 2021). Future work should consider interactions between features.

Wildfire policies; wildfire responses; collective action; owner collaboratives; local governments

Abstract

There is actually a broad consensus over the need to shift from fire suppression to fire prevention strategies. To inform policies that effectively promote this shift, we distinguish between actions aimed at more fire-resilient landscapes and those focused on the protection of people, i.e., wildfire mitigation and adaptation (WM&A), respectively.

With the goal of discussing the usefulness of this distinction and identifying local factors and external resources that promote preventive actions, we developed an analysis of collective WM&A actions across 116 parishes in a wildfire-prone region in Portugal, Pinhal Interior. Two principal component analyses were used to explore relationships between variables expressing collective WM&A actions. Random forest was used to model how those actions are related to local factors (land use/land cover, population, institutions) and external resources for wildfire prevention.

Our results showed that collective mitigation and adaptation responses to wildfire are independent, in coherence with their distinct goals, actors involved, and policy domains. Mitigation through owners' collaboration proved to be strongly related to policy funding, local economic dynamism, and demographic vitality, unlike community adaptation. In fact, adaptation responses from the local governments and the very few existing residents' collaboratives are very incipient. We conclude, on one hand, that mitigation and adaptation actions are currently supported by two unequally consolidated policy domains and, on the other hand, that both domains are equally underfunded, namely because of the difficulties in expanding owner collaboratives beyond favorable local conditions, i.e., in socioeconomically depressed regions.

1. Introduction

The shift from fire suppression to fire management through prevention has been increasingly discussed in the scientific and policy communities (Ager et al., 2018; EC, 2018; Leone and Tedim, 2020; Moreira et al., 2020; Fernandes et al., 2020). Within preventive actions we distinguish between mitigation and adaptation, taking into consideration the action itself, its objectives, and the actors involved, in line with the need to identify the policy recipients. Mitigation actions are primarily designed to reduce the susceptibility of the landscape to wildfire,

while protecting forest assets. Adaptation actions mainly seek to safeguard people and goods through reducing their exposure and vulnerability. Mitigation includes actions taken by landowners to reduce the amount or modify the kind and arrangement of fuel loads in forest and agricultural areas, thereby contributing to reduce wildfire hazard (Fernandes et al., 2014; Martins et al., 2021; Oliveira et al., 2013). Adaptation actions are taken by residents, homeowners, or communities to create defensible space on their properties and territories (Alcasena et al., 2019; Bihari and Ryan, 2012; Stidham et al., 2014) or to get insurance policies that allow a quicker recovery after a damaging event (Gan et al., 2015). Adaptation includes actions such as fuel treatments and protection strips in the surroundings of rural settlements and infrastructure, escape strategies, and shelters (Everett and Fuller, 2011).

These wildfire mitigation and adaptation (hereafter WM&A) actions can be carried out at different levels (Busenberg, 2004; Gill, 2005). This study is focused on the WM&A actions at a collective level (private owner groups, local communities, and local governments), unlike most empirical studies, which mainly address the individual responses (e.g., Fischer, 2011; Rodríguez-Carreras et al., 2020, Brenkert-Smith et al., 2012; Martin et al., 2009; McCaffrey et al., 2011; McGee et al., 2009; Olsen et al., 2017). The collective level is relevant because, to be effective, WM&A actions need to be coherently executed at a scale larger than the individual.

This study also aims to inform an effective paradigm shift from suppression to prevention by analysing collective WM&A actions within a wildfire-prone Portuguese region: Pinhal Interior. The WM&A actions are included in the same analysis, resorting to the same explanatory factors, but clearly distinguishing between mitigation and adaptation based on their different nature and goals and the actors involved in their implementation. We seek to define relationships between WM&A actions and both local factors (natural resources, population, and institutions) and external resources (access to policy funding) that favour or hinder mitigation and adaptation. The main goal of this study is to explore the usefulness of distinguishing mitigation and adaptation, and to identify local factors and external resources that promote each of them.

2. Data and methods

Data collection and analysis were executed at a parish level from primary and secondary data. A survey was applied to the presidents of Parish Councils to identify WM&A actions during the 2015-2020 period. These correspond to a set of 14 actions related to investments in firefighting, awareness and protection, land clearing, grazing and plantations. Five of the 121 parishes were excluded for non-answer reasons. Secondary data includes Forest Intervention Zones (FIZ), land use/land cover (LULC), population, institutions, public funding, or burnt areas.

A principal component analysis (PCA) was applied to the 116 parishes to understand the relationship between mitigation and adaptation. Four variables were used in the PCA: 1) number of adaptation actions (Numb_actions); 2) existence of an approved Forest Management Plan (FMP_approved); 3) proportion of the parish covered by FIZ (FIZ_extent); and 4) age of FIZ (FIZ_age). The last three variables express the FIZ's success in the implementation of collective mitigation actions. The principal components (PC) with eigenvalues greater than 1 were extracted.

Random forest modelling was used to determine relationships between PC scores (dependent variables) and a set of 51 independent variables, which were grouped in five dimensions: 1) LULC or resource system characteristics; 2) people and their relationships; 3) institutions; 4) external resources; and 5) wildfires. Mean squared error (MSE) was used to measure the effect of each independent variable in the models.

3. Results and discussion

3.1. Collective mitigation progression and adaptation effort display two locally independent dynamics

Two PC were extracted from the PCA, retaining together 88% of the total variance (table 1). PC1 (mitigation under FIZ) collects 64% of the variance and is associated with FMP_approved, FIZ_extent and FIZ_age. PC2 (community adaptation) represents 24% of the variance and is only associated with Numb_actions. These PC can be considered as orthogonal because all variables related to mitigation only contribute to PC1 and the

variable related to adaptation only contributes to PC2. Therefore, these PC are independent and not spatially related, which means that there is no association between progression of mitigation and adaptation effort.

It was possible to achieve this innovative result by comparing both responses to wildfire (actions for landscape protection and people's protection) across different territorial units for the first time. In fact, research on collective responses to wildfires are mostly confined to single territorial contexts and case studies (Danley et al., 2021). On the other hand, landowners' mitigation and residents' adaptation are either analysed separately or just assimilated (Everett and Fuller, 2011; Górriz-Mifsud et al., 2019; McLennan and Birch, 2005).

Table 1- Unrotated component matrix extracted from the PCA.

Acronym	Variable	Component	
		Mitigation under FIZ (PC1)	**Community adaptation (PC2)**
Numb_actions	Number of WM&A actions	-0.264	0.964
FMP_approved	Forest Management Plan approved	0.915	0.151
FIZ_extent	Proportion of the parish covered by FIZ	0.910	0.085
FIZ_age	Age of FIZ	0.909	0.042

3.2. Socioeconomic vitality, ownership structure, and leadership are key factors for WM&A action, unlike wildfire experience

Random forest models (figure 1) showed a much better fit for PC1 than for PC2 (58.5% *vs*. 6.8% of variance explained). This can be partly explained by the different territorial levels between actions and local and external resources. Data for some of the variables were only available at the municipal level, not allowing to fully capture the reality in each parish of the same municipality.

The highest scores of PC1 were obtained for parishes with higher values of built-up areas (*Built_up*), population densities (*PopDens*), agriculture areas (*Agricult* and *AgricBuff*), landscape heterogeneity (*Shannon*), younger people (*Young*), livestock (*LivStock*), tourism (*AccomCap* and *NightSty*), properties' dimension (*AvgUAA*), and capacity to raise public funding (*ForFund*). The propensity for landowners' collective mitigation under FIZ occur in parishes with more heterogeneous landscapes, larger built-up and agricultural areas, higher social dynamism, larger properties, higher amounts of money from public funding, and recent wildfires. On the contrary, there are no FIZ in parishes where people are older (and more vulnerable), landscape is more homogeneous, eucalyptus prevails, properties are smaller, and there have been fewer recent fires.

The PC2 model shows that only land registry (*LandReg*) stands out in variable importance (figure 1). The active role played by local governments in the promotion of land registry suggests that community adaptation depends on stronger leadership by local governments (Harris et al. 2011; Labossière & McGee, 2017). The PC2 scores are not clearly related to the other considered variables.

Historic and recent fires, namely the catastrophic years of 2003, 2005 and 2017, did not have significant effects on local collective mitigation or adaptation actions. This means that wildfire experience and awareness at the local level may not represent an effective trigger of collective mitigation and adaptation action, unlike what has been suggested in other studies (Jakes and Sturtevant, 2013; Mockrin et al. 2018; Muller and Schulte, 2011; Steelman and Kunkel, 2004).

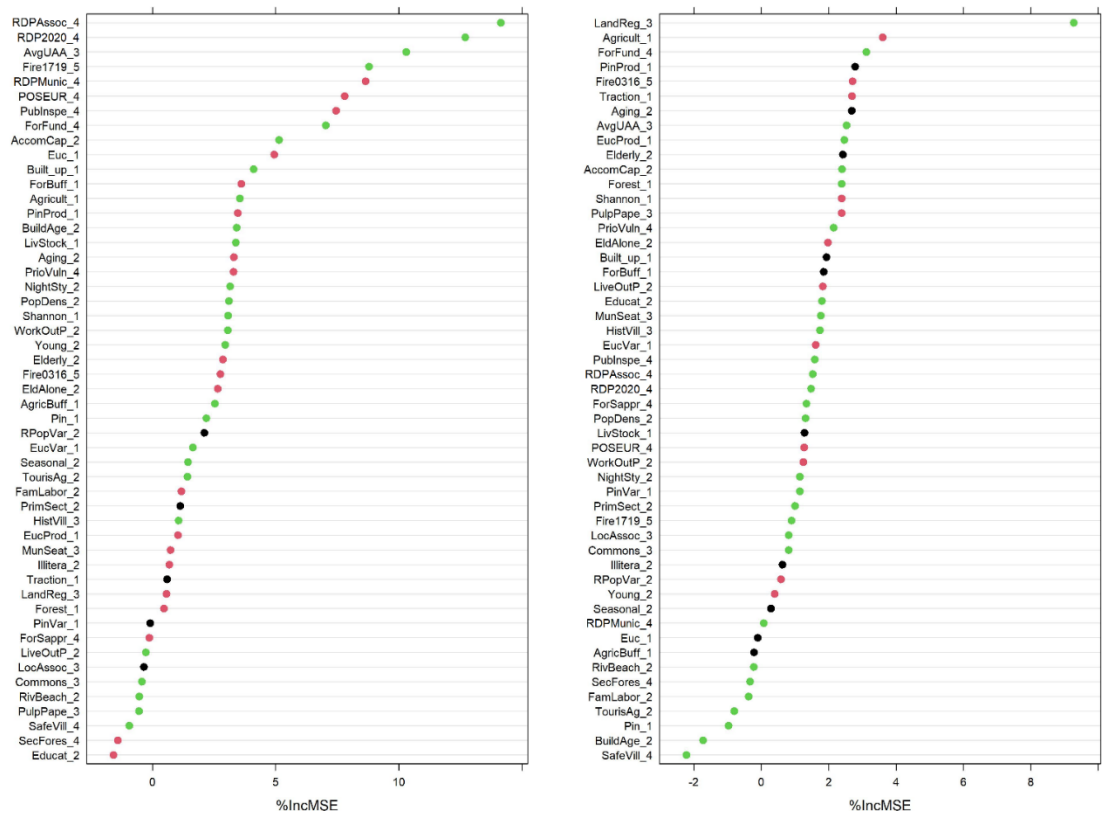

Figure 1- Variable importance for the random forest models for PC1 (left) and PC2 (right). Green, red, and black dots identify positive, negative, or unclear marginal effects of the variable on the scores of the PCs, respectively. Numbers following variable names refer to the corresponding dimension (see data and methods section).

3.3. Mitigation and adaption: a distinction supported by different policy domains

Most of the top variables in the PC1 model are included in the external resources dimension, demonstrating the vital role of public funding for collective mitigation progression (Canadas et al., 2016; OECD, 2013). This association is positive for public funding aimed at mitigation and negative for programmes aimed at adaptation. These associations reinforce the usefulness of distinguishing the two action spheres that are also supported by two distinct policy domains (OECD, 2016). Mitigation under FIZ is positively associated with landscape protection, agricultural and rural development policies.

Mitigation and adaptation actions on the ground are related to distinct policy domains, which are promoted by different policy actors and tend to protect different interests (table 2). However, these two policy domains seem to be unequally consolidated. The mitigation domain is supported by a set of well-established public and private agencies, policy measures and funding allocation already in place. The adaptation domain is more recent and less established, unlike what happens in the Anglo-Saxon countries (Everett and Fuller, 2011; McLennan and Birch, 2005).

Table 2- Programmes, entities, and policy domains supporting collective WM&A actions.

Programme	**Executing/funding entities**	**Policy domain**
"Secure Forests" Operation	National Republican Guard (Ministry of Internal Administration and Ministry of National Defence)	Adaptation
"Safe Village, Safe People" Programme	National Emergency and Civil Protection Authority (Ministry of Internal Administration), National Associations of Municipalities and Parishes	Adaptation
Rural Development Programme 2014-2020 (RDP 2020)	Ministry of Agriculture Co-financed by the European Agricultural Fund for Rural Development (EAFRD) and the Portuguese State Budget	Predominantly Mitigation
Permanent Forest Fund	National Forest Authority	Mitigation
Programme for Sustainability and Efficient Use of Resources [*POSEUR*]	Ministry of Environment Financed by the European Commission's Cohesion Fund	Predominantly Adaptation

Nevertheless, several drawbacks affect both action spheres and policy domains. Underfunding is among the main drawbacks pointed to mitigation policies (Santos et al., 2021). In fact, as in other countries, fire suppression has repeatedly attracted most public funds related to wildfires, thus limiting the resources for prevention (Calkin et al., 2011; Fernandes et al., 2020; North et al., 2015). The average investment in suppression in Portugal during the 2007-2016 period was three times higher when compared to prevention (Beighley and Hyde, 2018; Viegas et al., 2017). On the other hand, the results have demonstrated that the adaptation effort on the ground does not have a strong association with any funding or policy priority.

4. Conclusions

The proposed distinction between mitigation and adaptation has enabled us to reveal that, on the one hand, collective mitigation and adaptation are independent, i.e., mitigation action does not go along with adaptation action, and, on the other hand, WM&A are associated to different territorial variables and policy domains. The visibility given to the unequal consolidation levels between the two policy domains is an important outcome of that distinction.

The results suggest the local context, namely the economic and social vitality, ownership structure, and leadership by local governments, as the key factors to explain the different involvement of the territories in collective WM&A action. Unlike what is dominantly assumed in the literature the wildfire experience seems to play a minor role. Therefore, awareness campaigns targeted at landowners and local communities may prove insufficient to promote the desired WM&A action.

Although territorial differences are recognized in the wildfire literature, the consequences of those differences have not yet been fully explored, namely concerning the role of local government versus self-organization for collective WM&A actions. In the study area, owners' collaboration for mitigation has developed in parishes with higher demographic vitality and economic dynamism and resident collaboration for collective adaptation is almost absent. High levels of aging, low profitability of land-using activities and land management abandonment hinder both WM&A on strictly self-organization grounds. In fact, self-organization unlikely arises and thrives in similar regions, where local socioeconomic conditions markedly differ from those reported in the WUI literature.

Forest fuels, fire prevention, brazilian forest species, WUI.

Abstract

Classification of forest fuels according to their flammability is an essential component of fire risk assessment in the context of forest fire management planning. Surveys on the flammability of forest fuels are useful for fire management because they provide information on the reaction of individual fuels in heating a fire, make it possible to classify different plant species within an ecosystem in terms of fire hazard, and help with selection of suitable species to reduce the danger of fires in reforestation. The flammability characteristics of vegetation have been fundamental in recent methodologies for risk assessment of forest fires in several regions of the world. In addition, knowledge of how species differ in their flammability characteristics is necessary to draw up lists of recommended plants for urban and residential afforestation in wildland urban interface areas. In Brazil, there are no methodologies for classifying tree and shrub species according to the flammability characteristics of the vegetation. The choice of these species is made empirically, considering only the local experiences of vegetation specialists. This research aimed to consolidate in the country a methodology that has been adopted in several countries to characterize plant species according to the degree of flammability, facilitating the use of these species in protection activities against forest fires. The general objective of this research was to evaluate the flammability of native and exotic forest species from forest fragments and wildland urban interfaces (WUI) areas of Curitiba-PR and Gurupi-TO in Brazil, to support fire management planning in these environments. To achieve this objective, fifty-eight species were chosen from the fragment forests and wildland urban interfaces of Curitiba-PR and Gurupi-TO, Brazil, belonging to the southern and northern regions of Brazil, respectively, where forest activities are very important for the regional economy and to which fires cause significant damage. One of the analysis criteria for the selection of species were the morphological characteristics of the species. The selected species were submitted to flammability tests in the Forest Fire laboratories of the Federal University of Paraná and of the Environmental Monitoring and Fire Management Center (CEMAF) of the Federal University of Tocantins (Gurupi-TO)., The results indicated that of the analysed species, 44% had low flammability (IF = 0), and therefore, have potential for use in fire prevention activities at the wildland urban interfaces areas of the cities of Curitiba and Gurupi.

1. Introduction

The behavior of forest fires and the mechanisms involved in this process are highly complex. Studies on the behavior of fire in forest fuels have intensified a lot since the 20th century due to the growing need to develop fire prediction and simulation models to improve systems for preventing and fighting forest fires or, using a broader current concept, to provide more effective instruments for fire management.

Classification of forest fuels according to their flammability is an essential component of fire risk assessment in the context of forest fire management planning. Researchers and administrators have long identified the need to classify the flammability of forest species for use in fire prevention and combat plans and for the improvement of fire behavior prediction models. Surveys on the flammability of forest fuels are useful for fire management because they provide information on the reaction of individual fuels in the combustion process, make it possible to classify different plant species within an ecosystem in terms of fire hazard, and help with selection of suitable species to reduce the danger of fires in reforestation (DIMITRAKOPOULOS AND PAPAIOANNOU, 2001).

From the point of view of natural resource management, the interaction between natural and urban areas is called “wildland urban interface” (WUI). Forest fire prevention and mitigation programs educate and help communities in WUI areas to understand and be prepared for forest fires, including access, buildings and the

urban landscape. The techniques and measures to prevent forest fires in the urban landscape around the residences allow access of personnel and firefighting equipment and reduce the risks and damages due to fires. Usually the most effective measures are obtained through the vertical and horizontal separation of vegetation and in these cases the use of less flammable plant species is essential. (BEHM et al, 2004). Therefore, knowledge of how species differ in their flammability characteristics is necessary to draw up lists of recommended plants for urban and residential afforestation in WUI areas (WHITE and ZIPPERER, 2010).

Modeling has become an essential tool in research on forest fires and is currently a crucial tool in studies on risk mapping, fire propagation, as well as forest management (MADRIGAL et al, 2009). Experimental studies are needed both to calibrate and to validate the prediction models. Ignition, fire behavior, risk assessment and fire control require a thorough understanding of the chemical and physical processes involved in wildfires. How forest fuels burn and which parameters have the greatest influence on the combustion process are issues that need to be addressed (BARTOLI et al, 2011).

Forest fires affect vegetation which, in turn, affects fire behavior, as the plant species that provide the fuel for fires have specific flammability (CURT et al, 2011).

Climate change over the last few decades has been cited in numerous reports and surveys as one of the main causes of the increase in the frequency and magnitude of wildfires. Several climatological and ecophysiological models project drier and warmer conditions and, therefore, with greater risk of forest fires (MORENO, 2009, WESTERLING & BRYANT, 2008). But the frequency and magnitude of fires do not depend only on meteorological conditions, they also depend on the characteristics of the vegetation, especially its flammability (ALESSIO et al, 2008).

Flammability can be considered as the ease with which the material ignites and can also be understood as the resistance of the plant species to start and propagate fires (NUÑEZ-REGUEIRA et al, 2004). It can also be defined as the ease with which the material catches fire, both spontaneously and when exposed to certain conditions (ZHANG et al, 2011).

Flammability was initially defined based on three components (ANDERSON, 1970):

a- Ignition potential – time required for the fuel to reach ignition, after being exposed to a source of heat;

b- Sustainability – is the ability to maintain combustion after ignition;

c- Combustibility – is the burning rate after ignition.

Martin et al. (1994) added a fourth component: the amount of fuel burned (consumability).

The concept of flammability can be reduced to different aspects of combustion, according to the type of metric used in its evaluation, as can be seen in Table 1 (WHITE and ZIPPERER, 2010).

Flammability is experimentally evaluated by burning fuels in the laboratory, either in the form of the discrete elements (e.g. a leaf, a branch) for which the concept was coined, or as a bed of fuel or a heterogeneous set of individual units (FERNANDES and CRUZ, 2012).

Scale is an important issue when defining the methodology to be used to measure flammability. Vegetation flammability can be assessed at three levels: plant parts, whole plant and plant groups. In general, small-scale combustion tests are used to assess the flammability of plant parts. Large combustion tests are used to evaluate whole plants and groups of plants (GILL & ZYLSTRA, 2005).

Flammability characteristics are affected by several factors that can be classified into two groups: physical structures and components (twig size, leaf size and shape, dead material retention); and physiological and cellular elements (volatile oils and resins, moisture content, mineral content, lignin and greases), which are described in table 1 (WHITE and ZIPPERER, 2010).

Table 1. Criteria associated with favourable and unfavourable characteristics for determining plant fire resistance.

Favourable characteristics	Unfavourable characteristics
Architecture and Structure	
- Easy maintenance and pruning	- No maintenance and no periodic pruning
- Drought tolerant	- Fuel accumulator, including dry twigs, branches and leaves
- Free from dead leaves or needles and twigs	- Producer of large amounts of litter
- Thick, fleshy leaves and branches	- Dry or dead underground material
- Slow growing, with characteristics of - Prostrate or vine growth	- Dry and leathery leaves
- Little volume of leaves and small branches	- Needle-like or very thin leaves
- Difficult to ignite	- Compact and dense shape
- Does not keep flames for a long time	- Dense, abundant foliage
- Broad leaves	- Rough (shaggy) bark
- Produces limited dead and fine material	
- Low foliage density	
Physiological and Cellular	
- Low levels of volatile oils and resins	- High content of oils or resins, including gums and terpenes
- High moisture content, juicy	
- High ash and mineral content

2. Objectives

The general objective of this research was to evaluate the flammability of forest species used in forest fragments and (WUI) areas to support fire management planning in these environments. To achieve this objective, the following specific objectives were established: selection of species of frequent occurrence in urban and interface forest fragments of the cities of Curitiba-PR and Gurupi-TO, according to the favourable morphological characteristics of fire resistance and to determine, in laboratory, the flammability characteristics of the selected species.

3. Material and Methods

The flammability tests were carried out in the Forest Fire Laboratories of the Federal University of Paraná and CEMAF (Environmental Monitoring and Fire Management Center) of Federal University of Tocantins, Brazil.

Fifty-seven species were chosen from the fragment forests and wildland urban interfaces of Curitiba-PR and Gurupi-TO, Brazil, belonging to the southern and northern regions of Brazil, respectively, where forest activities are very importante for the regional economy and to which fires cause important damage. The criteria used for the selection of the species followed the recommendations of Biondi and Batista (2010). The selected species were: *Allophylus edulis, Anacardium occidentale, Antonia ovata, Araucaria angustifolia, Aristida sp., Aspilia montevidensis, Bauhinia rufa, Bougainvillea glabra, Byrsonima verbascifolia, Camellia japonica, Casearia sylvestris, Chytraculia concinna, Clethra scabra, Copaifera langsdorffi, Cupania vernalis, Curatella americana, Dalbergia miscolobium, Davilla elliptica, Dimorphandra mollis, Diospyros lasiocalix, Eriotheca gracilipes, Eryngium elegans, Eugenia uniflora, Euonymus japonicus, Guettarda viburnoides, Himatanthus obovatu, Hirtella ciliate, Hyptis meridionalis, Jasminum mesnyi, Lafoensia pacari, Lantana camara, Leandra australis, Leucena leucocephala, Ligustrum lucidum, Luehea divaricate, Macrolobium limbatum, Magnolia grandiflora, Michelia champaca, Mollinedia clavigera, Myrcia splendens, Ocotea puberula, Ouratea hexasperma, Persea americana, Pinus taeda, Pseudobombax grandiflorum, Psidium cattleianum, Qualea multiflora, Rhododendron simsii, Schinus terebentifolius, Tabebuia aurea, Tachigali aurea, Tapirira obtuse, Trachypogon spicatus, Vatairea macrocarpa, Verbena rigida, Viburnum odoratissimum, Ziziphus Cinnamomum.*

Flammability was determined according to the methodology recommended by Valette (1990) and Petriccione (2006). For each evaluated species, 50 firing repetitions were performed in the epirradiator, each one consisting of 1 ± 0.1 g of fresh fine forest fuel (< 0.7 cm in diameter). In the tests, the following combustion characteristics

were analysed: ignition time (IT), in seconds, time of complete combustion (TC), in seconds, maximum flame height (FH), in centimetres and ignition frequency (iF), in percentage. iF is the percentage of repetitions in which ignition occurred, considering a maximum IT of 60 seconds. The burnings that exceeded this time were classified as "negative burning" and received standardized values: IT equal to 61 seconds; TC equal zero seconds and FH equal zero centimetres. The flammability index (FI) of the selected species was obtained according to the iF and IT, varying as follow: 0 = very low flammable; 1 = low flammable; 2 = moderately flammable; 3 = flammable; 4 = very flammable; and 5 = extremely flammable (Table 2).

The data obtained were submitted to the flammability rating value (FI) and Cluster analysis, with the objective of validate the classification and identify the variables that present higher influence in the species flammability

Table 2. Classification of flammability according to the ignition time (IT), in seconds, and ignition frequency (iF), in percentage.

IT (s)	**iF (%)**					
	≤ 50	**50 - 79**	**80 - 84**	**85 - 89**	**90 – 94**	**> 94**
> 32.5	0	0	0	1	1	2
27.6 – 32.5	0	0	1	1	2	2
22.6 – 27.5	0	0	1	2	2	3
17.6 – 22.5	0	1	2	2	3	3
12.6 – 17.5	1	1	2	3	3	4
< 12,6	1	2	3	3	4	5

Source: Valette (1990).

4 Results and discussion

The results of the cluster analysis indicated that of the 57 species analysed, 44% were classified as very low flammable (22 native and 3 exotic species), 14 % as low flammable (8 native species), 15,8 % as moderately flammable (7 native and 2 exotic species), 8.8 % as flammable (2 native and 3 exotic species), 5,2 % as very flammable (2 native and 1 exotic species) and 12,2 % as extremely flammable (5 native and 2 exotic species).

The criterion used in this research for the selection of species through morphological characteristics proved to be adequate as a preliminary analysis to the flammability tests, considering that 74% of the analysed species presented low or null flammability. These preliminary results provide a good basis for continuing flammability studies for the potential use of low flammability species in wildland urban interface (WUI) areas and in forming safety green barriers highways and for forest fire prevention. The promising species to continue the flammability studies in the studied WUI areas are presented in table 3.

Regarding the origin of the species, 31% of the species classified as low or null flammability (FI = 0 or 1) belong to the Cerrado biome, a region heavily impacted by forest fires, although many of these species are naturally occurring in fire-adapted environments. This information reinforces the importance of knowing the flammability of the species for fire management in Brazil.

Table 3. Species with low flammability (FI = 0) with potential for use in the cities of Curitiba and Gurupi to prevent forest fires.

Species	**Origin**
Araucaria angustifolia	Native
Aristida sp.	Native
Aspilia montevidensis	Native
Bougainvillea glabra	Native
Cupania vernalis	Native
Dalbergia miscolobium	Native
Davilla elliptica	Native
Dimorphandra mollis	Native
Eriotheca gracilipes	Native
Eryngium elegans	Native
Eugenia uniflora	Native

Euonymus japonicus	Exotic
Hyptis meridionalis	Native
Lantana camara	Native
Leandra australis	Native
Ligustrum lucidum	Exotic
Luehea divaricata	Native
Macrolobium limbatum	Native
Myrcia splendens	Native
Ocotea puberula	Native
Persea americana	Exotic
Pseudobombax grandiflorum	Native
Psidium cattleianum	Native
Schinus terebentifolius	Native
Verbena rigida	Native

Ember; firebrand; accumulation; building; structure

Abstract

Embers, also known as firebrands, are the leading cause of building ignition during wildland-urban fires. This is attributed to direct ignitions of materials on, in, or attached to the building, and indirect ignition when they ignite vegetation or other combustible material near the building which can result in radiant heat and / or direct flame contact that ignites the building. Where and when embers accumulate near a building and ignitable fuel presents the potential for indirect ember ignition of the building. Factors that influence ember accumulation near a building include building geometry, such as flat wall and re-entrant corners, building wind angle, wind speed and the surface roughness characteristics of the horizontal landscape close to the building. Experiments conducted at the Insurance Institute for Business & Home Safety (IBHS) Research Center, using full-scale buildings with the above-mentioned factors provided a means to quantify ember accumulation on a mass per unit area basis.

1. Introduction

One of the main challenges to combating wildfires is that they spread through three main mechanisms, including flame impingement, radiant heat, and wind-blown embers, also referred to as firebrands. Ignition of a structure can be caused by direct flame contact from the primary fire front or from fires caused by localized fuel sources (i.e. vegetation, fences, etc.) near the structure (Potter and Leonard 2010, Quarles et al. 2010). Regardless of the source of the flame, ignition of the exterior of the building can result in ignition of internal contents. Buildings near flames are subjected to radiant heat and their vulnerability depends on both the intensity of the radiation as well as the duration (Potter and Leonard 2010).

The third mechanism of wildfire spread is by exposure to embers. This mode is the most important cause and accounts for up to 90% of structural ignitions (Potter and Leonard 2010). For example, two of every three homes destroyed in the 2007 Witch Creek fire in San Diego County, CA were ignited by ember accumulation (Quarles et al. 2010). The risk of ignition from embers depends on several features, including the number of embers, the ember characteristics, the amount of and type of combustible debris or materials near the building, duration of the ember attack, and environmental conditions. In some cases, ember attacks can result in the ignition of a building 12 hours after the initial fire front passes (Potter and Leonard 2010). The delayed ignition can be explained by either the continued production of embers from burning fuels after the fire front passed, or the smoldering combustion of a component or assembly that eventually transitioned to flaming combustion.

The lifecycle of embers that cause destruction of homes and building can be described in three stages: 1) production and release of embers from burning fuel; 2) transport of embers from the source to where they are deposited, including accumulation; and given sufficient accumulation and receptive fuel 3) ignition. Given the dominant role that embers play in wildfire spread and home ignition (Manzello et al. 2020) a considerable amount of research has been conducted and is underway on this topic. Experiments conducted by Suzuki and Manzello (2017) also studied accumulation zones created by stagnation planes in front obstacles. These investigations found that wind speed (6, 8, and 10 m/s) influenced the accumulation of firebrands in the stagnation plane on the windward side of obstacles and suggest experiments at wind speeds greater than 10 m/s would be desirable. In the stagnation zone roughness of horizontal surface affects the accumulation of embers (Suzuki & Manzello 2017). Later work investigated the effect of structure separation distance on firebrand

accumulation (Suzuki and Manzello 2021) which highlighted the role of firebrand behaviour between two structures. The heat flux, and ignition potential, from a pile of accumulated embers is distinctly different than from an individual ember (Hakes et al. 2019).

Nguyen and Kaye (2022) conducted a series of small-scale wind tunnel experiments investigating non-combustible ember accumulation on building rooftops and found that building geometry and wind angle were important factors for accumulation rates. Separate from and prior to these previous studied a set of experiments were conducted at IBHS to study the accumulation of embers near a building as a function of wind speed, building geometry, and wind angle. This work is the focus of the present paper.

2. Methodology

These ember accumulation experiments were conducted as part of the 2015 wildfire experimental campaign at the IBHS Research Center in Richburg, South Carolina. This research facility includes a wind tunnel large enough to hold full-scale one- and two- story residential and small commercial buildings, allowing for investigations to evaluate the performance of buildings subjected to high winds (Standohar-Alfano et al. 2017). The facility is able to generate wind speeds greater than 71.5 m/s (100 mph) using a 105-fan array. The wind tunnel can generate a constant wind speed or replicate observed, fluctuating wind records from hurricanes, thunderstorms, or open country conditions. For the 2015 wildfire experimental campaign, an open country wind record was used and was scaled to generate wind time histories defined as medium and high. The medium and high wind speed traces were fluctuating records with an average wind speed of 10.3 and 17.4 m/s (23 and 39 mph), respectively. Figure 1 shows the medium and high wind speed traces used in the experiments. In addition, an idle fan speed was used which ranged between 4.5-5.4 m/s (10-12 mph).

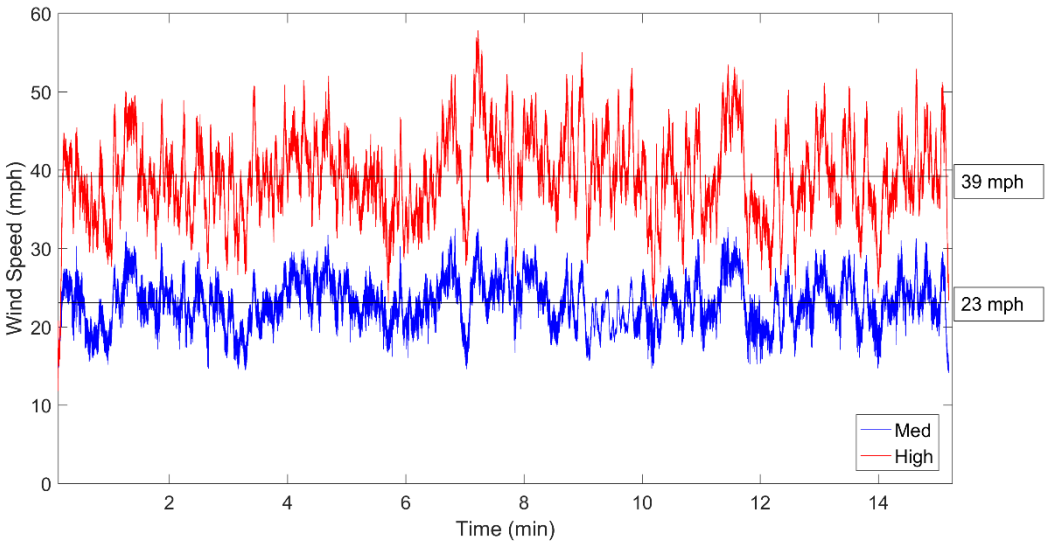

Figure 1. Medium and high wind speed records used in the 2015 wildfire experimental campaign (1 mph = 0.45 m/s). The average wind speeds for the "medium" and "high" wind speeds are boxed to the right of the respective record.

The wind tunnel utilizes a large turn table with a radius of 16.8 m (55 ft) which can rotate 360°, allowing for the full rotation of the test building and therefore the evaluation of the effect of wind speed and direction on the deposition of embers around the test building.

The 2015 wildfire experimental campaign used a custom-made system to deliver fuel and generate embers. The fuel was a mixture of southern yellow pine wood chips and wooden dowels processed from midwestern hardwood species, with a ratio of 80% and 20%, by weight, respectively. All raw material was dried to a moisture content less than 10%. The generators were used to burn fuel and create embers, as shown in Figure 2. The fuel was delivered into the generator by the auger feed line shown by Figure 2A. The fuel dropped on top of a metal grate immediately above a gas burner (not shown). A fan located under the burner (Figure 2B) pushed embers up and out of the exhaust chute indicated by Figure 2C. Eight generators were placed at equally spaced increments in front of the fan array.

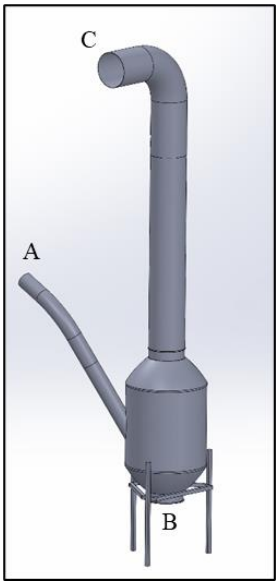

Figure 2. Schematic of the ember generators used. A is the auger feed line which introduced the fuel into the generator; B is the location of the vertically oriented fan; and C is the exhaust chute.

An overview of the auger system, generators, and test building is shown in Figure 3. Prior to testing, fuel was placed in the hoppers shown in Figure 3A. Five augers (not shown) dropped fuel into the pneumatic feed lines. The feed rate was controlled by powering the augers on and off. The desired feed rate was obtained when individual augers were turned on for a predetermined length of time between 3-5 seconds and then off for 10-20 seconds. Establishing the on/off times for each individual auger was determined based on visual inspection of ember output and observed overheating of the generators. The goal of using the intermittent fuel delivery was to ensure a consistent output of embers by all generators without damaging the generators from excessive heat.

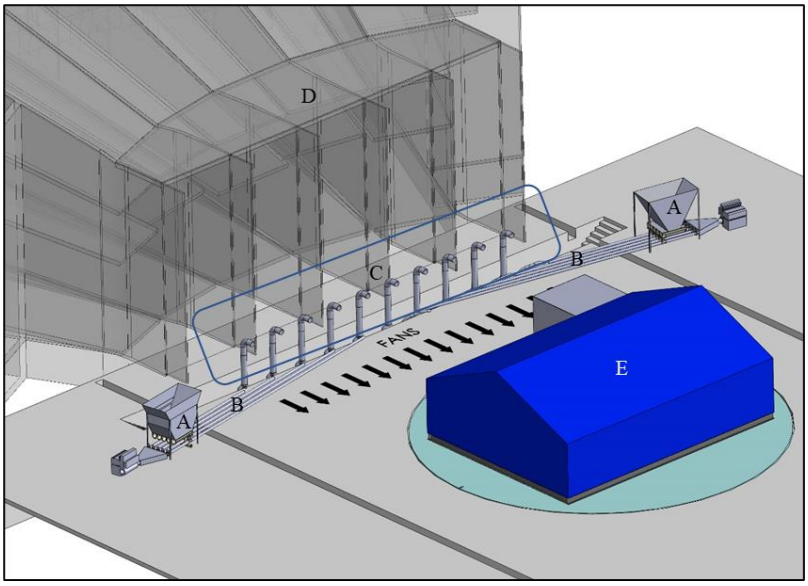

Figure 3. Experimental setup, including auger feed and ember generator system. The left and right hoppers are shown in A; B indicates the auger feed lines which deliver fuel to the 10 generators indicated in C; D is the fan array behind the generators; and E is the test building.

The auger delivered fuel to feed lines shown as B in Figure 3. These feed lines delivered the fuel to the generators (Figure 2A and Figure 3C). As described earlier, the generators burned the fuel and a fan pushed embers up the exhaust chute. Using the wind traces shown in Figure 1, the fan array (Figure 3D) created the wind flow in the test chamber. The test building shown by E in Figure 3 was then subjected to an ember exposure. The duration of the exposure was 15-minutes. The system used in this study is shown in Figure 4. By placing a building in the wind field and exposing it to embers, embers were collected at various near-building locations.

Figure 4. Test building and ember generator system used in the accumulation study. As shown, the collection trays were initially covered with a solid panel until steady flow from the generators was observed.

To evaluate ember accumulation in the vicinity of a building, a full-scale structure was positioned in the wind tunnel (Figure 3E and Figure 5). The structure was one-story with a building footprint of 9.1 m x 12.2 m (30 ft x 40 ft). To evaluate the vulnerability of a re-entrant corner, a 3 m x 3 m (10 ft x 10 ft) cube was placed on one corner of the long axis, as shown in Figures 4 and 5. This cube detached and re-attached at different locations on the test building. The building and cube were clad with fiber-cement panels. The orientation of the building was varied to assess the impact of wind direction on ember accumulation.

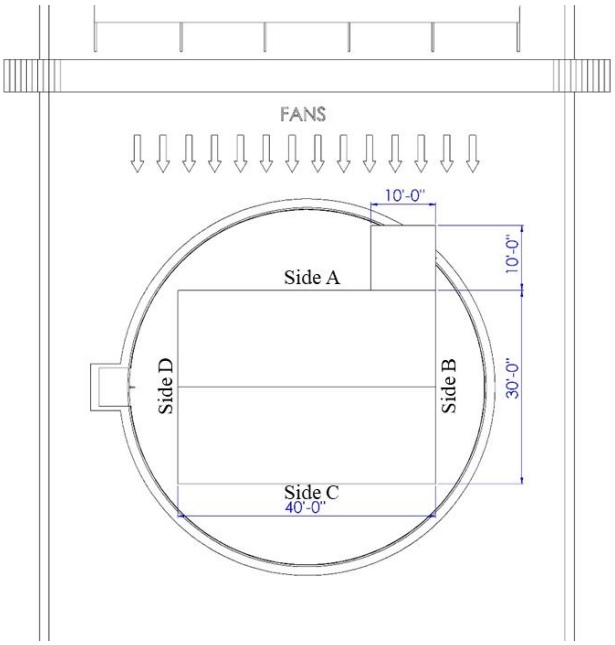

Figure 5. Plan view of the test building used in the accumulation experiments.

2.1. Ember Accumulation and Characterization

For the ember accumulation portion of the experiments, water-filled pans were placed at various locations on the test building. The building was then subjected to an ember exposure for 15 minutes. Thirteen scenarios were

examined at both medium and high wind speeds, as shown in Table 1. With the exception of the 270 orientation, a water-filled pan was placed in the re-entrant corner. Two additional water-filled pans (defined as WP 1 and WP 2) were positioned at selected locations along the building, as indicated in Table 1. Location information is also provided in Figure 6.

Table 1. Ember Accumulation Test Matrix.

	Pan		
Orientation	Corner	WP 1	WP 2
0°A	Yes	1.5 m (5 ft)	1.5 m (5 ft)
15°A	Yes	1.5 m (5 ft)	1.5 m (5 ft)
330°B	Yes	0 m (0 ft)	0 m (0 ft)
345°B	Yes	0 m (0 ft)	0 m (0 ft)
0°B	Yes	0 m (0 ft)	0 m (0 ft)
15°B	Yes	0 m (0 ft)	0 m (0 ft)
30°B	Yes	0 m (0 ft)	0 m (0 ft)
60°	Yes	0 m (0 ft)	3.8 m (12.5 ft)
75°	Yes	0 m (0 ft)	3.8 m (12.5 ft)
90°	Yes	0 m (0 ft)	3.8 m (12.5 ft)
105°	Yes	0 m (0 ft)	3.8 m (12.5 ft)
120°	Yes	0 m (0 ft)	3.8 m (12.5 ft)
270°	No	1.5 m (5 ft)	3.1 m (12 ft)

As indicated in Table 1, there were four main parent orientations investigated, shown in bold (0°A, 0°B, 90°, and 270°). With these four scenarios, the face closest to the fans was perpendicular to the wind field. For three of the main orientations (0°A, 0°B, and 90°) the re-entrant corner was directly impacted by the wind field (i.e., not on the leeward side of the building). In order to assess the impact of wind direction on ember accumulation the building was rotated in 15° increments. The location of the re-entrant corner on the test building was assessed with two of the main orientations (0°A and 0°B). For scenarios with an A orientation, the cube was in its original location at the end of the building as indicated in Figure 5. For the cases with a B orientation, the cube was moved to the mid-length of the building (centered at 6.1 m (20 ft)).

The pan location is also included in Table 1. The corner pan was located in the re-entrant corner and there was only one orientation where it was not utilized. There were two wall pans (WP 1 and WP 2) used in the ember accumulation experiments. The location is given as the distance from the closest corner. For the A scenarios, both pans were placed 1.5 m (5 ft) from the corners of the windward side. For the B scenarios, both of the wall pans were placed at the corner (0 m). For the cases where the main (parent) orientation was 90°, one pan was placed at the corner and the second pan was placed 3.8 m (12.5 ft) from the same corner. This resulted in a spacing of 2.3 m (7.5 ft) between the pans. For the 270° orientation, one pan was placed 1.5 m (5 ft) from one corner and the second pan was placed 3.1 m (12 ft) from the other corner.

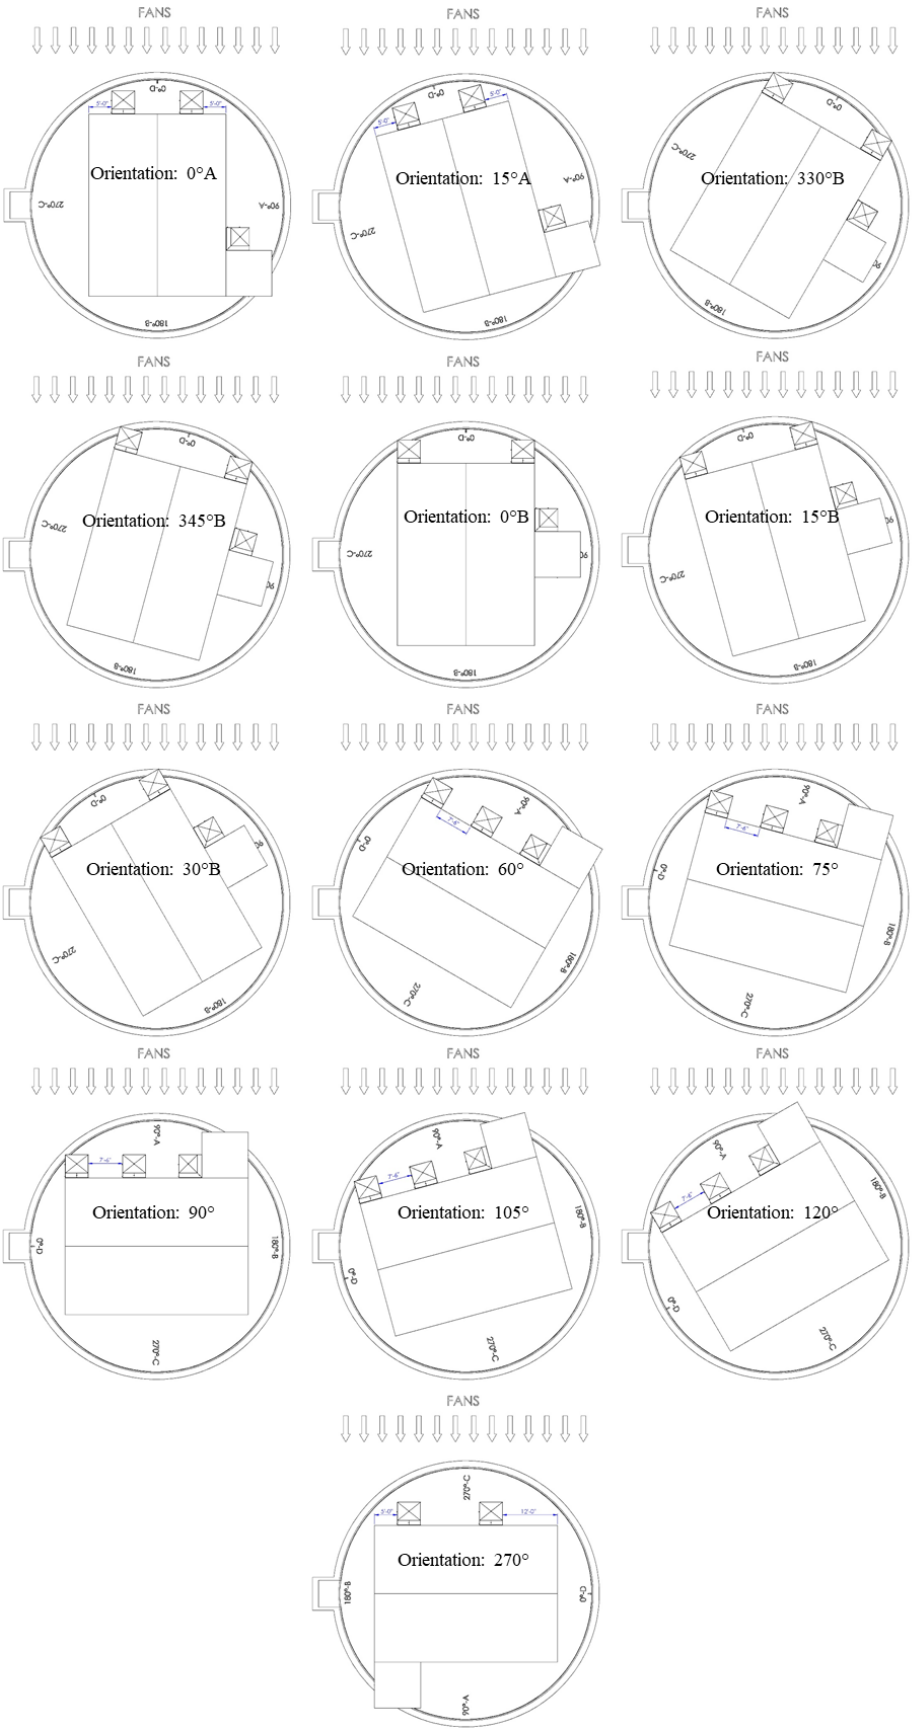

Figure 6. Pan location for all orientations.

At the beginning of each test, during the time the generators were starting up and output was non-uniform, the pans were covered. Once the generators reached a steady state the cover was removed and the wind speed record began, marking the start of the 15-minute exposure. The orientations summarized in Table 1 were subjected to both the medium and high wind speed traces.

The water-filled pans used in the ember accumulation study measured 1.5 m x 1.5 m (5 ft x 5 ft) and were divided into two sections defined as field and wall. The wall section was the area closest to the exterior wall. For all pans, this was 0.3 m (1 ft) from the wall edge. The field section was larger than the wall section and was the remaining portion of the water-filled pan that was not immediately adjacent to the building. Figure 7 shows an image of the two types of pans used in the accumulation study. Figure 7a illustrates the pan that was placed in the re-entrant corner. Since this pan had two edges against a wall, the wall section was larger than the pans placed elsewhere on the building.

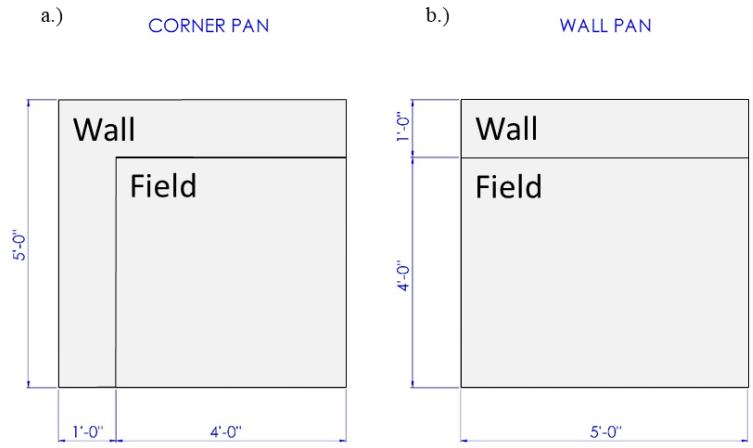

Figure 7. Water-filled pan dimensions and sections where a.) is the pan at the re-entrant corner and b.) is the pan placed along the flat wall (WP 1 and WP 2).

In addition to estimating the ember accumulation in the water-filled pans, the mass and surface area of individual embers was also measured. This was done to study the variability in ember characteristics. The surface area was calculated using image processing software and the mass was found using a high-precision electronic scale.

3. Results and Discussion

Results from the accumulation study are shown in Figures 8 through 11. There was variability in the accumulation depending on orientation, wind speed, pan section (wall or field), and pan placement along the wall of the test building. Thirteen orientations were investigated. The orientation of the test building with Side A facing the fans, as shown in Figure 5, was designated as the 90°orientation. Side B was designated 180°, Side C was designated 270° and Side D was designated 0°.

The results for the 270°orientation are shown in Figure 8. This was the only orientation that was tested at the idle (non-fluctuating) wind speed. This orientation positioned the cube on the leeward side of the building, so no embers were collected in the corner pan. The results for this orientation indicated that maximum ember accumulation occurred in the wall sections. At this orientation, the difference in accumulation between the wall and field sections increased with increasing wind speed.

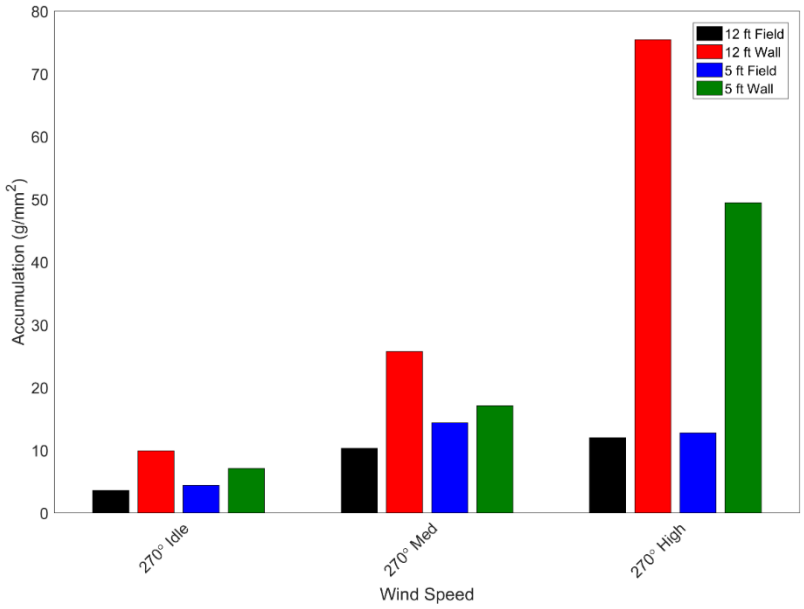

Figure 8. Ember accumulation in water-filled pans. The length direction of the test building faced the fans.

For the orientations in the 90° parent orientation (Figure 9), the 60° had the highest accumulation for both the medium and high wind speeds. At this orientation, WP 1 and WP 2 were closer to the ember generators and the re-entrant corner was positioned so that embers were naturally caught in the corner pan. For this reason, accumulation values were relatively high. At 105° and 120°, ember accumulation decreased. For these orientations, the cube used to simulate the re-entrant corner did provide some shelter for locations on the leeward side of the cube where the water-filled pans were placed.

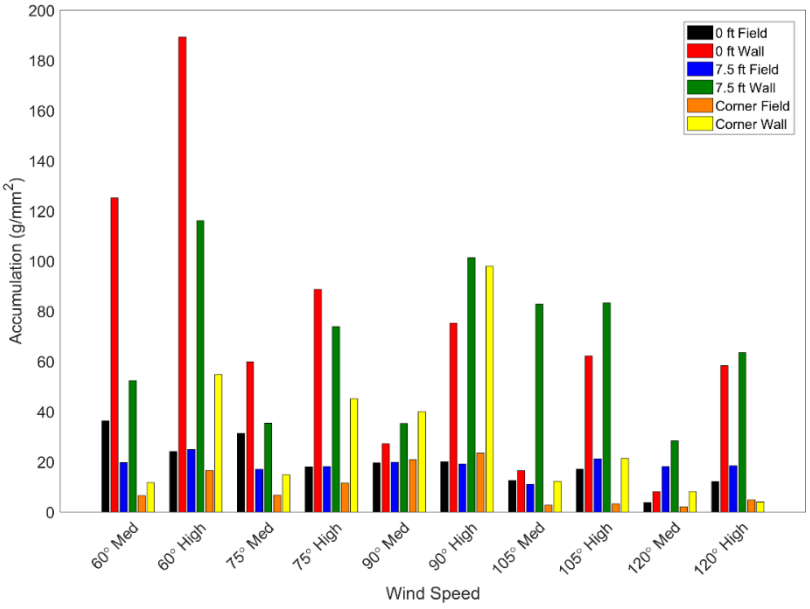

Figure 9. Ember accumulation in water-filled pans. Results are presented for the 90° parent orientation.

The results of accumulation for the 0°A and 15°A orientation is shown in Figure 10. As with previous orientations, the wall section of the pans had higher accumulations than the field sections for a given wind speed. Likewise, the high wind speed record did result in higher values of accumulation. Since the re-entrant corner was located 9.1 m (30 ft) from the windward edge of the building, ember accumulation in the corner pan was minimal due to the distance from the ember generators.

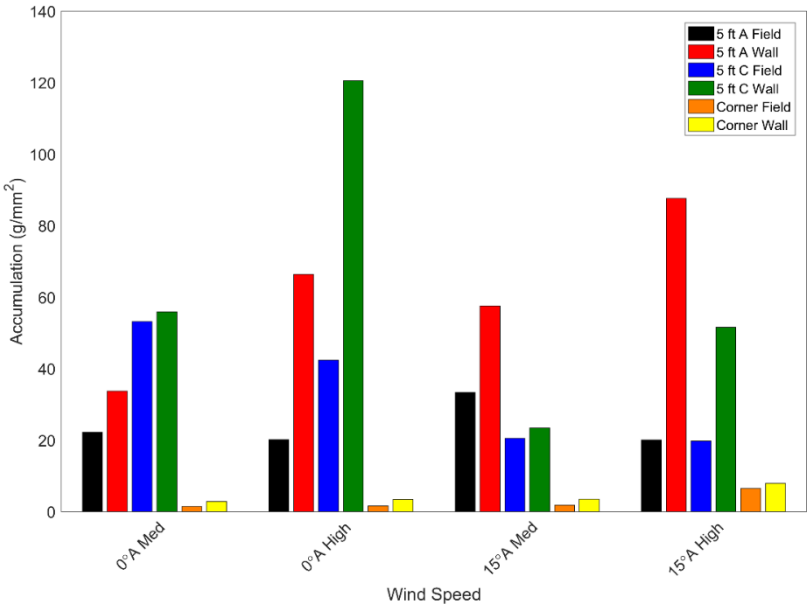

Figure 10. Ember accumulation in water-filled pans. Results are presented for the 0°A parent orientation.

Finally, the results of the 0°B parent orientation are shown in Figure 11. For these orientations, the re-entrant corner was located at the mid-span of the test building and was closer to the ember generators. As with other orientations, the wall section of the water-filled pans saw larger values of ember accumulation as compared to the field section. Likewise, high wind speeds typically resulted in higher values of accumulation. The 330°B and 345°B orientations had higher accumulations in the water-filled pan located on the C side of test building. With these orientations, the test building was rotated such that the C side was closer to the generators, so this result was not surprising. Similarly, for the 15°B and 30°B orientation, the A side of the building was closest to the generators, so accumulation was greatest in the water-filled pan located on the A side of the windward wall. Likewise, as the test building was rotated counter-clockwise from 0°B, the re-entrant corner moved closer to the generators and there was an observed increase in ember accumulation at the corner pan.

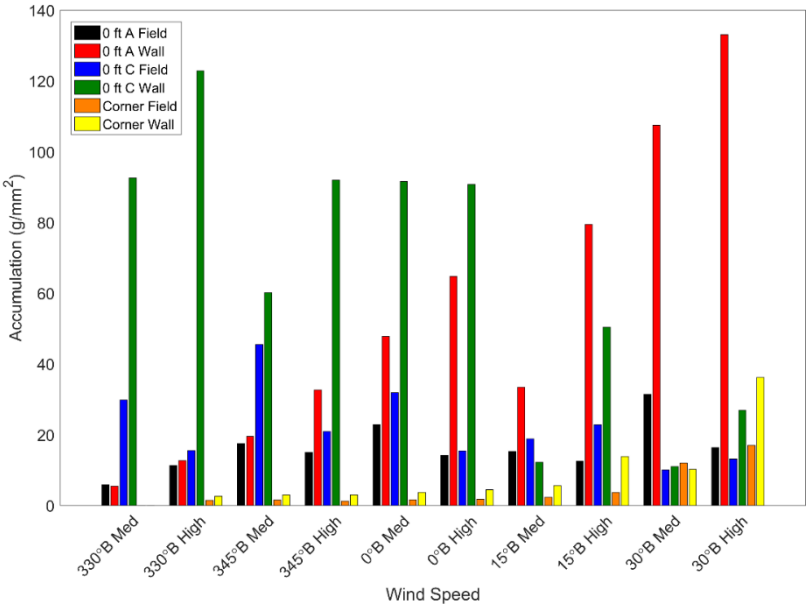

Figure 11. Ember accumulation in water-filled pans. Results are presented for the 0°B parent orientation.

In addition to quantifying ember accumulation, characterization of individual embers was also performed by measuring mass and surface area. The goal of this portion of the work was to add to the knowledge base regarding the quantification of ember exposure since this is an area of needed research. Due to the large number

of orientations investigated, only embers from the four parent orientations (270°, 90°, 0°A, and 0°b) were included.

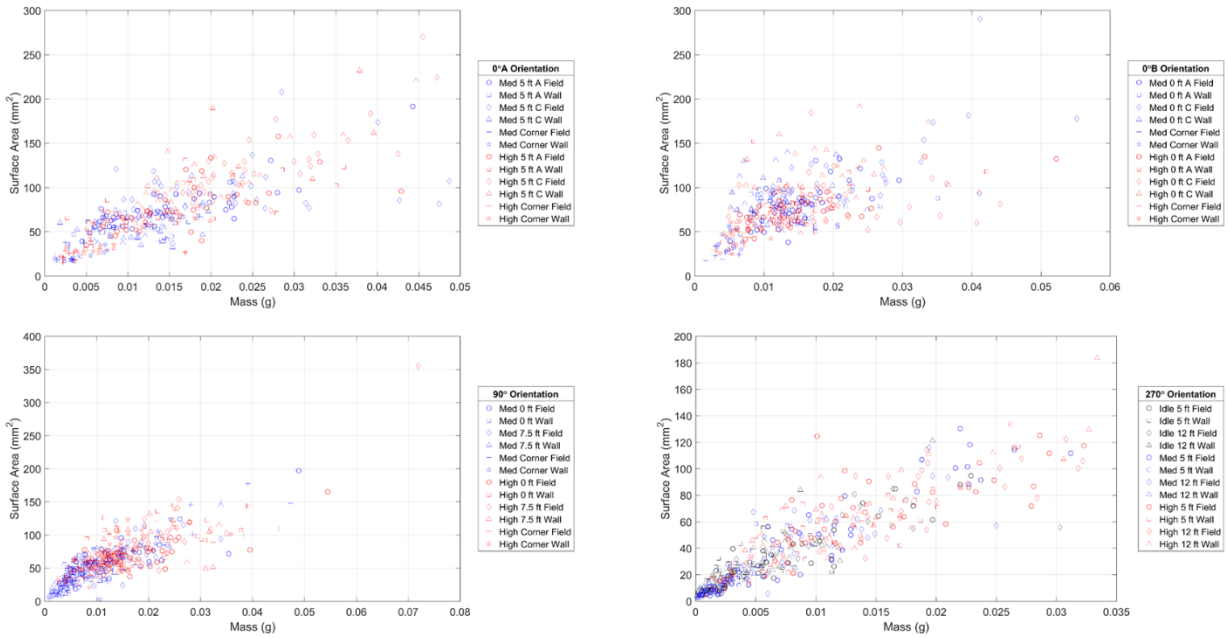

Figure 12. Ember characteristics, mass and surface area, from ember generators and collected in water-filled pans.

The relationship between mass and surface area is relatively linear and as the surface area increases, so does the mass. There did not appear to be any strong dependency between wind speed and ember surface area or mass. Likewise, the orientation did not appear to have an important impact on ember surface area or mass. This was not surprising since fuel type plays a larger role in ember characteristics than building orientation. As data regarding ember characteristics from active wildfires becomes available, a comparison can be made to the embers created with the IBHS generators. Using that information, the generators and/or fuel can be modified to better replicate embers collected in the field.

4. Conclusion

Overall, the data suggested that the accumulation for the wall section was higher than the accumulation for the field section, thus indicating greater vulnerability at locations immediately adjacent to the building. For the wall sections, higher wind speeds resulted in greater accumulation. Higher wind speeds allowed more embers to reach the building and become caught in the recirculation where they were forced into the water-filled pans. For the field sections, accumulation values were typically largest for the medium wind speed record, however, the dependency of accumulation on wind speed was lower. This likely resulted in the relatively large size of the field section, so at medium wind speed, lower momentum embers could land directly in the field section since they were unable to reach the building.

These results have important implications, especially for rough ground surfaces immediately adjacent to buildings. If embers strike a building and become contained in the recirculation, they can be forced down to the ground. If the ground surface is rough (i.e., mulch), it will capture the embers and allow them to accumulate closer to the building. Any combustible material near accumulated embers can potentially ignite which would result in direct flame contact or elevated levels of radiant heat near a building.

Wildfires at Urban Interface, Fire propagation in parcels and structures, Wind-driven laboratory tests, WUI numerical modelling

Abstract

Fires in wildland-urban interfaces (WUIs) are resulting from intertwined physical processes at different scales: landscape, settlement, parcel, building and material (Vacca et al., 2020) and are causing growing damage worldwide in context of climate change and large urban sprawl.

The significant damage caused by these fires requires effective reinforcement of the resistance of structures and parcels against exposure to fire. Recent methodologies (Vacca et al., 2020 ; Benichou et al., 2021; Maranghides et al., 2022) have emphasised the need to look at these objectives by considering the spatial relationships between fuels, exposures and building resistance, in the perspective of a fire propagating in WUI according to so-called "fire pathways". At parcel scale, the fire pathways often involve ornamental vegetation, that highly raises the damaging potential of the wildfire, this vegetation being at short distance to the structures and having a comparable size with buildings. Horizontal and vertical discontinuities in this vegetation do largely impact the exposure (Cohen, 2008) and installing such discontinuities is becoming part of the protection regulation against wildfires in different countries (Maranghides et al., 2022).

While the impact of embers has been extensively studied in the Insurance Institute for Business and Home Safety (IBHS) facilities (Manzello and Suzuki, 2014; Suzuki and Manzello, 2020), the effect of the fuel discontinuities on the reduction of thermal attack when approaching the building has been poorly addressed. This study aims at simulating in laboratory conditions a moving fire front pushed by wind and propagating from the surface to a canopy of ornamental vegetation, with fuel discontinuities. The experimental setup is composed of a fire lit in a surface excelsior fuelbed, propagating to a nearby vertical ornamental structure (excelsior and cypress) exposed to controlled high wind exposure (up to 3 m/s). The work is completed by a comparison of numerical modelling between the WFDS and FDS models.

The first steps of this study are shown here, showing a coherent sensitivity of the rate of spread to fuelbed width and fuelbed load, and showing the ability of WFDS and FDS to reasonably reproduce this rate of spread. The ability of FDS to propagate to an isolated vertical tree with the same modelling processes is also well established.

1. Introduction

Significant efforts have been made to understand the development and expansion of fires at the wildland-urban interface (WUI) (Cohen, 2008; Vacca et al., 2020), showing how the nearest combustible elements to the building are crucial for the propagation of the fire to the building. On the other hand, tree canopy fire contamination in native forests have independently been subject to various studies (Rothermel, 1991; Fernandes et al., 2009).

At homeowner scale, ornamental vegetation (isolated garden trees, hedges, climbing plants, ...) strongly enhances the danger coming initially from the native forest. In most tests and numerical simulations of WUI fires, these elements, located between the native forest and the building, are generally not represented. However, if represented they burn under very low wind conditions (Suzuki and Manzello, 2020; Li et al., 2021; Di Cristina et al., 2021), though in real fires (particularly true in South-East of France), fires in these ornamental elements occur under very gusty and chaotic wind conditions.

This study aims at experimentally reproducing a surface fire (excelsior fuelbed) propagating to a nearby vertical ornamental structure (excelsior and cypress), under high wind exposure (3 m/s) in the laboratory (*i.e.* at reduced scale). Additionally, a numerical setup composed of the models WFDS/FDS is used to compare and validate the codes against the experimental data.

This contribution describes the first steps of this study: the first section describes how zero-wind surface fire experimental data are generated to evaluate the sensitivity of Rate Of Spread (ROS) to fuel load and fuel width. The second section describes the setup of FDS and WFDS models that will be used in the entire study. Then results of some nominal and intermediate model configurations are presented. The last section is dedicated to the intermediate conclusions and to introduce the next steps of the study.

2. Calibration of the zero-wind surface fire in the experimental setup

The first step consisted in evaluating the ROS of a surface fire under zero-wind condition, in order to gain in reproducibility of surface fires for the full experimental setup. This is a first validation before developing the full experimental setup composed of a surface fire propagating to an ornamental vegetation under high wind exposure (Figure 1b). 85 experiments were performed with zero-wind surface fires (Marchand et al., 2014, 2019). They were carried out on excelsior as fuelbed (Figure 1a) and the sensitivity to fuelbed width and fuelbed load was investigated. The combustible material was fully characterised in a previous work by Marchand et al. (2019). The first 45 experiments were conducted with a constant vegetation load (0.5 kg/m²) and with fuelbed width ranging from 25 cm to 3.5 m. The excelsior was spread onto the table in order not to exceed a maximum average height of 8.5 cm. The fire was ignited on a line along the whole bed width. The last 40 fire tests were conducted with a constant fuelbed width of 2 m and with a fuel load ranging from 0.1 kg/m² to 1 kg/m². Visible cameras combined with image processing (Otsu algorithm) were used and a direct linear transformation (DLT) algorithm was developed in order to quantify fire behaviour properties (ROS, fire length, etc.).

(a)  (b) 

Figure 1 - Zero-wind fire spread test on the surface fuelbed, (b) View of the high wind exposure facility

A summary of main results is shown in Figure 2. For the sensitivity of ROS to fuelbed width, ROS is shown to increase at low values of fuel bed width and seems to reach a constant value of about 1.5 cm/s for a 2 m fuel bed width and beyond. In such configurations, the fire fronts are near-parabolic, but the front curvature varies with the line width and the rate of spread is also affected. For the sensitivity to fuelbed load, ROS is shown to globally increase with fuel loads from 0.3 cm/s for the lowest load to 2.6 cm/s in average for the highest load. The repeatability of tests showed discrepancy up to 0.5 cm/s as compared to the average value that can be significant but explained by ambient conditions (different seasons and ambient conditions).

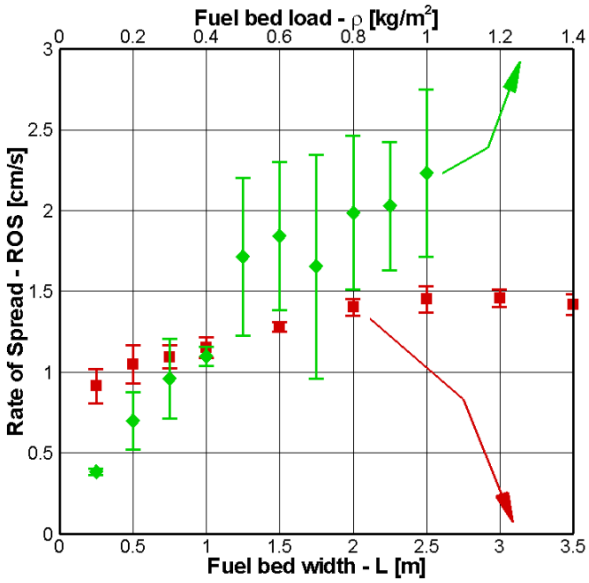

Figure 2 - Distribution in the 85 experiments of the rate of spread as a function of fuelbed width (red colour) for a constant vegetation load of 0.5 kg/m² and as a function of fuelbed load (green colour) for a constant fuelbed width set at 2 m.

3. Wind-driven surface fire experiments

A second step consisted in evaluating the ROS of the wind-driven surface fire. Five different wind fans of the "wind wall" were activated with the same constant frequency in each individual experiment. The wind measurements collocated to the fans and at different horizontal distances from the fans, at 0 m and 1m ground heights are shown in Figure 3. The wind at z= 0 m ground height is more affected by the distance to the fans than the wind at z= 1 m. All fan frequencies cannot be used when burning the vegetation since above 30 Hz the excelsior is heavily washed from the table by the wind.

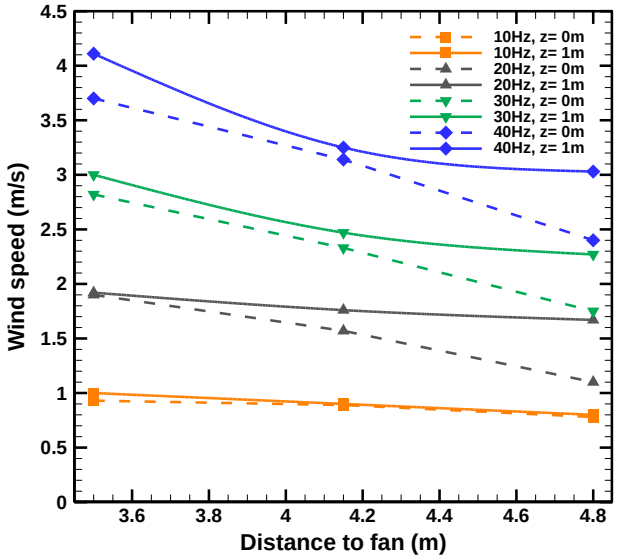

Figure 3 – Wind speed wih horiztonal distance to the fans, and at two different ground heights (z=0m and z=1m)

Different tests of excelsior burning under different wind speeds have been conducted at two different vegetation loads, set at 0.23 kg/m² and 0.4 kg/m². The excelsior fuelbed was positioned at a distance of 1.3 m from the fans.

As shown on Figure 4, the ROS exhibits a strong increase when going from zero-wind to 0.88 m/s wind speed, with a multiplication of ROS by 4 for the 0.23 kg/m^2 case and by 6 for the 0.4 kg/m^2 case. Then a plateau of ROS is observed between 0.88 m/s wind speed and 1.9m/s wind speed and finally another strong ROS increase occurs when reaching 2.4 m/s wind speed.

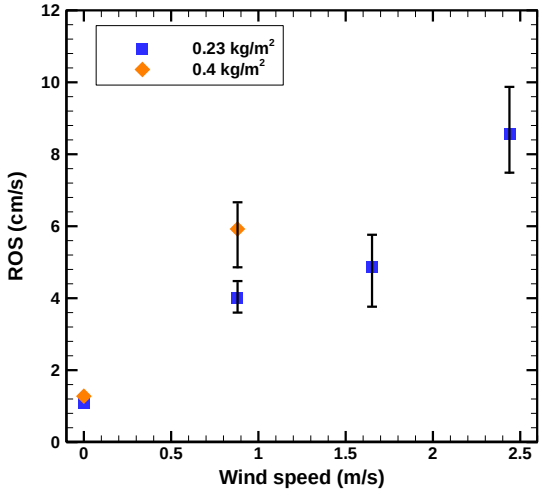

Figure 4 – Rates of spread in function of the wind speed for two different loads (0.2 kg/m^2 and 0.4 kg/ m^2)

4. Calibration of the surface and canopy fires, with wind, in the experimental setup

Finally, the full experimental setup composed of a surface fire propagating from excelsior to an ornamental vegetation in form of a very thin hedge, with and without wind exposure, has been tested, with the same objective of monitoring ROS.

Two types of vegegation were sampled to constitute the hedge: cypress and oleander. This vegetation was arranged with equal fuel load on a vertical mesh of 1 m large and 1.5 m height, by intertwinning the branches with the fine diameter coarse galvanized steel mesh, which has the advantage of preventing the vegetation from collpasing when burning. A simple evaluation showed that the very fine diameter of the mesh would not modifiy significantly the fire power or the ROS over the hedge. Same fuel load was imposed on the entire mesh with respectively about 1.2 kg/m^2 and 4 cm depth for cypruss and about 1.2 kg/m^2 and 6 cm depth for oleander, collected in gardens and let drying for a minmum of 15 days. Size distribution of <2mm, 2-4 mm, and 4-6 mm diameters were found for cypress of 34.7 %, 55.1%, and 10.2 %. Size distribution of 2-4 mm, 4-6 mm, and 6-8 mm diameters were found for oleander of 48 %, 44 %, and 8 %. The Figure 5 shows cypress and oleander branches and the bulk density evaluation by tube test.

Figure 5 – Property measurements: (left) oleander weighting, (middle) cypress branches clustering for size distribution evaluation, (right) cypress bulk density evaluation

The Fuel Moisture Content (FMC) was sampled 1 day before the experiment. FMC of cypress was about 23.8 % on dry matter basis. FMC of oleander was about 10.7 %. The FMC for cypress has been measured 15 times with a SD (standard deviation) of 9.6%, 6 times with a SD of 1.3% for oleander, and 5 times with a SD of 0.7% for excelsior. For ROS measurements, a total of 8 thermocouples (TCs) were vertically-positioned, 4 being vertically aligned along the middle of the hedge and 4 others vertically aligned along the exterior side of the

hedge. Each TC is 50 cm distant from another, covering a distance of 0.1 m to 1.6 m over the table. Two visible cameras were also placed, one at the back of the hedge and another one on the side.

A series of 2 experiments were conducted with cypress under zero-wind conditions, while 1 experiment was conducted with cypress under 10 Hz wind conditions (around 0.88 m/s) (outputs not shown here), and 2 experiments were conducted with oleander under zero-wind conditions. Under zero-wind conditions, the fire contaminates the hedge only after the excelsior fire has arrived very close to the foot of the hedge (Figure 6).

Figure 6 – Fire contamining from excelsior fire to the hedge under zero-wind conditions, (upper) for cypress and (lower) for oleander. Propagation visualized in 5 phases (from left to right): excelsior fire approaches, excelsior fire at the foot of the hege (reference time t=0s), fire at maximum development in the hedge, fire largely decreasing, fire in extinction phase

ROS of the fire in the hedge was quantatively extracted from the vertically-positioned TCs under zero-wind conditions, but the oscillatory flames did contaminate the vertical sensors in an erratic sequence (with higher TCs contaminated prior to lower TCs), preventing from getting the ROS this way. The measurements from visibles cameras revealed a robust way to measure ROS, the imagery being preliminatorily distance-referenced (Figure 7). Cypress fire exhibited ROS values respectively between 35 cm/s and 43 cm/s under zero-wind condition, and 55 cm/s under 10 Hz wind condition. The oleander exhibited ROS values between 22 and 24 cm/s under zero-wind condition. More experiments have been scheduled to gain statistical robusntess of these results. Additionally the calibration of the WFDS and FDS models is in ongoing process on these data.

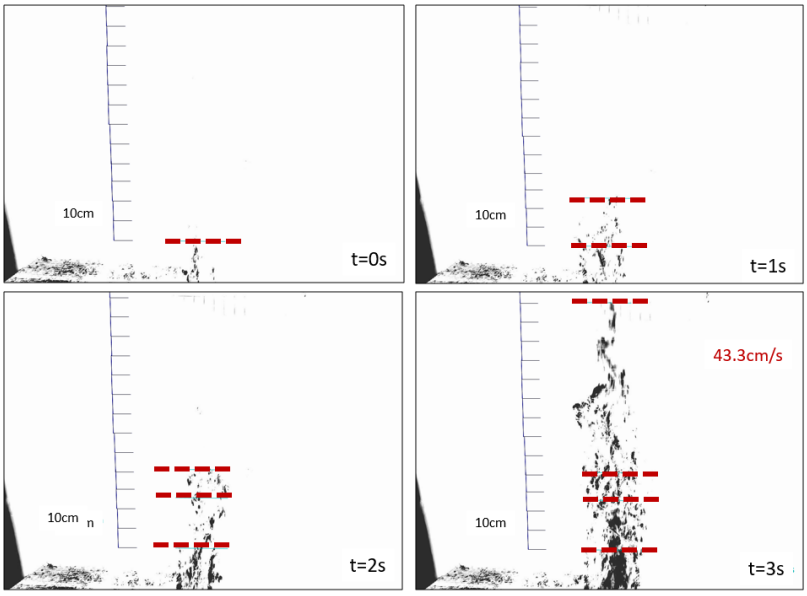

Figure 7 – Zero-wind condition cypress ROS measured by manual interpretation on distance-referenced thermal camera imagery

5. Numerical setup

The two versions of "FDS" (Fire Dynamic Simulator), the classical FDS and its WFDS derivation (Widland Fire Dynamic Simulator) are used in this study. Each numerical model has its own parameters to represent the vegetation fuel and should be calibrated. In the literature, grid resolution to reproduce laboratory "forest fire" experiments may vary from 2 cm (Morandini et al. (2019) for rockrose shrubs) or 5 cm (Wickramasinghe et al. (2020) for Douglas fir) and up to 10 cm (Mell et al. (2009) for the same Douglas fir).
The WFDS model in 7.6 version is used here with a uniform spatial resolution along the three directions of Δ= 2 cm. The linear pyrolysis model is employed in WFDS.
The Fire Dynamic Simulator (FDS) in version 6.7.5 is used here with either (1) a uniform spatial resolution along the three directions of Δ= 2 cm, or (2) with $\Delta x=\Delta z$ =1 cm and Δy= 2 cm. The pyrolysis and char oxidation processes are driven by an Arrhenius model.

6. Nominal WFDS and FDS calibration on the intermediate setup of a zero-wind surface fire

The tests modelled with WFDS for the zero-wind surface fire require to attribute values to eight key parameters of the pyrolysis model: the maximum value allowed for the MLR [MLRmax in kg/m^3/s], the bulk density of vegetation [ρbulk in kg/m^3], the density of vegetative fuel [ρ in kg/m^3], the surface-to-volume ratio of vegetation [σ in 1/m], the moisture fraction Hu in %wt calculated on a dry mass basis), the fraction of dry virgin vegetation that becomes char τchar (in %wt), the heat of combustion [ΔHr in kJ/kg] and an adimensional multiplicative drag coefficient Cf.

Raw values of these parameters have been previously obtained by Marchand et al. (2019) and are presented in Table 1. Simulations were made to determine the ROS evolution as a function of the fuelbed width for a 0.5 kg/m² vegetation load using these raw values as input data. Despite that, the global trend is well captured as the ROS increases with the fuel bed width, these simulations exhibited a strong underestimation (60 % differences with the experimental data). Therefore, these values have been fitted: a local sensitivity analysis revealed that MLRmax and ΔH_r were the most significantly sensitive parameters for the ROS predicted by the WFDS model. An identification algorithm (Particle Swarm Optimisation method according to Kennedy and Eberhart (1995)) was then used to identify the best values for these two input parameters, keeping all others at their initial experimental values. As presented in Figure 8, with these new parameters, the numerical trend of ROS with fuelbed width is in a good agreement with the experimental data.

The tests modelled with FDS for the same test configuration require to attribute values to several parameters driving the thermal decomposition and char oxidation. More details about model formulation can be found in Mell et al. (2009), Perez-Ramirez et al. (2017) and Morandini et al. (2019) or Porterie et al. (2009). Most of the parameters are extracted from these previous studies. Namely, the parameters describing the dehydration of the vegetation are taken as $E_{H_2O} = 5800K$, $A_{H_2O} = 6 \times 10^5 s^{-1}K^{-1/2}$ and $\Delta H_{H_2O} = 2.2596 \times 10^3 J.kg^{-1}$ (endothermic). The parameters describing the decomposition of the vegetation into combustible duel are $E_{pyr} = 7250K$, $A_{pyr} = 3.63 \times 10^4 s^{-1}$ and $\Delta H_{pyr} = 1.297 \times 10^3 J.kg^{-1}$ (endothermic). The latter parameter is the only parameter that is not extracted from Perez-Ramirez et al. (2017) or Porterie et al. (2009), its value was fitted so the predicted ROS under zero-wind condition was similar to the experimental one with a fuelbed of 0.5 kg/m² and a fuel width of 0.25 m. The char oxidation model and its inputs was extracted from Perez-Ramirez et al. (2017). Namely, the following parameters were used in our study : $E_{char} = 9000K$, $A_{char} = 430\ m.s^{-1}$ and $\Delta H_{pyr} = 32 \times 10^3 J.kg^{-1}$ (exothermic).

Table 1 -Input parameters used for WFDS: comparison between raw experimental values and fitted optimised values

Features	Initial experimental values	Fitted Optimal values
MLRmax [kg/m³/s]	0.22	0.43
ρbulk [kg/m³]	5.55	
ρ [kg/m3]	519	
σ [1/m]	14 600	
Hu [-]	0.12	
τchar [-]	0.31	
ΔHr [kJ/kg]	16 480	14 497
Cf [-]	0.375	

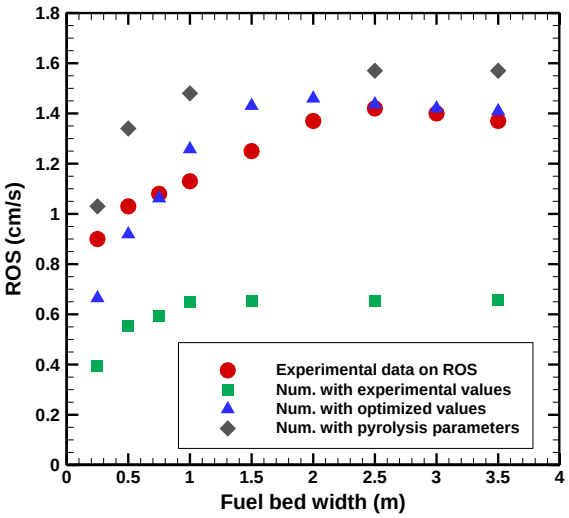

Figure 8 - Results of the two sets of WFDS simulations of ROS, with raw experimental values of the pyrolysis model parameters, and fitted optimal values

Simulations of FDS conducted with too low fuel loads (0.23 kg/m²) did exhibit no propagation, and calibrating different char oxidation parameters did not change this limiting model behavior. As seen in next section, when using a value of 0.3 kg/m² as in Meerpoel-Pietri et al. (2022) did not exhibit this problem.

7. Nominal FDS simulation on the intermediate setup of a wind-driven surface fire

The configuration of Figure 4 is simulated using the FDS model, using a fuel load of 0.5 kg/m². The model shows a coherent tendency in respect to the observations, with a lower increase of ROS with wind. More experiments at 0.4 kg/m² with wind have been scheduled to gain statistical robusntess of these results, to be compared with simulation at 0.4 kg/m².

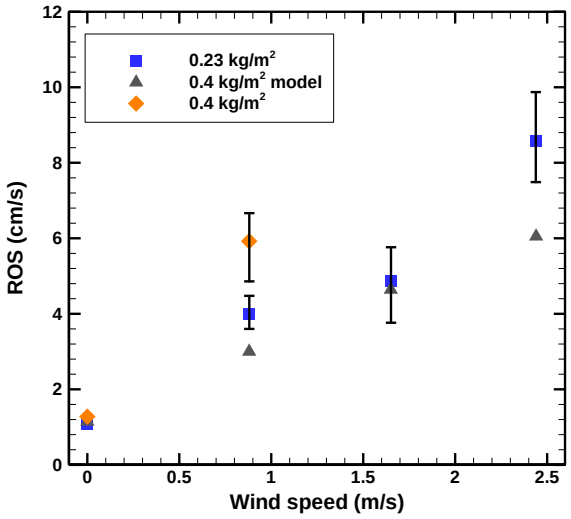

Figure 9 – Comparison of rates of spread varied with wind intensity, for two different loads (0.2 kg/m² and 0.4 kg/m²) for the experiments, and for one load (0.5 kg/m²) for the model

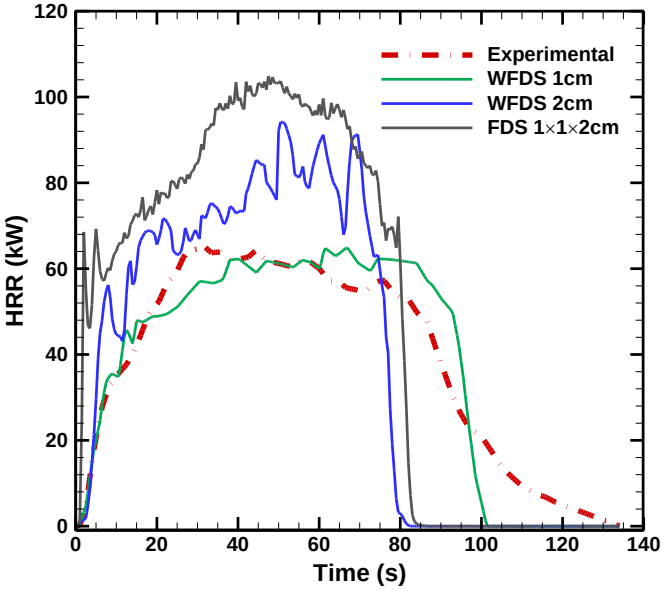
8. Nominal FDS simulations in similar setups

A simulation setup is used to illustrate the ability of FDS model to reproduce a zero-wind surface fire, extracted from Meerpoel-Pietri et al. (2022) referred hereafter as MP2022, with additional 20 % slope of the fuelbed. The fuelbed is also there composed of excelsior. The configuration from MP2022 as well as the input values given by the authors for the Arrhenius pyrolysis model are used within the FDS model, while the authors used the WFDS model.

As shown in Figure 10, the FDS outputs have a very similar intensity curve as the WFDS at 2 cm resolution from MP2022 , while being globally 22 % higher in intensity in the period between 5 s and 77 s. The difference in terms of intensity may be explained by the difference of the two codes. However, the ROS is coherent with the WFDS results and with the experimental data.



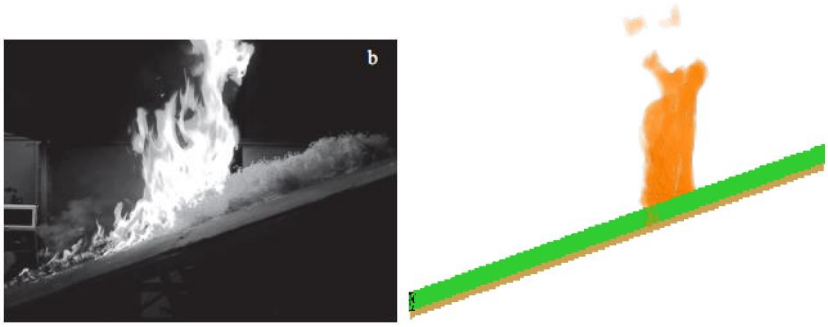


Figure 10. (upper row): Comparison of the intensity-time curves: the WFDS 1 cm and 2 cm and the experimental data are taken from MP2022 while the FDS is from current study, (lower row): Comparison in side view along the full slope of the observed (left) and modelled (right) flame height at timestep 51 s (source: observed flame photo is from Meerpoel Pietri et al. (2022))

A second similar setup as the full ornamental vegetation setup of this study is the single-tree canopy fire under zero wind provided by Mell et al. (2009), referred hereafter as M2009. The Mass Loss Rates (MLR) are calculated with FDS in this study for two different grid resolution, 10 cm and 25 cm, together with two different pyrolysis schemes: Arrhenius (same scheme as in the previous nominal zero-wind surface fire test) and simplified Arrhenius (scheme from older FDS versions). As shown in Figure 11 for a 5 m tree, the M2009 WFDS simulation is the closest to the experimental data, but all simulations from our study vary here only with a delay of less than 5 seconds in the peak MLR value, and with less than 20 % difference in peak value.

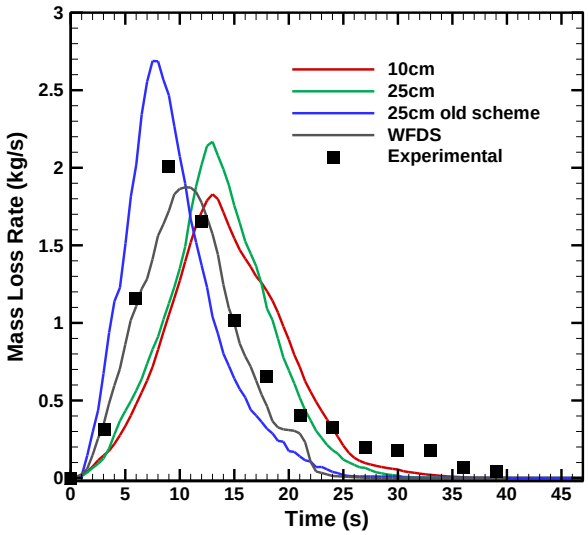

Figure 11 - Time evolution of MLR in current FDS version with both pyrolysis schemes and both resolutions (10 cm and 25 cm), compared with the Mell et al. (2009) experiment data and numerical WFDS outputs

These nominal simulations of FDS based on current state model should be confronted with observations of next coming surface and canopy fire tests in the study.

9. Conclusions

Based on experimental data on zero-wind surface fire propagation, this contribution showed promising results on the ability of WFDS and FDS to reproduce well the fire front behaviour. Moreover, the ability of FDS to propagate to an isolated vertical tree with the same modelling processes is also presented and validated.

A new experimental setup allowing simulating a scenario of fire contamination from the surface to an ornamental vegetation, under high wind conditions, is in ongoing development. It involves a surface fire

scenario, represented by a fire in Excelsior, which contaminates an ornamental vegetation. Some targeted nominal intercomparisons with the WFDS and FDS models will be presented in the final contribution. This new experimental setup will allow in a coming future to evaluate the impact of vertical discontinuities (low branches position of the ornamental vegetation), as well as effect of wind intermittency.

Wildfire simulation, fire-spotting, RandomFront, PROPAGATOR, cellular automata.

Abstract

Wildfire propagation is a non-linear and multiscale system in which there are involved multiple physical and chemical processes. One critical mechanism for the spreading of wildfires is the so-called fire-spotting: a random phenomenon which occurs when embers are transported over large distances by the wind, and causing the start of new spotting ignitions which jeopardize the fire-fighting actions. Due to its nature, fire-spotting is usually modeled as a probabilistic process. Three principal processes are involved during the fire-spotting: firebrands generation, transport joined with landing, and spot ignition. In this work, the physical parametrization of fire-spotting RandomFront (Trucchia et al. 2019) has been implemented into the operational wildfire spread simulator PROPAGATOR (Trucchia et al. 2020), which is based on a cellular automata approach. In the routine RandomFront, the downwind landing distribution of firebrands is modeled by means of a lognormal distribution, which is parameterized by taking into account the physics involved in the phenomenon. The considered physical parameters are: wind field, fire-line intensity, fuel density, firebrand radius, maximum loftable height, as well as factors related to atmospheric stability and flame geometry (Trucchia et al. 2019; Egorova et al. 2020,2022). As a matter of fact, similarity analysis cannot be applied to wildifres (Egorova et al. 2022, Section 2) thus the outputs of the simulations are checked against a real test case. In particular, we have considered the evolution of a real wildfire occured in Italy in August 2021 during which the fire-spotting played a critical role. In addition, we have implemented into PROPAGATOR also other two schemes for fire-spotting already available in literature and suitable for cellular automata-based wildfire simulators (Alexandridis et al. 2011; Perryman et al. 2013). We compared the performance of these three fire-spotting models. The results show that, on the one hand, the RandomFront parametrization reproduces the main spotting effects similarly to the available literature models (Alexandridis et al. 2011; Perryman et al. 2013), and, on the other hand, RandomFront generates also a variety of fire-spotting situations together with long-range fluctuations of the burning probability by allowing for complex patterns.

1. Brief introduction

Fire-spotting occurs when firebrands are transported away from fire and start new fires known as spot-fires (Brown and Davis 1973; Werth et al. 2011). These new fires can occur near the fire propagation front, accelerating the spread of fire, or kilometers away from the source fire, causing new secondary ignitions that increase the extinction difficulty and in which civilians and firefighters can result trapped (Koo et al. 2010). The conducted research to understand this phenomenon has been done in two ways. On one hand, there are extensive experimental studies focused on the characterization of the firebrands generation and transport process (Manzello et al. 2007, 2008; Suzuki et al. 2012; Thomas et al. 2017; Himoto and Iwami 2021; Wickramasinghe et al. 2022). Unfortunately, the short scales of the experiments limit its application into the calculation of the landing distribution (Pérez et al. 2011; Sullivan and Cruz 2015). On the other hand, firebrand transport models

have been developed to estimate the landing distribution and flight paths of the firebrands (Tarifa et al. 1965, 1967; Albini 1979, 1983; Himoto and Tanaka 2005; Sardoy et al. 2007, 2008; Wang 2011; Kaur et al. 2016). We highlight that the validation of these models in reduce-scale experiments are unreliable, in particular, in cases with important wind-fire or multiple fire interactions (Egorova et al. 2022, Section 2).

Wildfire modeling has been studied from several approaches (Sullivan 2009a; b; c), but Cellular Automata (CA) based methods have demonstrated to be a quick, efficient, and versatile approach to simulate the wildfire spreading (Clarke et al. 1994, Duarte 1997, Hargrove et al. 2000, Encinas et al. 2007, Gharakhanlou and Hooshangi 2021). Some of the developed CA-based models include the effect of the fire-spotting. We highlight the model developed by Alexandridis et al. (2008, 2011), which was revisited by Freire and Dacamara (2019) to reproduce a forest fire in Portugal, and the model developed by Perryman et al. (2013).

In this work, we have implemented into the operational wildfire spread simulator PROPAGATOR (Trucchia et al. 2020) the recently developed parametrization RandomFront (Trucchia et al. 2019; Egorova et al. 2020, 2022) as well as both previously cited CA-based fire-spotting models to be compared. In addition, we have reproduced a wildfire that occurred in Italy in August 2021, in which the fire-spotting effects were critical, for validating the results.

2. Fire propagation model and firebrand landing parametrizations description

2.1. Propagator fire-spread simulator

In this work, PROPAGATOR (Trucchia *et al.* 2020) was used to simulate the spread of fire. PROPAGATOR is an operational software based on a CA approach and assisted with high resolution data from the topography and land fuel cover. The fire spread is computed through vegetation type, slope, wind direction and speed, and fuel moisture content, therefore, the burned surface evolves in a stochastic sense. The input parameters are the wind intensity and direction, the start point of fire and the adopted ROS model. PROPAGATOR is designed to compute an ensemble of simulations in a fast way, being its basic and natural output a georeferenced map which represents the probability of each cell to be affected by fire.

2.2. Alexandridis *et al.* (2011) firebrand landing parametrization

The model developed by Alexandridis et al. (2008, 2011) , consist of a CA approach focused on the efficient simulation of wildfire spreading. The first part of their fire-spotting parametrization models the firebrand landing distance as follows:

$$d_p = r_n \cdot P_w = r_n \, exp\left(U_{C_2}(Cos\,\varphi - 1)\right), \qquad (1)$$

where r_n is a random number drawn from a normal distribution, φ is the angle between the direction of the wind and the direction of the blasting, and $U_{C_2} = U \cdot C_2$ is the mean-wind velocity times a fitted constant. In addition, the probability of spot ignition, *i.e.*, when a blasting firebrand will ignite or not a new spot-fire, is computed as:

$$P_C = P_{C0}\,(1 + P_{cd}), \qquad (2)$$

where P_{c0} is a constant probability corrected by P_{cd}, which is a factor that depends on type and fuel density.

2.3. Perryman *et al.* (2013) firebrand landing parametrization

The model developed by Perryman et al. (2013) consists of an ensemble of four sub-models adapted to a CA environment. Their firebrand landing distribution was implemented following the statistical model developed by Sardoy et al. (2008) for the firebrands which are blasted parallel to the wind, and the Himoto and Tanaka (2005) results for firebrands blasted perpendicular to the wind field. The landing distance of the parallel firebrands are computed following a lognormal distribution function:

$$p(d) = \frac{1}{\left(\sqrt{2\pi}\,\sigma_{FB}\,d\right)}\, exp\left(\frac{-\left(ln(d) - \mu_{FB}\right)^2}{\left(2\sigma_{FB}^2\right)}\right), \qquad (3)$$

where d is the distance away from the line front. The mean μ_{FB} and standard deviation σ_{FB} depend on the current wind intensity U, the fireline intensity I_f, fitted constants and if the firebrands are buoyancy driven or wind driven. To discern between both cases, the Froude number Fr is computed:

$$Fr = \frac{U}{\sqrt{g\left(\frac{I_f}{(\rho\, c_p\, T_A\, g^{1/2})}\right)^{2/3}}}, \qquad (4)$$

where g is the acceleration of gravity, I_f is the fire intensity, ρ is the ambient gas density, c_p is the specific heat of gas and T_A is the ambient temperature. If Froude number is less or equal to one, buoyancy driven regime is considered and for Froude number greater than one, wind driven plume regime. The firebrand distance of the embers generated parallel to the wind are modeled by means of a normal distribution, assuming zero mean and standard deviation $\sigma_v = L/2$, where L is the cell size.

2.4. RandomFront firebrand landing parametrization

The landing distance is parameterized by means of a log-normal distribution (*i.e.*, Eq. (3)) combined with the physics involved in the firebrand transport (Trucchia *et al.* 2019). The mean of the distribution μ^* depends strongly on the atmospheric conditions, specifically on the Atmospheric boundary layer (Egorova et al. 2020):

$$\mu^* = H\left(\frac{3\rho C_d}{2\,\rho_f}\right)^{1/2}, \qquad (5)$$

where C_d is de Drag coefficient and ρ_f is the density of the wildland fuels. The maximum liftable height of the firebrands H is computed as a fraction of the injection height $H = 0.4 \cdot H_{smoke}$. The injection height of the smoke H_{smoke} is described by the formula (Sofiev et al. 2012, formula (10)):

$$H_{smoke} = \alpha\, H_{ABL} + \beta\left(\frac{I_f}{d\, P_{f_0}}\right)^{\zeta} exp\left(-\frac{\delta_{FT}\, N_{FT}^2}{N_0^2}\right), \qquad (6)$$

where H_{ABL} is the height of the atmospheric boundary layer, $N^2{}_0$ and $N^2{}_{FT}$ are the Brunt-Väisälä frequency at the current height and in the free troposphere respectively, and P_{f0} is the ratio of reference fire power. The standard deviation σ involves the effects of the horizontal wind, flame geometry and the slope over the fire-spotting landing distance Egorova et al. (2020, 2022):

$$\sigma = \sigma(\varphi,\omega) = \frac{1}{z_p} ln\left\{\frac{U\,Cos\,\varphi}{\sqrt{gr\left(1+Tan^2\,\omega\right)}} + \beta_2\sqrt{\frac{2\rho_f}{3\rho C_d}}\,\frac{1.4U\,Cos\,\varphi + \sqrt{gh_0\left(1+\phi_{wind}+\phi_{slope}\right)^{2/3}\,Tan\,\omega}}{\sqrt{gh_0\left(1+\phi_{wind}+\phi_{slope}\right)^{2/3}} - 1.4U\,Cos\,\varphi\,Tan\,\omega}\right\}, \qquad (7)$$

where φ is the angle between the wind and the direction in which a firebrand is ejected, ω is the slope of the cell in which the ember is generated and:

$$L_f = h_0\left(1+\phi_{wind}+\phi_{slope}\right)^{2/3} = \beta_0\, I_f^{2/3}, \qquad (8)$$

where:

$$\beta_0 = \left(\frac{1}{2g\left(\rho c_p T_A\right)^2}\right)^{1/3}. \qquad (9)$$

Fire-spotting in the RandomFront parametrization is considered as a downwind phenomenon. A critical angle φ_0 is defined as the angle for which the ember is not considered ($\sigma <= 0$). By means of the probabilistic distribution, this is the angle for which σ becomes negative.

3. Area of study and simulations

3.1. Area of study

The reproduced wildfire took place 1st August 2021 in the municipality of Campomarino, in the Adriatic coast of Italy (Fig. 1).

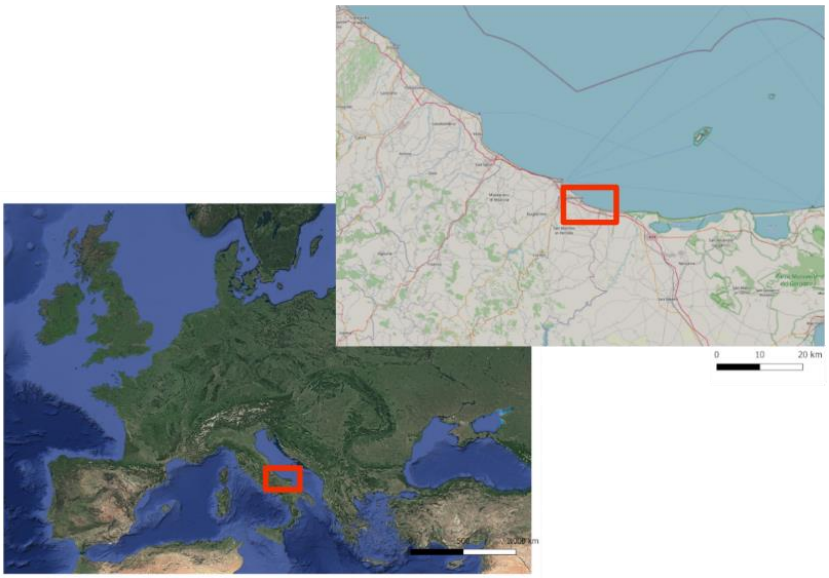

Figure 1- Study area.

The burnt perimeter is exposed in Fig. 2 – (a). The wildfire started burning around 12:00 am and finished around 5:00 pm. The fire-spotting effects were reported around 3:00 pm from the East to the West part of the port. We defined a rectangular area of study with 2.98 km^2 around the wildfire extension to run the simulations. Each cell of the cellular automaton has a resolution of 20 m^2. The fuel types have been adapted from the Corine Land Cover (CLC) classification (Feranec et al. 2016) t o the propagator classes (Fig. 2 – (b)). Specifically, we took *Pinus pinaster Aiton* as the reference tree specimen associated with the fire-prone conifers fuel type (Tihay *et al.* 2009). The data labeled as "non-burnable" have a low but non-zero probability of being burnt. The orography data were obtained from a Digital Elevation Model (DEM) but due to the proximity to the sea, a null or very tiny variation of the slope is reported over the fire-prone conifers.

3.2. Methodology and simulations

For each parametrization an ensemble of 100 independent realizations was generated under the same conditions (Trucchia *et al.* 2020). The computational time for each ensemble is less than two minutes. Each simulation was stopped after 5 hours of simulated time. The weather was reported to be unstable and turbulent when the wildfire occurred, with peaks up to 70 km/h. To reproduce these conditions, we consider a constant wind speed of 40 km/h and, each 15 minutes of simulated time, a stochastic constant derived from a normal distribution with mean 0 and standard deviation 20 is added to the mean wind speed. In addition, the main wind direction, which came mainly from south, is also perturbed each 15 min with a stochastic variable derived from a normal distribution with mean 0 and standard deviation $\pi/8$. Two processes still needed to be characterized for a complete fire-spotting description: firebrand generation and spot ignition. Despite the considerable number of studies focused on both previous phenomena at the laboratory scale, there is a lack of research focused on the development of a physics-guided probabilistic model to characterize them. Due to this reason, we have modeled the firebrand generation for each burning cell by means of a Poisson distribution and the spot probability through Eq. (2). Next, we show the probability maps computed from the ensemble of simulations after 3 and 5 hours, which are the times at which fire-spotting was reported and the fire stopped, respectively.

3.2.1. Alexandridis et. al. (2011) sub-model results

The port separates both coniferous areas with 190 m, so the mean of the normal distribution which will generate r_n in the Alexandridis parametrization Eq. (1) was implemented as 190. We also consider to implement the

standard deviation equal to 25 as reasonable value. The computed burn probability map for this firebrand landing distribution after 3 and 5 hours is exposed in Figure 3 respectively.

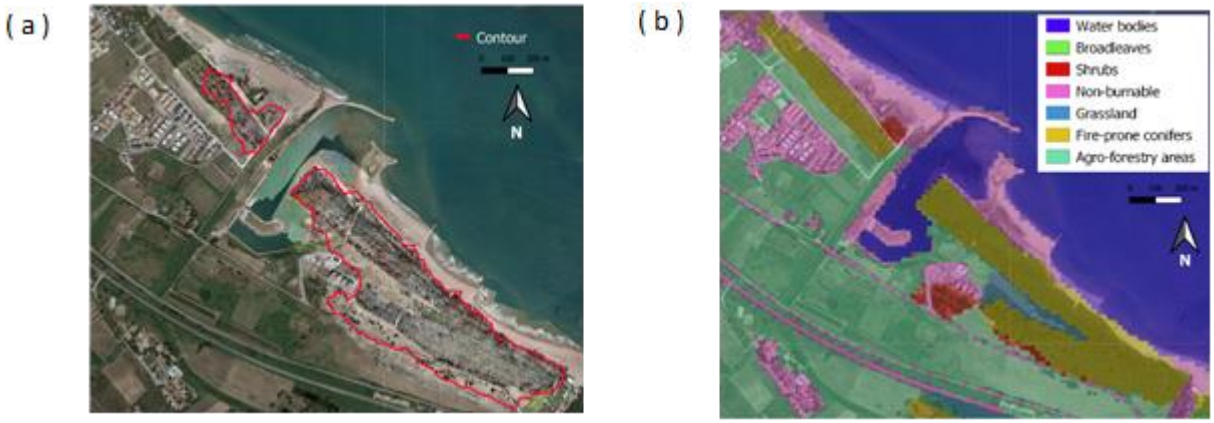

Figure 2- Studied area. Figure 2-(a) shows the true color orthomosaic derived by UAV survey done after the wildfire occurs. The red line defined the burnt area, based on high resolution photointerpretation. Figure 2-(b) displays the land cover classification used.

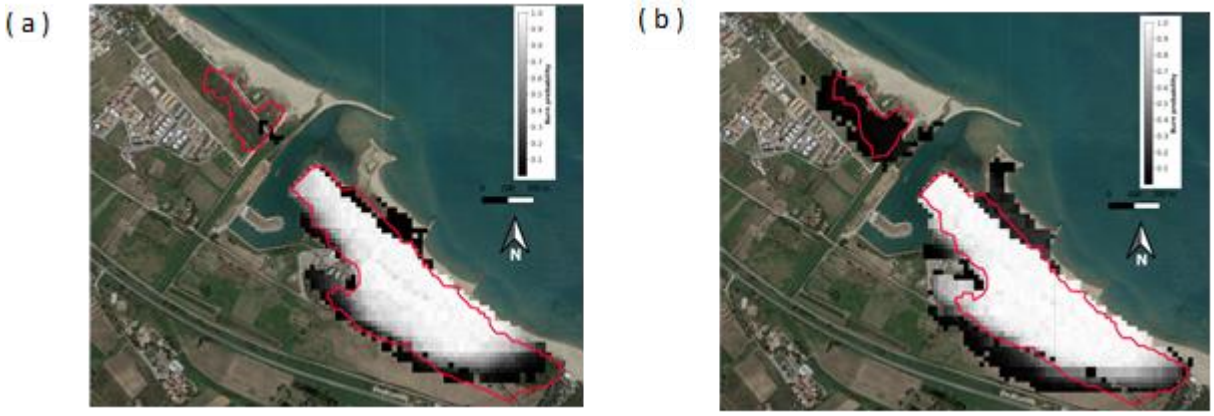

Figure 3- Computed burn probability map with the Alexandridis parametrization implemented. Figure 3-(a) shows the burn probability after 3 hours and Figure 3-(b) after 5 hours.

3.2.2. Perryman et. al. (2013) sub-model results

The burn probability map after 3 and 5 hours with the Perryman firebrand landing distribution is shown in Figure 4.

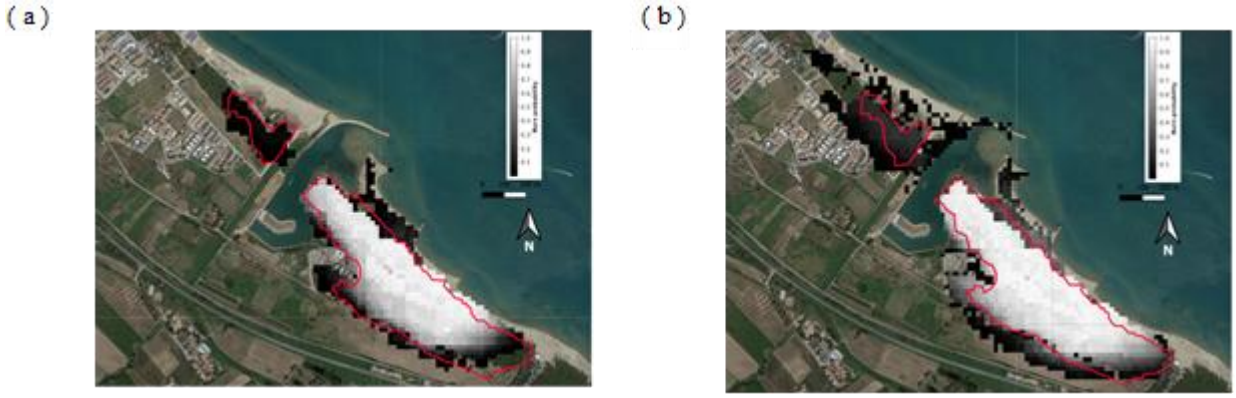

Figure 4- Computed burn probability map with the Perryman parametrization implemented. Figure 4-(a) shows the burn probability after 3 hours and Figure 4-(b) after 5 hours.

3.2.3. RandomFront sub-model results

The burn probability map after 3 and 5 hours with the RandomFront firebrand landing distribution is shown in Figure 5. Due to the instability of the weather and the summer conditions we consider the height of the Atmospheric Boundary Layer equal to H_{abl} = 2600 m.

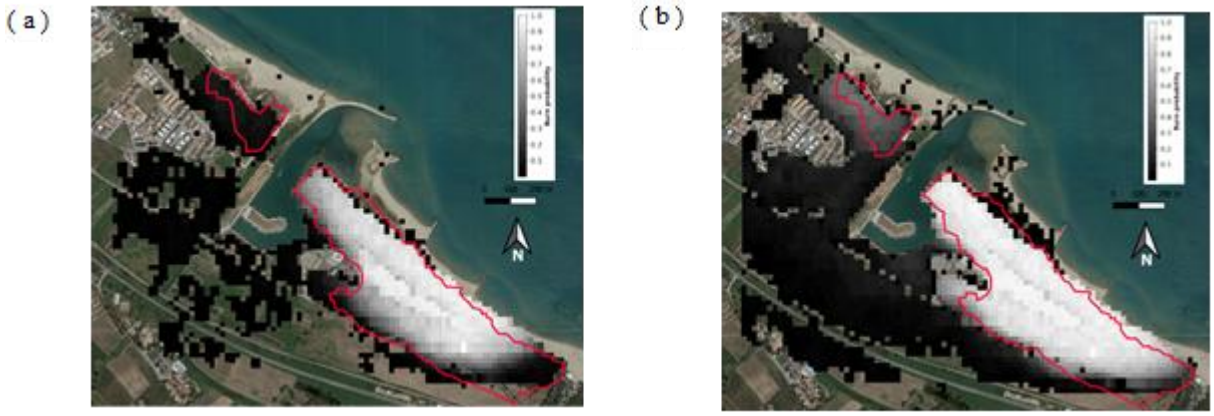

Figure 5- Computed burn probability map with the RandomFront parametrization implemented. Figure 5-(a) shows the burn probability after 3 hours and Figure 5-(b) after 5 hours

4. Brief discussion

To validate the model against the shape of the reference wildfire and quantify the obtained results, the averaged probability was computed for the two reference areas at both sides of the port, see Table 1. This measure is defined as the sum of the probabilities associated to each cell in the reference domains divided by the number of cells inside the reference domains.

Table 1- Averaged probabilities computed inside the reference perimeters.

Area	Alexandridis *et al. (2011)*	Perryman *et al. (2013)*	RandomFront
East	0.7937	0.7370	0.7303
West	0.0358	0.1330	0.2868

Table 1 shows that the averaged probability in the reference area at the West part of the port is, in the ensemble generated with RandomFront parametrization, one order of magnitude higher than the one obtained by using Alexandridis *et al.*, and more than twice when compared with the Perryman *et al.* parametrization. This agrees with Figures 3, 4 and 5 displayed results. Figure 3 shows how Alexandridis *et al.* parametrization is unable to assign any burning probability to the West part of the port when the fire-spotting was indeed reported. In addition, at the end of the simulation, a poor spread pattern is observed. The Perryman *et al.* parametrization of the firebrand's landing distribution displayed in Figure 4 generates a bit more complex spread pattern than by using Alexandridis *et al.*, but a low burn probability remains assigning to the West part of the port. By contrast, RandomFront firebrand's landing parametrization can generate a clear but low burn probability when the fire-spotting was reported. In addition, at the end of the simulation, an averaged burnt probability of 28.6% is assigned to the reference area at the West part of the port, as well as quite complex spread pattern is observed.

The implementation of fire-spotting routines causes deviation between simulations output when performed with different fire-spotting models (but fixed input data), see Figures 3, 4 and 5. In particular, from both the spread pattern and the probability to burn, we have that that the fire-spotting parametrization RandomFront performs better than the other two models.

5. Main conclusions

In this work, we have implemented the recently developed RandomFront fire-spotting landing distribution into the operational software PROPAGATOR. In addition, we have compared against other two fire-spotting models developed for a cellular automaton setting. To compare the performance of these three parametrizations, a real wildfire affected by fire-spotting effects was reproduced and used as validation test: actually, because results at laboratory scale are unreliable due to the multi-scale nature of wildfires. The ensemble computed with the

RandomFront parametrization displays a more complex spread pattern than the other parametrizations and a non-zero burnt probability in the West area of the port where the fire-spotting was indeed reported. In addition, at the end of the simulation in the area affected by the fire-spotting, RandomFront provides higher burnt probabilities than the other implemented parametrizations. Firebrand rate generation and spot ignition probability, which are still poorly for probabilistic modelling approaches, embody future development of the present research.

Wildland urban interface; WUI; fuel characteristics; plants, trees, fire behavior, fire modelling

Abstract

The large fires in recent years have caused tragic episodes that have led to the death of many hundreds of people and the loss of buildings of great social and economic value. Several of these impacts could have been avoided if the fuel management around buildings had been appropriate. Many studies on flammability are dedicated to wild fuels present in the forests, shrublands or grasslands. However, the existing data on the vegetation typical of the surroundings closest to the constructions (e.g., gardens) is scarce. Besides being the fuels closest to the buildings, these are fuels that normally can be effectively managed by the building owners, i.e., their management is within the reach of the common citizens.

This work aimed to characterize the flammability parameters for several typical garden species in the Mediterranean Basin. An extensive experimental program was carried out to characterize individual plants of the following species: holly (Ilex aquifolium), linden (Tilia nobilis), anacardia (Rhus typhina), laurel (Laurus nobilis), olive tree (Olea europaea), pacific madrone (Arbutus menziesii), apple tree (Malus sylvestris), cherry tree (Prunus avium), sloe (Prunus Spinosa), fig tree (Ficus carica), loquat (Eriobotrya japonica), kiwi plant (Actinidia deliciosa), grapevine (Vitis vinifera), hydrangea (Hydrangea macrophylla), oleander (Nerium oleander), ivy (Hedera helix). In this work, the results for only three of those plants will be presented, namely: oleander, fig tree and laurel. The following parameters will be presented: mass-loss rate, vertical profile of temperature, heat flux and flame dimensions.

This study has two main objectives: 1) to provide data that allows fire behavior modelling in the proximity of dwelling houses; and 2) the determination of the acceptable safety distance that species must be from buildings to prevent their ignition. Some of the tests performed showed that the presence of some species in the proximity of buildings (not attached) can be beneficial due to their low inflammability and because they can constitute an obstacle to the passage of firebrands, which can ignite the construction.

1. Introduction

The greatest impacts that have been registered in the last decade as a result of wildfires highlighted the relevance of the wildland-urban interface (WUI), with a special focus on the potential loss of people and animals' lives, as well as the destruction of buildings. The various studies concerning large wildfires (Viegas et al., 2017; Viegas et al., 2019) concluded that improper fuels management in the vicinity of constructions is among the main causes of its destruction. In addition, the lower confidence of citizens regarding the fire resistance of buildings leads to people often feeling impelled to leave their homes putting their lives at risk due to untimely evacuation processes.The fuel management in the WUI scenario requires knowledge of the flammability characteristics of the fuels. For example, it is important to know the minimum distance at which a certain tree shall be planted from a construction, to avoid ignitions by direct heat transfer from vegetation to houses. Moreover, this knowledge is important for selecting the species that should be placed closer to buildings or those that should not exist in their immediate vicinity. Naturally, the probability of ignition of a structure depends not only on the characteristics of the surroundings, but also on the construction characteristics and the self-protection capacity (e.g., sprinkler systems) that may exist.

The fuels around buildings can be divided into natural fuels (e.g., trees, ornamental plants) and man-made fuels (e.g., vehicles, plastic covertures, GPL tanks). The present work is exclusively dedicated to natural fuels, namely typical garden plants. Thus, any mention of fuels in this text shall be understood in that context.

In the analysis of fire behavior modelling in WUI, the knowledge of the flammability characteristics of the species that feed the combustion processes is essential. Although there is some information on the flammability of wild species (e.g., forests, shrublands or grasslands), the characterization of the typical species of the areas in the immediate surroundings of the buildings is poorly developed – Weise et al. (2005), Ganteaume et al. (2013) and Zhang et al. (2011) are examples of exceptions. Thus, the accuracy of the fire behavior simulators applied to the WUI is compromised. Physical properties of the fuel, e.g., fuel moisture content (FMC), bulk density, porosity, thermochemical characteristics such as the equivalent hydrocarbon (CHON) content for gas-phase reactions, and applying realistic boundary conditions are major factors to be considered in the fire dynamics simulations (FDS) (Weise et al., 2005). The boundary conditions entail several parameters, e.g., domain characteristics, heat release rate per unit area (HRRPUA) of the burner, environmental conditions with a trade-off between the grid size, and the computational capacity of the solver.

A laboratory work program was carried out to determine the flammability characteristics of typical garden plants, specifically: holly (*Ilex aquifolium*), linden (*Tilia nobilis*), anacardia (*Rhus typhina*), laurel (*Laurus nobilis*), olive tree (*Olea europaea*), pacific madrone (*Arbutus menziesii*), apple tree (*Malus sylvestris*), cherry tree (*Prunus avium*), sloe (*Prunus Spinosa*), fig tree (*Ficus carica*), loquat (*Eriobotrya japonica*), kiwi plant (*Actinidia deliciosa*), grapevine (*Vitis vinifera*), hydrangea (*Hydrangea macrophylla*), oleander (*Nerium oleander*), ivy (*Hedera helix*). The results of this study apply to other scenarios where these species are present – for example, the road sides, the surroundings of industrial facilities or the periphery of settlements. The main objective of this work is to provide relevant data for modelling fire behavior in the WUI and to increase the knowledge that allows defining with scientific support the best practices of fuel management in the immediate surroundings of buildings. In this manuscript, as an example, the results for one shrub – oleander – and for two trees – laurel and fig tree – will be presented (Figure 1). Besides the flammability data a valuation of the acceptable safety distance between those plants and a building will be provided.

(a) (b) (c)

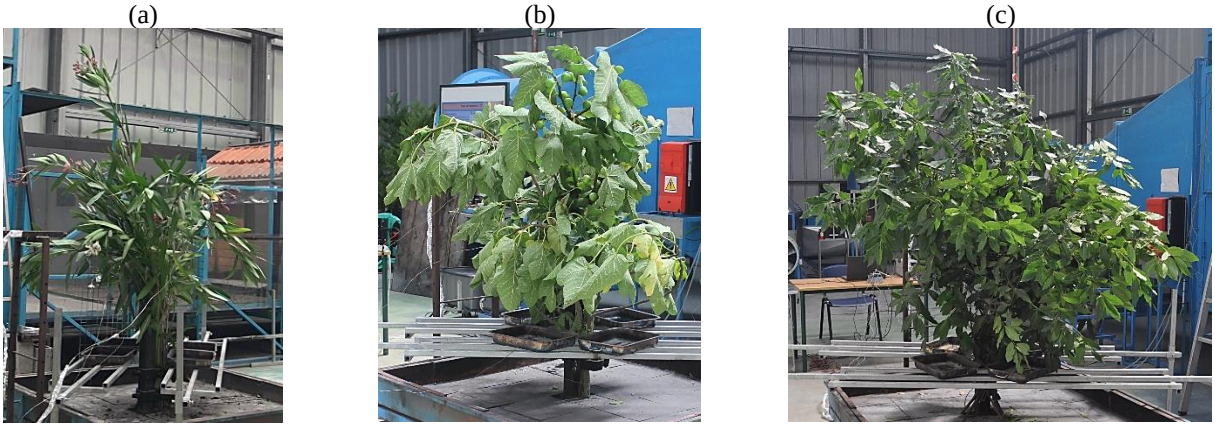

Figure 1: Image of the species used in the tests that will be described: a) oleander; b) fig tree; c) laurel.

2. Methodology

The laboratory tests were performed at the ADAI's Laboratory for Forest Fire Studies, in Lousã - Coimbra (Portugal). All tests were performed between July and August 2021.

2.1. Experiments description

Fuel sampling

Each plant to be tested was collected from its natural environment no more than 24 hours before being burnt. After their transport to the laboratory, the plants were kept in a shady environment, with indoor conditions never exceeding 25ºC.

Experimental setup

The plants were burnt in the "Tree Burning Platform" (Ganteaume et al., 2013) that has attached a weighing system allowing the determination of the mass decay throughout the burning. A *Pitot* tube and a thermocouple

were placed above the plant at a fixed height of 3.5m to determine the convective flow velocity. Besides the thermocouple at a height of 3.5m, in the same vertical axis connecting the center of the plant to the *Pitot* tube, two thermocouples were also placed in the middle and at the top of the plant's crown. A radiative heat flux meter was installed at 1.0m height and 50cm from the edge of the plant canopy. Furthermore, the tests were recorded with a pair of IR cameras and another pair of RGB cameras, settled parallel and transversally to the flame front. The analysis of the images captured by these cameras allowed the determination of the flame dimensions - height, length and depth - along with the test. Figure 2 presents the experimental setup described.

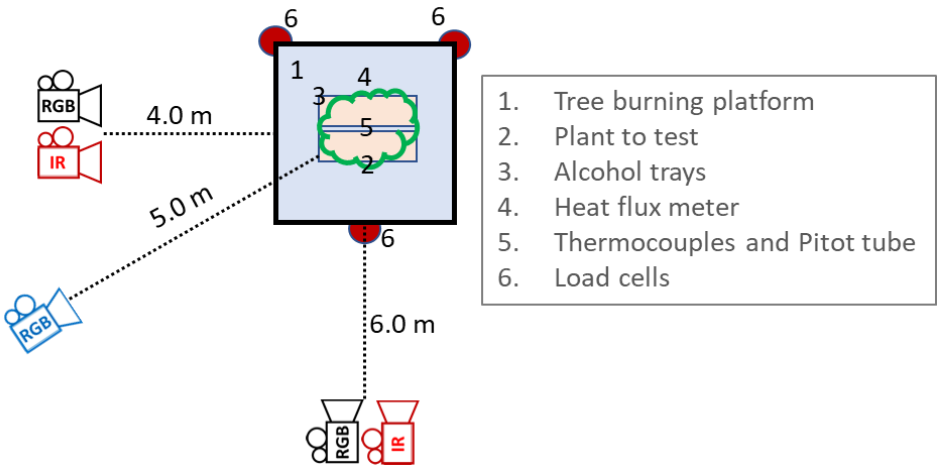

Figure 2 – Experimental setup.

Experimental procedure

Ignition: Since the plants tested alone could not sustain the fire, it was necessary to add a heat source. Thus, 20cm below the base of the plant crowns, trays were placed with denatured alcohol (96% v/v) allowing the ignition and sustaining the fire, just like what happens with the understory in real fire events. The trays were used to distribute the heat evenly to the entire base of the canopy. It was used an area of trays per horizontal projected area of the crown of 0.75 m^2/m^2, which corresponds to 1.6 L of alcohol per cm^2 of the horizontal projected area of the plant.

To facilitate data synchronization, the measuring equipment was started simultaneously with the ignition that occurred at the same time in all trays.

The trays were installed on a shelf that did not interfere with the mass acquisition system so it was not necessary to make the correction of this parameter. A reference burning test was performed only with alcohol in order to understand the influence of this fuel on the heat flux acquisition values during the regular tests. The methodology used throughout these experiments was the same as described in Almeida et al. (2021). Five repetitions per plant were carried out.

2.2. Calculations

Mass loss coefficient

The mass loss was analyzed based on the mass loss coefficient *k* of Equation 1 for determining the absolute value of mass *m* and for Equation 2 which allows the determination of the relative mass m_r. In these equations m_0 corresponds to the initial mass and *t* is the time elapsed since ignition.

$$m = m_0 \times e^{-k \times t} \quad \text{[Equation 1]}$$

$$m_r = \frac{m}{m_0} = e^{-k \times t} \quad \text{[Equation 2]}$$

Figure 3 shows an example of mass loss determination with the respective curve for each test carried out for the same species. The final *k* value for each species is determined based on of the mean value of the *k* values obtained in the five test repetitions.

(a) (b)

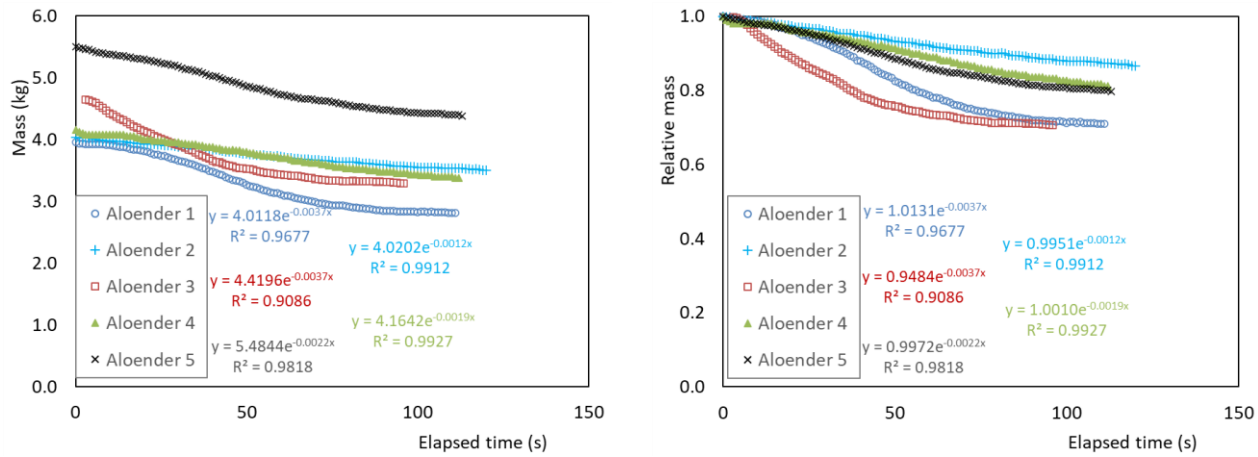

Figure 3: Example of the mass loss curves for the five tests performed with oleander: a) absolute mass values (Equation 1); b) relative mass values (Equation 2).

Heat flux reference tests

Reference tests were performed with the same configuration and quantity of trays containing the same amount of denatured alcohol used during the experiments with plants. It was found that the heat flux recorded is higher than in some tests with plants (Figure 4). This is because the plants are themselves a barrier to heat flux from the alcohol. Thus, the error associated with the burning of alcohol is assumed not to be very high and so is not considered.

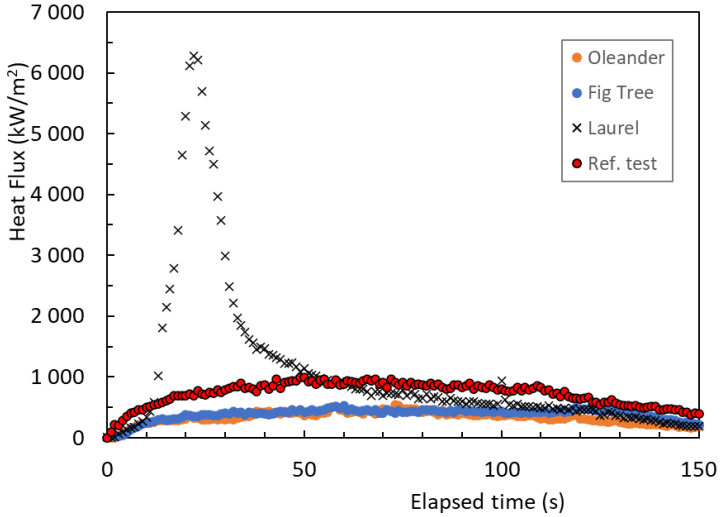

Figure 4: Heat flux values emitted by denatured alcohol and plants.

Acceptable safety distance

The acceptable safety distance *ASD* was determined using the model developed by Rossi et al. (2011), presented by Equation 3. Table 1 expresses the details of the Rossi's *ASD* definition.

$$ASD = \left[\frac{L_f \cos(\gamma)\sqrt{-4\Phi^2+\left(BT_f^4\varepsilon\tau\right)^2}}{2\Phi_{thres}} + L_F \sin(\gamma)\right] \times \left[1 - exp\left(-\frac{2L}{L_f}k\right)\right] \quad \textit{[Equation 3]}$$

Table 1: Description of the variables in Equation 3 and presentation of the values used in the simulations.

Symbol	Parameter	Values used
ASD	Acceptable safety distance	Variable
L_F	Flame length (m)	Variable

Φ	Heat flux limit (W.m-2)	Variable
h	Height difference between the base of the flame and the target (m)	1.7
k	Empirical parameter	1
L	Half of the length of the flame front (m)	20
γ	Angle of inclination of the flame (°)	0
B	Stephan-Boltzmann constant ($W.m^{-2}.K^{-4}$)	5.670374419×10^{-8}
Tf	Average flame temperature (K)	1350
τ	Atmospheric transmittivity	0.9
ε	Equivalent flame emissivity	0.8

2.3. Resume

Table 2 – Summary of the experiments: m_0- initial mass; m_f- final mass; FMC- fuel moisture content; CH- crown height; CD- average crown diameter; CBH- crown base height.

Species type	*Case*	m_0 (kg)	m_f (kg)	FMC%	CH (m)	CD (m)	CBH (cm)
Oleander	1	3.98	2.89	50.4	0.90	0.90	15
	2	3.97	3.10	36.2	1.75	1.15	15
	3	4.57	3.63	36.2	1.80	1.05	30
	4	4.00	3.28	36.9	1.85	1.55	17
	5	5.50	4.30	37	1.70	1.00	15
Fig tree	1	5.25	4.82	43.6	1.5	1.15	25
	2	5.94	5.49	58.8	1.4	1.30	25
	3	5.41	4.85	59.2	1.3	1.15	25
	4	6.10	4.88	58.8	1.4	1.25	25
	5	5.46	4.58	58.9	1.35	1.15	25
Laurel	1	3.89	2.24	53.7	1.50	1.30	15
	2	4.44	3.12	53.7	2.00	1.35	15
	3	3.45	2.12	53.7	1.30	1.10	20
	4	3.17	2.04	57.7	1.85	1.00	15
	5	3.97	2.89	63.4	2.00	1.05	10

3. Results and discussion

Mass loss

As previously mentioned, the mass loss is presented through the average value of the mass loss coefficient *k* for each species, as presented below. Fig tree is clearly the species that presents the lowest value of *k*, i.e., a slower mass decay. On the other side, the laurel presents a very high value of *k*, which is a reflection of its great inflammability, which was verified in the tests.

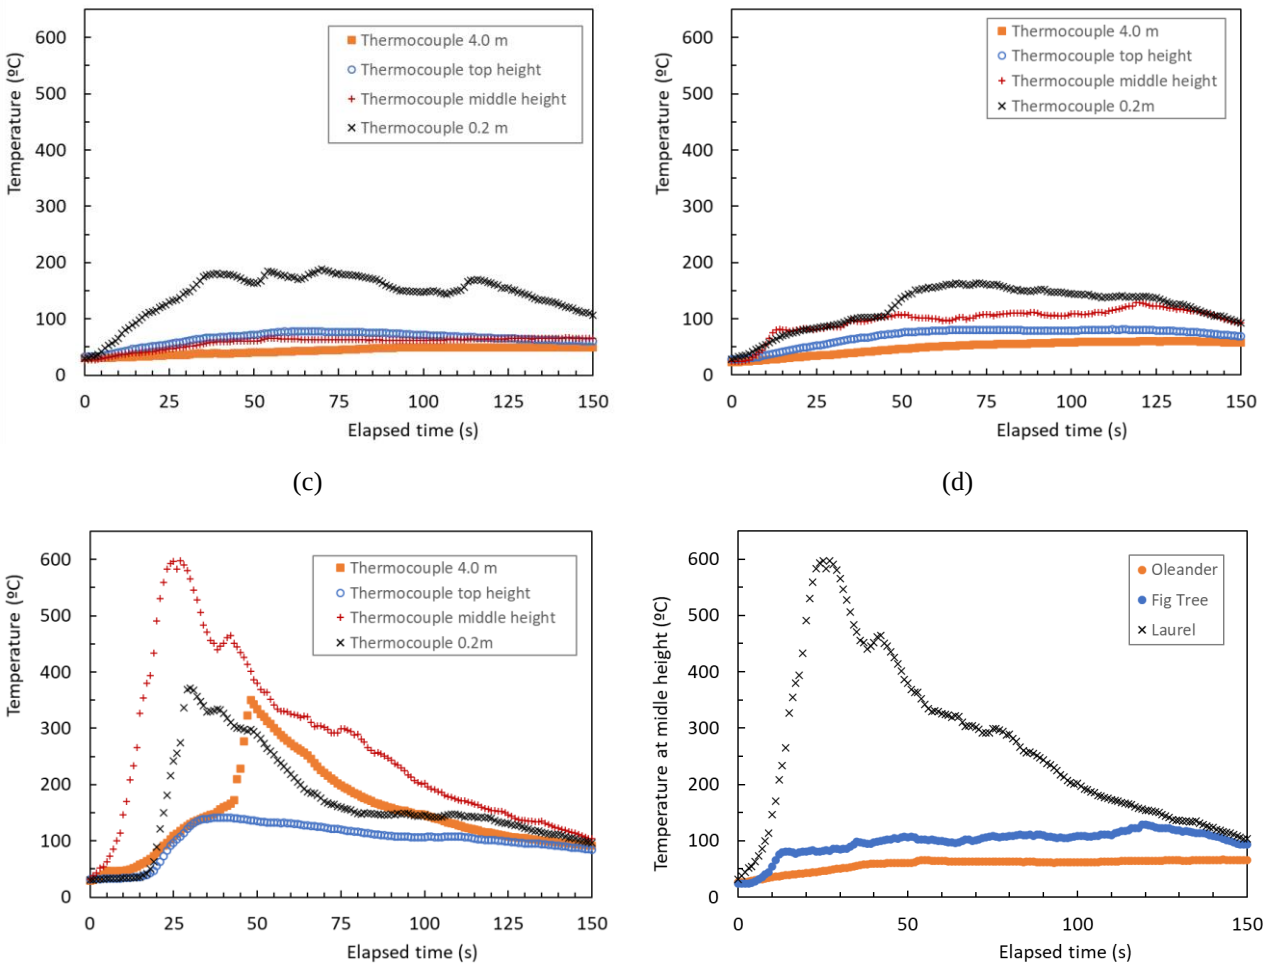
Table 3: Average mass loss coefficient determined for each species. In parentheses the standard deviation values are shown.

Parameter	Oleander	Fig tree	Laurel
Mass loss coefficient *k* (s^{-1})	0.00254 (0.0012)	0.00106 (0.00058)	0.00776 (0.00425)

Temperature

The temperature values were measured in the central longitudinal axis of the plant at various heights, as previously mentioned. Figure 5 (a, b, c) presents the temperature variation along the tests, for several heights. Figure 5d presents the temperature variation measured in several tests in the thermocouple located at half the height of the plant. The values obtained for the oleander and fig are very close, while the temperature values for the laurel are much higher. In the first two species, the thermocouple located at 20 cm is the one that reaches higher temperatures because it is close to the trays with alcohol. However, in the tests with the laurel, due to the higher intensity of the flame, the highest temperature value was obtained for the thermocouple located at mid-height of the plant.

(a) (b)



(c) (d)

Figure 5- Temperature variation along the tests since ignition (t=0s). a), b) and c) refer to the measurements obtained at the different thermocouples for the oleander, fig tree and laurel, respectively; d) comparison between the temperature variation recorded at the thermocouple located at mid-height of the plant.

Heat flux and flame dimensions

Figure 6a presents the heat flux variation values for the three species. Once again, the heat flux measured in the tests with oleander and fig tree are merely residual, while the values reached for laurel present a maximum of 6281 kW/m^2.

(a) (b)

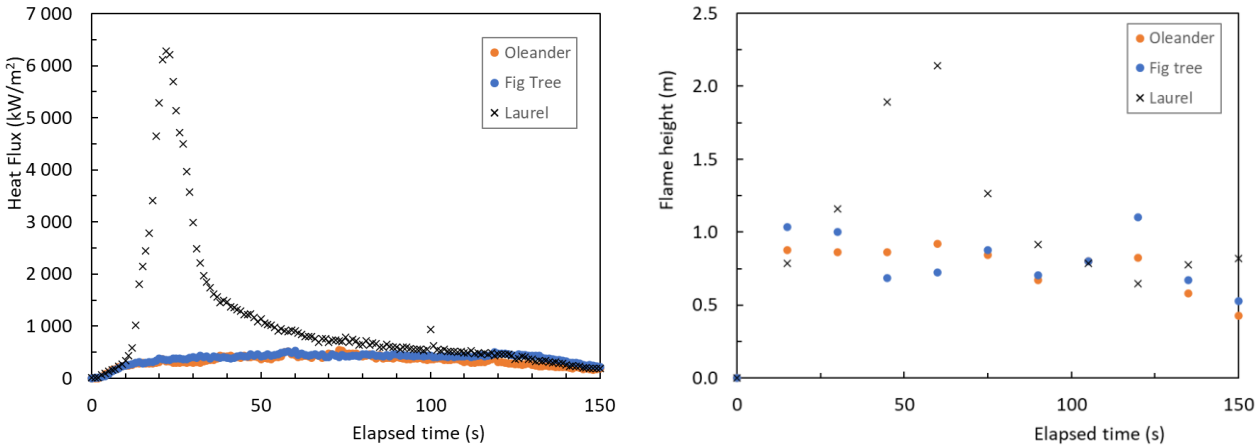


Figure 6 – Variation of heat flux (a) and flame height (b) during the tests performed for each species

Figure 6b presents the values of the flame height for the various species. Once again, the flame size of the laurel burning stands out from the other species due to its high burning intensity.

Acceptable safety distance

The table below presents the ASD values determined for the three species. In the sequence of the results presented above, it is easy to understand that laurel is the species that should be more distant from a building.

Table 4: Resume of the Acceptable safety distance determined for each species.

Species	Oleander	Fig tree	Laurel
Acceptable safety distance (m)	1.4	1.4	12.8

4. Conclusions

Values of flammability parameters for three species typically used in gardens, namely oleander, fig and laurel, were presented. These results may be of great interest for simulations of fire behavior in areas where these species exist. The laurel was the species that exhibited the highest flammability.

In addition, these test results allow the determination of what should be the acceptable safety distance that these species should be from a building. Normally, the regulations and standards in the scope of these matters do not distinguish between the species of shrubs and trees. However, as could be seen, trees such as laurel should be much more distant from buildings than, for example, fig trees. Given its low flammability, the existence of trees such as fig tree in the WUI can be beneficial to reduce the wildfires risk since they hardly spread fire to buildings, constituting a barrier to the projection of firebrands and reducing the turbulence in these areas.

5. Acknowledgements

The authors developed this work through the House Refuge Project (PCIF/AGT/0109/2018) which is funded by the Portuguese Foundation for Science and Technology (www.fct.pt), to whom they would like to express their acknowledgement.

LPG cylinders, Wildland Urban-Interface, Forest Fire, Accidents

Abstract

Incidents or accidents involving domestic liquefied petroleum gas (LPG) tanks have occurred at Wildland-Urban Interface (WUI) areas in Portugal, the USA, Spain and Greece, among others. The presence of LPG tanks in the WUI may cause severe events, especially when they are stored close to wildlands or artificial fuels. This work is a review aimed at presenting an overview of the cases related to accidents/incidents with LPG tanks stored during WUI fires. Fourteen recent accidents/incidents are described and lessons are taken in order to make recommendations to homeowners.

1. Introduction

Accidents and incidents related to Liquefied Petroleum Gas (LPG) stored at Wildland Urban-Interface (WUI) areas have been mentioned by authors (Barbosa et al., 2022; Caballero et al., 2019; Scarponi et al., 2020; Viegas et al., 2017, 2019). Due to the amount of energy stored, the vessel may become a hazard when a wildfire occurs.

Heating an LPG cylinder can cause severe events. For instance, it may trigger a boiling liquid expanding vapor explosion (BLEVE). The BLEVE occurs in pressurized vessels, which can cause severe damage to people and surrounding infrastructure. The main BLEVE effects are thermal radiation from a fireball (when the fluid is combustible), fragments projected and overpressure, all of which jeopardize the surroundings (Casal and Salla, 2006; B. Hemmatian et al., 2017; Behrouz Hemmatian et al., 2017; Planas-Cuchi et al., 2004). The BLEVE may be avoided if the cylinders have a PRD coupled, given the fact that the valve may prevent exacerbated pressure increment. However, in the few cases that heat dose is high, the BLEVE can still happen. If the PRD works, instead of explosion, a less dangerous event, a jet fire may occur. However, either event can trigger a domino effect.

This work is a review aimed at presenting an overview of the cases related to LPG stored at WUI fires. Fourteen accidents and incidents are described in this work as well as their effects.

2. Some recent events with gas storing occurred during WUI fires

2.1. Cases 1 and 2: Wildfire in Funchal, Portugal, August 2016

In August 2016, adverse weather conditions caused by an anticyclone in the northeast of the Iberian Peninsula and a depression in Morocco led Madeira Islands to have extreme values of temperature and relative humidity between 5 – 10th August. In the south of Madeira, the air humidity reached 10-20% and temperatures around 38ºC. On August 9th, the most extreme weather conditions were registered: the wind reached 35 km·h-1 with wind gusts of 80 km·h^{-1}; the minimum temperature registered was 29.6 ºC, which is 3.7 ºC higher than the last highest value registered in 1976 (Caballero et al., 2019; IPMA, 2016).

On August 8th, around 15:30h, an ignition occurred in forest area close to the WUI area. The local conditions of high temperatures, low humidity and strong wind, increased fire spread, namely to WUI areas, and ultimately, to urban areas. The fire spread initially up the hill through the forest zone, coming down the hill afterwards due to the prevailing wind direction. These extreme conditions exposed houses, the water treatment plant and a five-star hotel. Even on the 9th, 36 houses burned, 600 habitants were moved, the João de Almada Hospital was evacuated and three fatalities occurred.

In two houses, LPG cylinders were directly affected by the fire. Non-natural fuels and forest fuels in the surroundings of the house contributed to the cylinder´s fire impingement.

In the first house (case 1), the cylinder burst. Damages made by the BLEVE were found in the door and windows.

In the second house (case 2), four LPG cylinders were impinged by flames. The house was destroyed by the fire, but a BLEVE did not happen.

No fatalities related to LPG cylinders were registered for cases 1 and 2.

2.2. Cases 3 and 4: Pedrógão Grande Fire Complex, Portugal, June 2017

Pedrógão Grande Wildfire was a large fire in Portugal, possibly the second worst in Portuguese history. It caused 65 fatalities and around 200 injuries and 45328 hectares were burned. This large wildfire was caused by at least two different ignitions, on the same day, June 17th, at around 14:30h and 15:30h (local time), respectively in Escalos and Regadas. On June 17th, the Portuguese Institute for Sea and Atmosphere (IPMA) registered 80% of the Portuguese territory having dry conditions. The accumulated precipitation was close to the lowest in the period registered (1970-2017). The Fire Weather Index (FWI) was 26, which means a very high risk (Ribeiro et al., 2020; Tedim et al., 2020; Viegas et al., 217).

2.2.1. Case 3

In the early morning of the 18th a blind person who lived alone in a house in Balsa, did not realize that the fire had ignited an annex of the house where a gas cylinder was kept. The subsequent explosion destroyed that part of the house where the lady lived and killed her (Viegas et al., 2017).

2.2.2. Case 4

In the fire zone, near Louriceira, there was a motorhome that was used for summer vacation by an immigrant. On June 20th, the fire reached the motorhome at around 17:00h. An explosion was heard by firefighters that were nearby and they saw a dense smoke spreading upwards. A save and rescue team was sent, but they soon realized that a cylinder burst had happened. Inside the motorhome there were two mobile LPG cylinders. The first cylinder burst and became fragmented. The second one was hit by the burst that created a hole in cylinder´s surface causing LPG release and burning until the cylinder became empty (Viegas et al., 2017).

2.3. Cases 5 - 7: October Wildfire, Portugal, October 2017

Due to the long dry season, the same cited in case 3, combined with the Ophelia Hurricane (level 2-3 in the Saffir-Simphson scale), which caused powerful winds (50 $km \cdot h^{-1}$), many ignitions occurred on October 15th, leading to fast fire spread in multiple locations. October 2017 was the warmest since 1931 and the driest since 1997. In 24 hours, 220 thousand hectares were burned. On this day, 10% of moisture content of fine forest fuels was registered and in some places values close to 5% were found. The dry season, powerful winds and the low moisture content triggered a large wildfire, resulting in the largest burned area registered in Portugal. The FWI was 82 (maximum risk) and 532 ignitions were registered on October 15th. This wildfire caused 51 fatalities (Viegas et al., 2017, 2019)

Cases 5, 6 and 7 happened during the October Wildfire.

2.3.1. Case 5

In Oliveira do Hospital, a house on a hill was reached by a fire spreading very fast up the hill. The house had walls built with stone. The kitchen and its roof were totally destroyed and only the stone walls were left standing. After visiting the house ruins, a cylinder burst was suggested by the research team as the cause for the greater destruction. A fatality that happened in this house may have been related to the burst (Viegas et al., 2019).

2.3.2. Case 6

Around 16:00h, the wildfire had reached a small village called Vale do Laço. Citizens and firefighters were trying to save themselves, their houses and their belongings. A house nearby, situated on a slope and close to forest fuels, was affected by the wildfire. There were two brothers living there. It wasn't until around 20h, in the aftermath of the fire, that firefighters and habitants mentioned a previous suggestion made to the two brothers, asking them to leave and go into the town. However, the brothers had declined this advice and remained at home. They later observed smoke coming from the attic, probably caused by an ember that entered through an open window. They tried to extinguish it, but unsuccessfully which led to one fatality. On the day after, during the fire aftermath, an LPG cylinder burst destroying a large part of the house, but fortunately without causing casualties (Viegas et al., 2019).

2.3.3. Case 7

In Oliveira do Hospital, a warehouse was severely damaged by fire. 21 LPG cylinders with a volume of approximately 0.026 m^3 each were found. The cylinder´s size is usually the domestic size. It can be filled with up to 13 kg of LPG if it is butane or up to 11 kg of propane. Thus, up to 271 kg of LPG was stored, and this very large amount of energy caused great concern and damage to the surrounding structures when the various cylinders exploded. In this case, only the destruction of infrastructure was observed (Viegas et al., 2019).

2.4. Cases 8 e 9: Benitatxell Fire, Spain, September 2016

This fire is a consequence of an arsonist, on a day with a temperature of 35 ºC, relative humidity below 25% and wind gusts of 52 $km \cdot h^{-1}$. During this fire, around 1400 persons were evacuated, 470 received medical care, and 200 structures were affected by fires, but only three structures were severely damaged. The burned area was 898 hectares (Caballero et al., 2019; Rodríguez-García et al., 2022; Vacca et al., 2020).

Two LPG tanks placed nearby forest fuels were affected by the fire. In both cases jet fires were registered, being both LPG tanks equipped with PRD that were able to prevent the BLEVE (Caballero et al., 2019; Scarponi et al., 2020).

2.5. Cases 10 and 11: Mati Fire, Greece, July 2018

This wildfire is cited as the most lethal natural disaster in the history of the Modern Greek state. The wildfire broke out in the forest surroundings of the Ntaou region on Peneli Mountain, approximately 20 km northeast of Athens. On July 23rd, the temperature was nearly 40 ºC, relative air humidity was 19% and wind gusts were up to 100 $km \cdot h^{-1}$. The fire caused 100 fatalities, 200 people injured and 998 structures were destroyed (Caballero et al., 2019; Efthimiou et al., 2020; Molina-Terrén et al., 2019; Palmos et al., 2021; Tedim et al., 2020; Vacca et al., 2020).

During this fire, several explosions were reported and at least two LPG related cases were registered. The first one (case 10) is related to an LPG tank with at least 1 m3 exposed to fire. Case 11 was related to a mobile cylinder. Both vessels were found seriously damaged (Caballero et al., 2019).

2.6. Case 12: Llutxent, Spain, August 2018

This fire began on August 6th on a slope in the municipality of Llutxent. The ignition was caused by a thunderstorm and five fires were registered at the same time. The burned area was 3270 hectares, 163 persons were evacuated, 50 structures were affected and 10 houses were destroyed. The fire was completely extinguished by August 13th and no fatalities were reported (Caballero et al., 2019).

Five LPG mobile cylinders were burned during the fire and were found on a porch. BLEVE and jet fire were not reported, which may be explained by residual amount of LPG in the cylinders.

2.7. Case 13: Quinta do Colaço Fire, Portugal, August 2015

This fire occurred during the summer of 2015, in the District of Coimbra, reaching the municipalities of Almalaguês, Ceira, Semide and Rio de Vide. The burned area was 5500 hectares. 722 civil protection agents and firefighters worked to suppress the fire while they kept receiving new alert calls. The fire broke out in Quinta do Colaço around 12:42h. Unfortunately at 16:13h, the air support reported another 7 spot fires, which were suppressed by 7 fire trucks (Almeida, 2015).

A small building in a hill, probably used as a workshop and close to trees was affected by fire. Gas cylinders were placed inside the building and one of them burst. In principle, those cylinders were used to do metallurgic works using acetylene and oxygen. The cylinders were seriously damaged, and it was not possible to identify the fluid previously stored in them. The small building collapsed after the exposure to the fire and BLEVE (Almeida, 2015).

2.8. Case 14: Calabasas Fire, The USA, June 2016

During the summer of 2016 a brush fire occurred threatening thousands of homes in Calabasas. The burned area was around 208 hectares. Due to the fire, mandatory evacuations at Calabasas Highlands, Eddingham and Adamsville and voluntary evacuations in adjacent areas forced around 5000 people to leave their homes. The fast-moving wildfire swept through hills in Calabasas, it reached a preschool complex, burning outbuildings and heating a propane storage tank that caused a jet fire (Bartholomew 2016; Weber 2016; Scarponi et al. 2020).

3. Recommendation

Through the information gathered in the cases of accidents related to gas stored at WUI, we found some unsafe practices that occurred in more than one case, which should not be done. The accidents could be avoided through good practices carried out by the users, for instance: place the cylinder at a safe distance from the forest and artificial fuels; only one cylinder should be stored; and forest fuels (and other types of fuels) in the house´s surroundings should be eliminated.

Steel cylinders that are still being traded without PRD are not recommended to be used in houses that might be exposed to wildfires. For domestic applications we encourage the use of steel cylinders filled with butane and always with PRD coupled to the valve.

A protection made with a non-combustible fabric, low cost and easy to build was suggested by Barbosa et al. 2022

The users should consider the eventual jet fire direction through the PRD opening and its length before placing the cylinder. These safe practices may avoid future LPG accidents at the WUI.

Forest gaps, firebreaks, rural-urban interface, wind gust, Large Eddy Simulation

Abstract

Forest canopy can impact fire behavior through modulating both subcanopy atmospheric turbulence and wake turbulence at the forest edge. The 2020 Lake Ōhau fire happened at a rural-urban interface where the heavily fire-damaged village was surrounded by a heterogeneous forest canopy. Evidence shows that high wind speeds with strong gusts were present throughout the fire outbreak, indicating a strong wind-driven wildfire. Since the village was surrounded by complex terrain including a forest canopy, the forest canopy might play an important role in modifying the wind conditions within the village which could impact the fire spread behavior.

This research uses Large Eddy Simulation (LES) to study wind gusts and other near-surface wind characteristics in the Lake Ōhau area under the weather conditions of the 2020 Lake Ōhau fire. The work especially focuses on how the forest canopy around the village could change the wind gust within and around the village area. To do so, a LiDAR field campaign was also undertaken to obtain ultra-high resolution (grid resolution < 10m) forest canopy and other geoinformation.

Results also show that the village was impacted by two mesoscale wind systems - an offshore westerly downslope wind from west of the village and a northerly wind coming down over Lake Ōhau. The LES results were also used to further explore how simulated forest gap orientation might impact the downstream wind. Previous studies have shown that creating forest gaps or firebreaks can significantly change the wind characteristics within and at the edge of the forest. Three additional scenarios were studied by modifying the forest canopy around the village, including one without any forest canopy, one with horizontal (West-East orientation) forest gaps and one with vertical (North-South orientation) forest gaps. Total removal of the forest canopy increased the average wind gust in almost all areas within the village while the changes were spatially more heterogeneous in the horizontal and vertical gap scenarios. Differences of the spatial wind gust distribution might be related to how different forest gap alignments change the dominant inflow wind component. Next steps of this work will utilize passive tracers and temporal analysis to identify the processes driving these differences.

1. Introduction

The 2020 Lake Ōhau fire was one of the largest fires in recent New Zealand history with 54 residential buildings damaged and all residents forced to evacuate (Fire and Emergency New Zealand, 2021). The fire started at about 2.00am, October 4th local time (1.00pm October 3rd UTC) and burnt 5043 hectares of land in total. The extent of the fire can be seen in the short-wave infrared (SWIR) imagery from the Sentinel 2 satellite (Figure 1, the brown patches). The FENZ 2021 report highlighted the extremely high wind gusts (up to 167.2 km/h) measured at the closest automatic weather station (AWS) during the incident. The presence of such strong wind gusts suggests that atmospheric flow, especially surface atmospheric turbulence, will play an important role in the fire spread behavior.

The Lake Ōhau village settlement (Lat: -44.271, Lon:169.847) lies at the confluence zone of complex valley outlet systems to the west, the lake coastline to the north and east, and a relatively large pine forest to the northwest (Figure 2). With the complex terrain features (including topography and forest canopy) in this rural-

urban interface, it is paramount to understand how these features modulated localized wind turbulence during the fire. Due to the limited on-site measurements (the closest long-term weather station is more than 50km away and situated in a different valley), high resolution turbulence-resolving numerical simulations are the best tools available to study the wind behavior.

Figure 1: The Lake Ōhau fire from Sentinel 2 satellite short wave infrared (SWIR) imagery, October 3rd 2020 (UTC).

This research focused on the forest canopy around the village. Studies have shown that both the vertical structure of the forest canopy and forest gap location can impact the fire-atmospheric interaction through modifying fire-induced atmospheric turbulence (Kiefer et al., 2016, 2018). Forest gaps or firebreaks can be naturally formed or intentionally created. They have been used in recent decades as a silvicultural tool to reduce wildfire risks (Scarascia-Mugnozza et al., 2000). Most studies on forest gaps or firebreaks focus on the efficiency of the gaps in delaying or stopping fire from spreading further. However, a few studies have investigated the role of forest gaps on wake turbulence and how the turbulence mixing and flow reattachment at the wake of the forest canopy can impact fire behaviors like ember transport (Chung & Koseff, 2021). These studies are mostly based on idealized simulations using homogenous (evenly distributed) vegetation canopy. Questions remain about how different alignment of forest gaps can impact the near-surface atmospheric turbulence within a highly heterogenic environment such as the rural-urban interface (RUI).

Previous studies have compared the Large Eddy Simulation (LES) to field measurements and shown that LES models with a vegetation canopy module is capable of simulating atmospheric turbulence within and at the wake of the forest canopy (Kiefer et al., 2022; Mueller et al., 2014). Thus, an LES model was used in this study to investigate the role of the forest canopy in modulating the atmospheric flow during the Lake Ōhau fire.

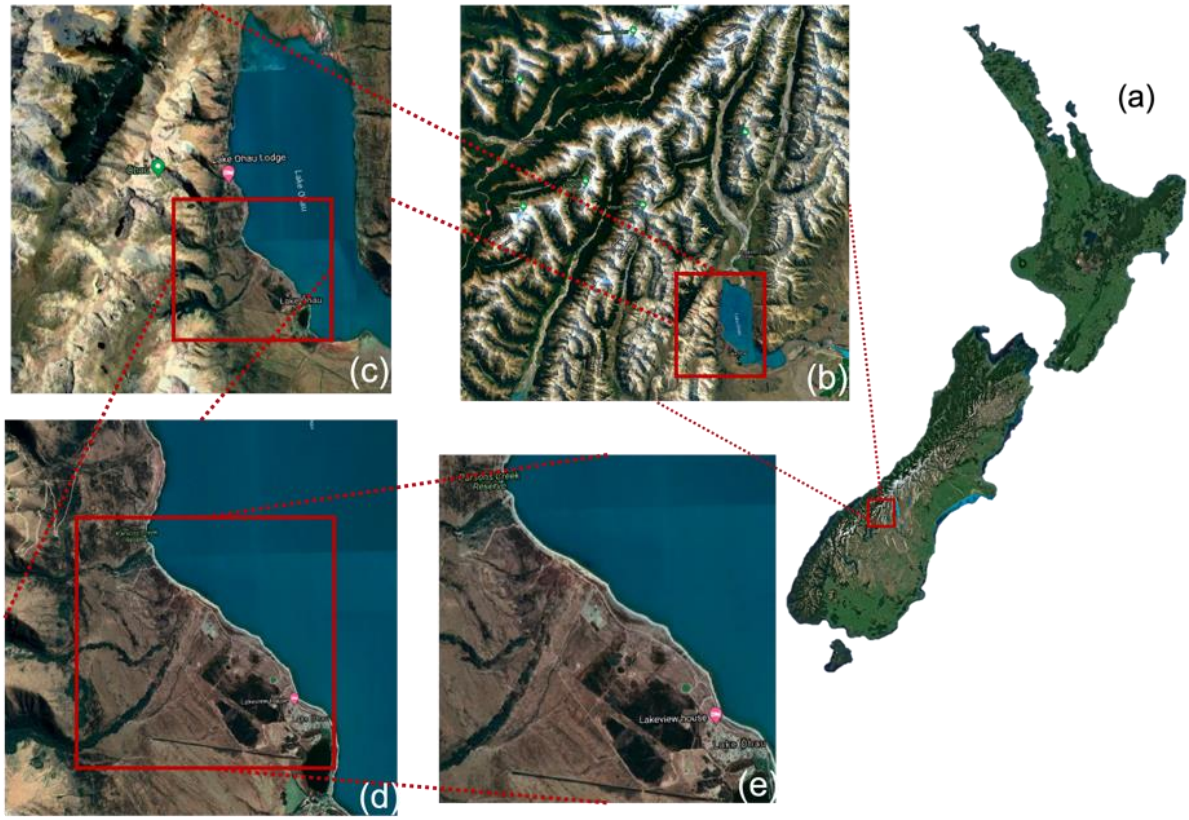

Figure 2 - Image of Lake Ōhau and surrounding topography from Google Earth. Areas from (b) to (e) are covered in our nested large eddy simulations as domain D2 to D5.

2. Methods

2.1. Mesoscale weather condition during the fire

Mesoscale weather information was obtained through the Weather Research and Forecast (WRF) simulation (Figure 3a). The simulation results aligned well the nearest AWS observation (Figure 3, the location is about 50km northeast of the Ōhau village). The AWS data was consistent with synoptic charts and showed a high intensity northwest downslope wind with hourly average wind speed around 10m/s during the event. The simulated mesoscale wind speeds on the majority of the downwind slopes of the region, as shown in Figure 3, were around 20m/s or greater

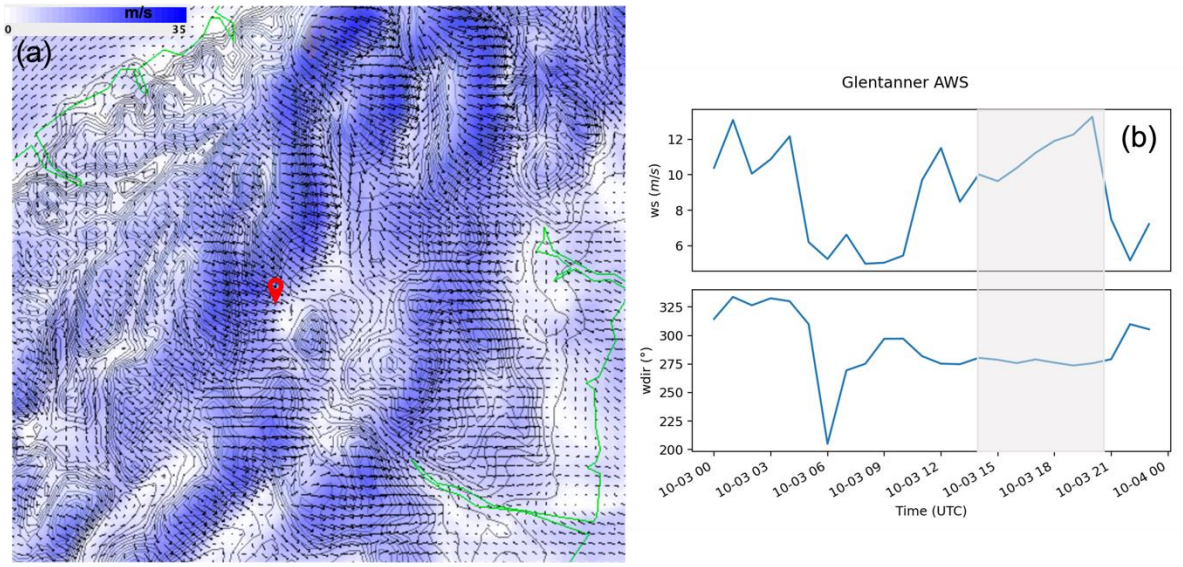

Figure 3- a) Hourly surface wind speed (10m AGL) at 2020-10-03 21:00 (UTC) from a 3km WRF simulation. The marker indicates the Lake Ōhau village area. b) Hourly wind speed and wind direction from the Glentanner AWS (-43.91498S, 170.12862E). The grey area indicates the fire ignition and early spread period.

2.2. Model description and initialization

The LES model used in this study is called the PALM model (B. Maronga et al., 2015; Björn Maronga et al., 2020; Raasch & Schröter, 2001). The model was set up using nested simulation domains with the second largest domain covering 62km in both horizontal dimensions around the Lake Ōhau area to allow a well-developed terrain-induced atmospheric inflow to the village area. The inner-most domain was focused on the Lake Ōhau village area with very fine horizontal (9m) and vertical (3m) grid resolutions to resolve the small scale near-surface atmospheric turbulence. The detailed domain configuration can be found in Table 1 and Figure 2.

Table 1. LES simulation domain setup. D1 domain was used to avoid numerical instability caused by steep terrain. For D2 and D3, the terrain information (DEM and land cover information) is taken from Land Information New Zealand (LINZ). For D4 and D5, merged terrain information was used based on both the LINZ datasets and our LiDAR field campaign. The vegetation and urban canopy were used only in the finer domains (D4 and D5). Detailed information can be found in section 2.2.2.

Domain name	Domain size ($L_x \times L_y \times L_z$) (km)	Domain resolution ($\Delta x \times \Delta y \times \Delta z$) (m)	Terrain information	Vegetation and urban canopy
D1	93×78×12	243×243×81	Flat and homogeneous	No
D2	62×62×10	243×243×81	Yes	No
D3	16×16×4	81×81×27	Yes	No
D4	5.8×5.8×1.3	27×27×9	Yes	Yes
D5	3.5×3.5×1.2	9×9×3	Yes	Yes

2.2.1. Field campaign and geoinformation reconstruction

To carry out an ultra-high resolution LES simulation, same-resolution geoinformation is needed including land cover information (vegetation type, urban land type etc.), leaf area density (LAD) profiles at all spatial locations, and urban building location and height information. The land cover information and urban building locations are taken from the Land Cover Database version 5.0 and NZ Building Outlines created by Land Information New Zealand (LINZ). The LAD and building height information is derived from the data obtained during our terrestrial LiDAR helicopter campaign. To simulate the pre-fire vegetation/urban canopy impact on the near-surface atmospheric turbulence, the work also reconstructed the pre-fire vegetation/urban canopy information (Figure 4 shows the detailed process). The reconstructed vegetation shows more consistency with the pre-fire satellite image from Google Earth (Figure 5).

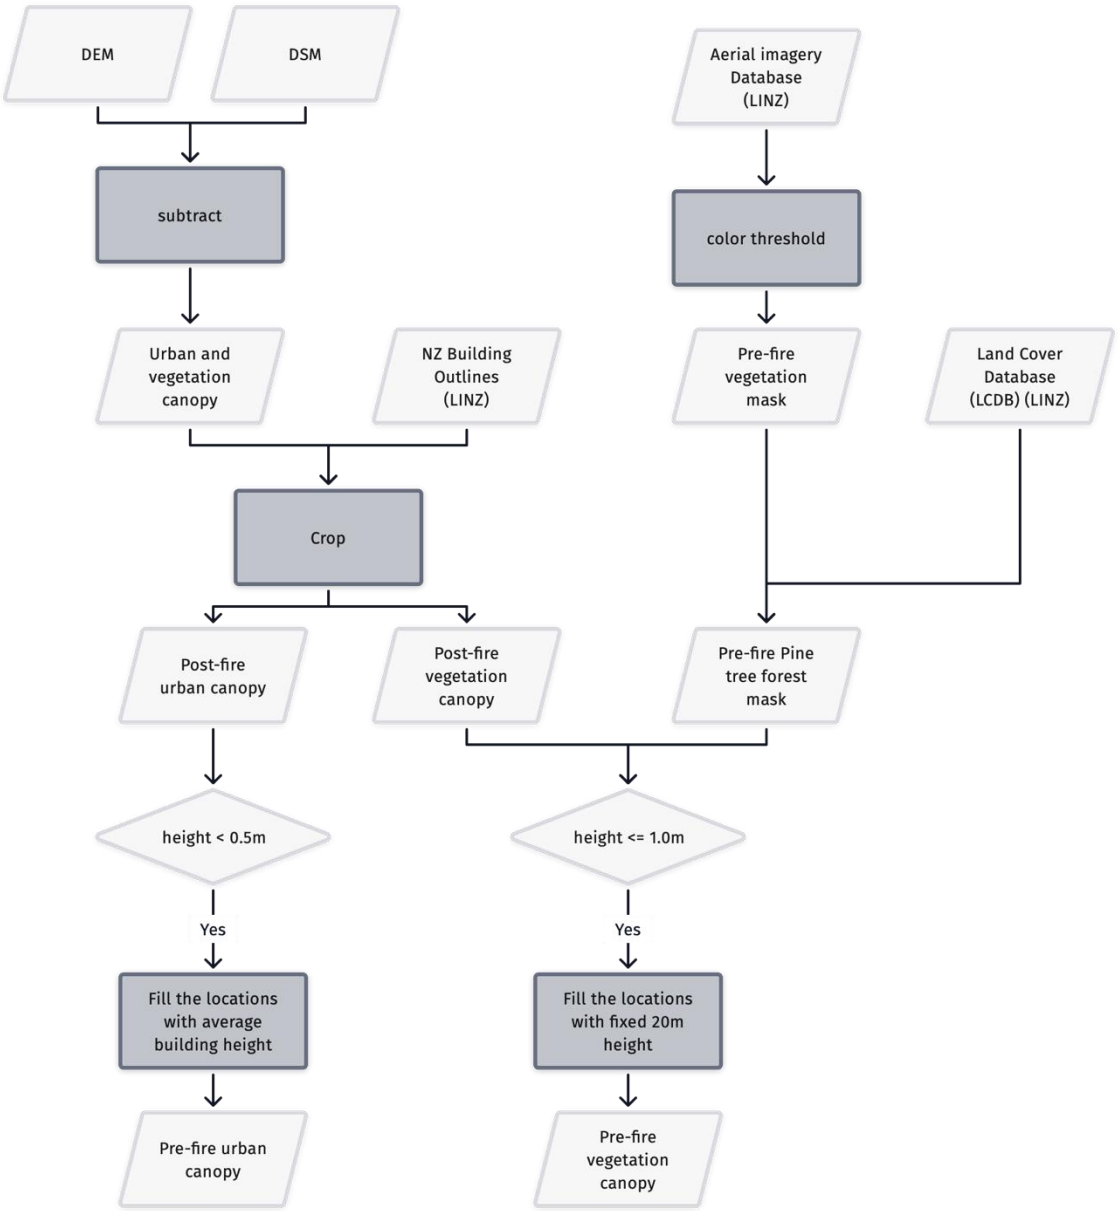

Figure 4- Process diagram - reconstructing the pre-fire vegetation and urban canopy.

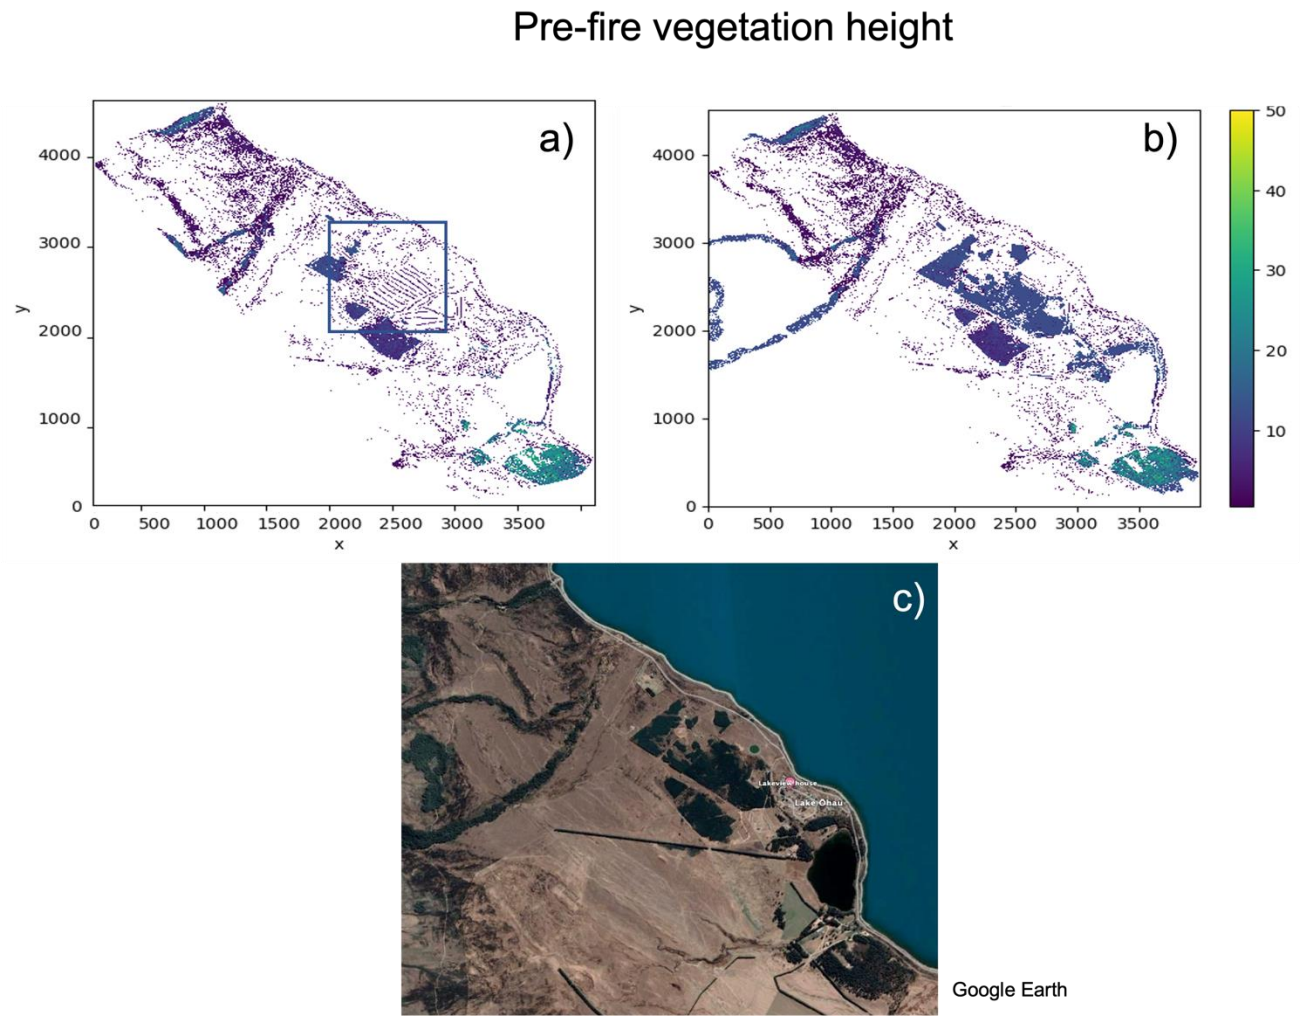

Figure 5- Vegetation height derived from LiDAR (a) reconstructed vegetation height (b) and pre-fire satellite image (c) from Google Earth image taken on 19/9/2019.

2.2.2. Simulation cases

Four scenarios were studied to address the impact of vegetation on the near-surface atmospheric turbulence during the fire: (i) the base case (Original) with the original reconstructed pre-fire geoinformation, (ii) all the vegetation around the village was completely removed (Noveg), (iii) 27m-wide horizontal (East-West orientation) gaps were created for all the trees around the village (Hgap) and (iv) 27m-wide vertical (North-South orientation) gaps were created for all the trees around the village (Vgap) (Figure 6). To incorporate the mesoscale forcing in the LES simulations, all the simulations carried out were initialized using average vertical profiles of velocity and temperature from the WRF simulation. In all scenarios, the LES model used the same initialization conditions from the WRF simulation data; the only differences being the modified vegetation canopy information. All simulations were run for 2 hours with the first 1.5 hours as model spin-up time. The last 30 minutes of data is analyzed below.

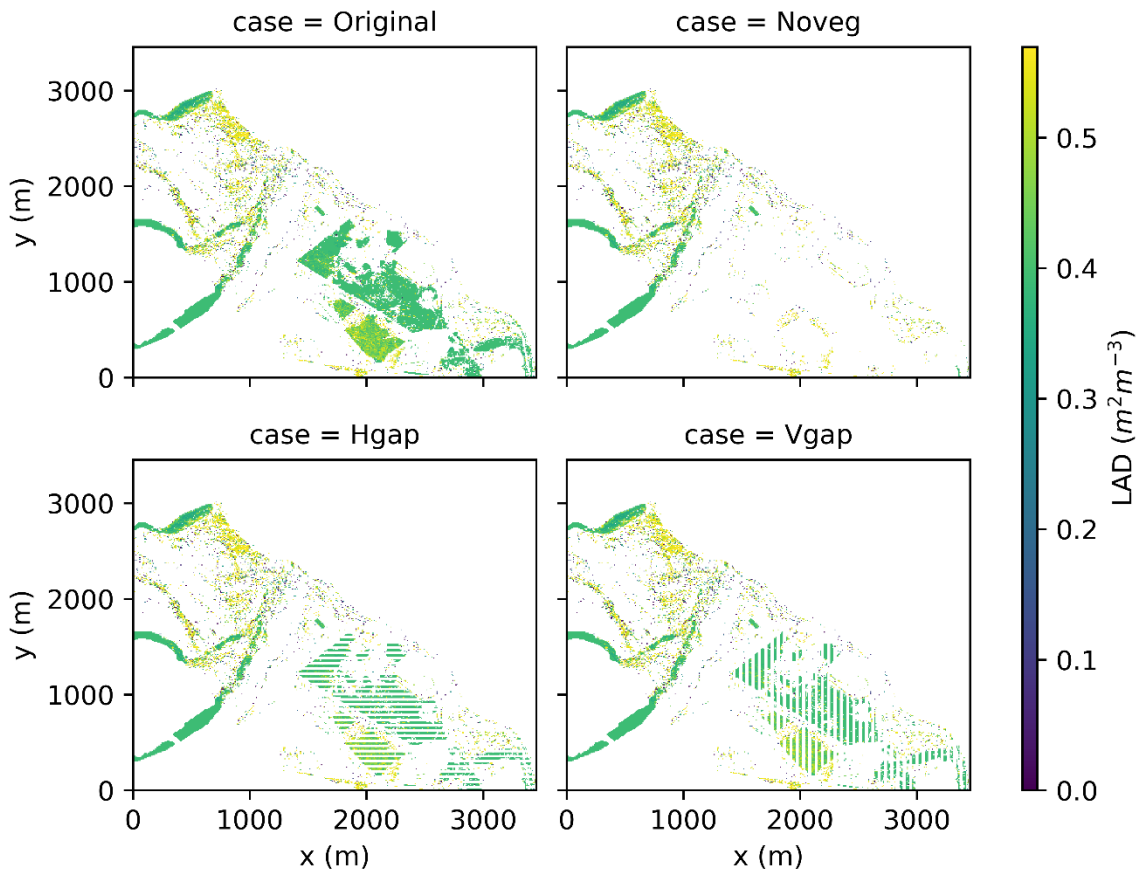

Figure 6- Leaf Area Density (LAD) at the first grid level above the ground (1.5m AGL) from four simulation cases. Original represents the original reconstructed pre-fire vegetation, Noveg represents removing all the trees around the village, Hgap represents the horizontal tree gap scenario, Vgap represents the vertical tree gap scenario.

3. Results and discussion

The base (Original) simulation shows that the village and the surrounding area were impacted by two main wind components. One is westerly downslope wind descending from the steep slope to the west of the village and the other one is the northerly down valley wind that traveled down across the lake (Figure 7). The result is consistent with the larger scale forcing from the WRF simulation.

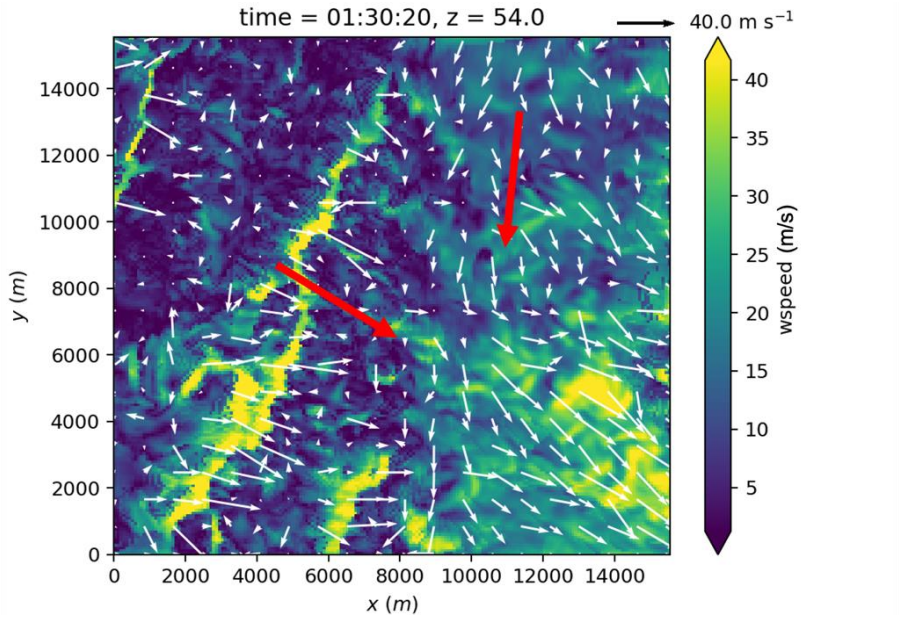

Figure 7- Instantaneous wind speed at 54m AGL from D3 domain. The red annotation shows two upstream incoming wind components that impacted the Lake Ōhau area during the fire event. Evidence of these two upstream wind components can be found from the instantaneous wind vector (white arrows) in the figure. Although not shown here, the two upstream components exist throughout the simulation.

Wind gusts are one of the important factors representing fire danger, especially in complex terrain where we still lack understanding of the spatial-temporal characteristics of wind gusts (Cheney & Sullivan, 2008; Letson et al., 2019). By simulating four different scenarios, the work found that modifying the vegetation canopy around the village can change the wind gust characteristics not only within the village but also in surrounding areas. Wind gust is calculated based on the World Meteorological Organization (WMO) standard (maximum value of the 3 second running average wind speed within one minute).

Figure 8 shows zoomed-in view of the differences in average wind gusts between the modified vegetation canopy simulations and the base case (Original) simulation from the D5 domain. Without surrounding vegetation (Noveg), almost all areas in the village experience an increase in wind gusts. A decrease in average wind gusts is only found in the wake of the buildings. This might indicate a more constant predominant wind direction resulting from the removal of vegetation which could act as a barrier to hinder the merging of the two wind components. Wind gust differences have more spatial variability in the horizontal forest gap (Hgap) and vertical forest gap (Vgap) simulations. The average wind gust is stronger in the central left area (solid boxes in Figure 8) in the Vgap scenario compared to the Hgap scenario. Both forest gap scenarios have weaker wind gusts in the bottom right of the village (dashed box in Figure 8). However, the wind gust decrease is more significant in the Vgap simulation than the Hgap one.

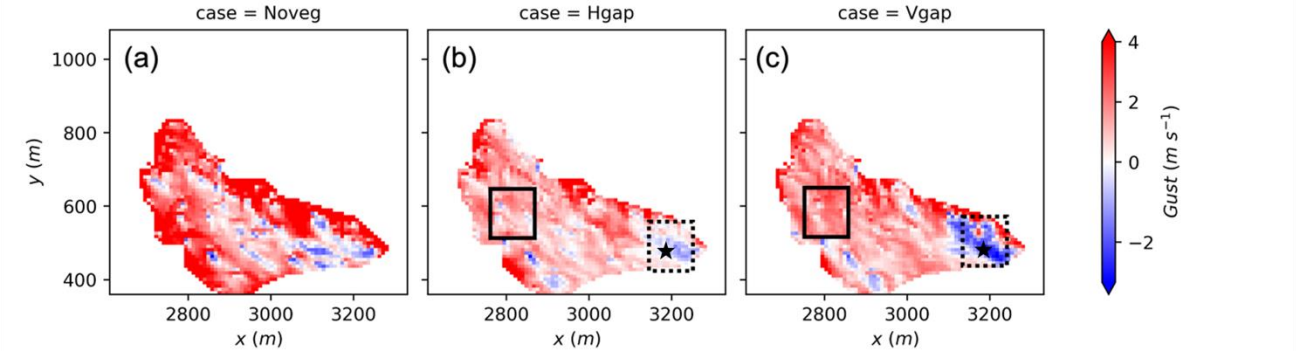

Figure 8- The difference of the average wind gust between each simulation with modified canopy and the base simulation during the last half hour simulation. Solid boxes in (b) and (c) show the area where the vertical gap simulation has stronger average wind gust compared to the horizontal gap simulation. The dashed boxes show the area where the horizontal forest gap simulation has stronger average wind gust than the vertical forest gap simulation. The star marker shows the location of which the wavelet analysis was carried out.

Areas with the average wind gust surpassing 30 m/s or 108 km/h can be found mainly over the lake area close to the village (Figure 9). Both the Noveg scenario and Hgap scenario have higher average wind gusts in the lake area while the Vgap scenario has similar wind gusts to the Original scenario.

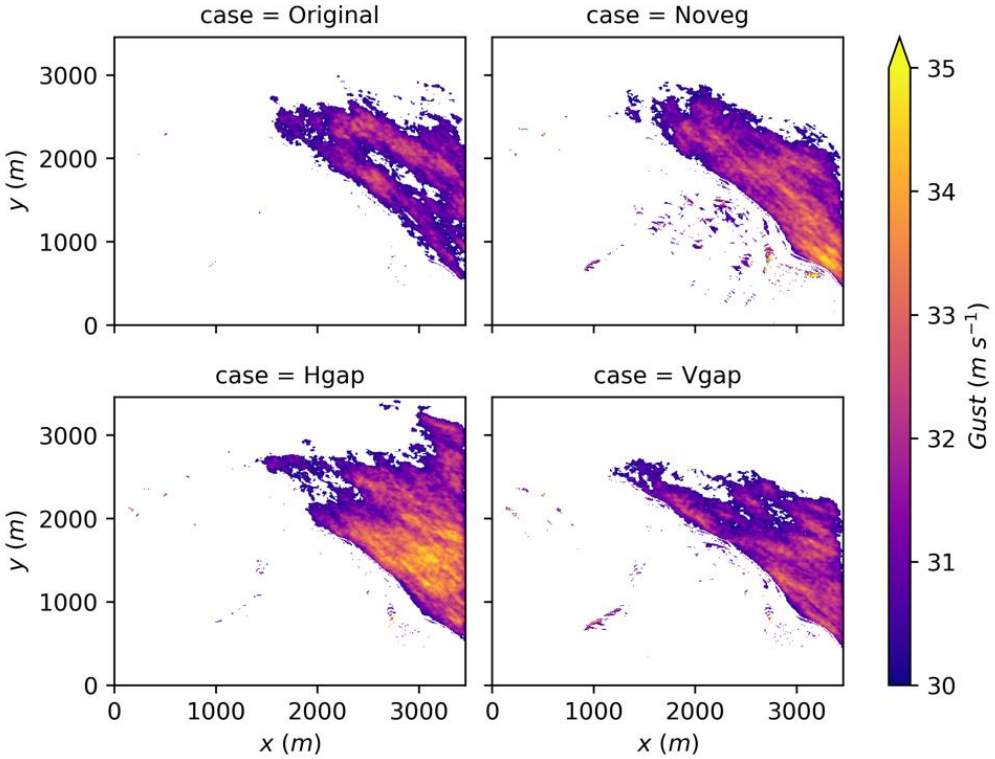

Figure 9- The average wind gust higher than 30 m/s at 6m AGL from the D5 domain.

4. Discussion and future work

The above results suggest that, with the two inflow wind streams (offshore westerly downslope wind and onshore northerly wind), different forest gap alignment might change the predominant inflow wind component by channeling one inflow stream and/or blocking the other. Time series analysis (Figure 10) shows slightly different integral scales between different forest gap alignments. At the selected location (star maker in Figure 8), the Horizontal gap (Hgap) scenario have more high frequency signals with period shorter than 32s (dashed blue line in Figure 10). This suggests more small-scale turbulence which might be caused either by shifting the predominant inflow components or locally generated turbulence coherent structures within the canopy. Further spatial/temporal signal analyses are needed to confirm the mechanism behind the spatial heterogeneity of the wind gust changes among different forest configurations. Future work will also use a passive tracer released at different sides of the forest patch edge (Figure 11) to further evaluate the fire risk (potential ember transport etc.) associated with atmospheric flow around the RUI.

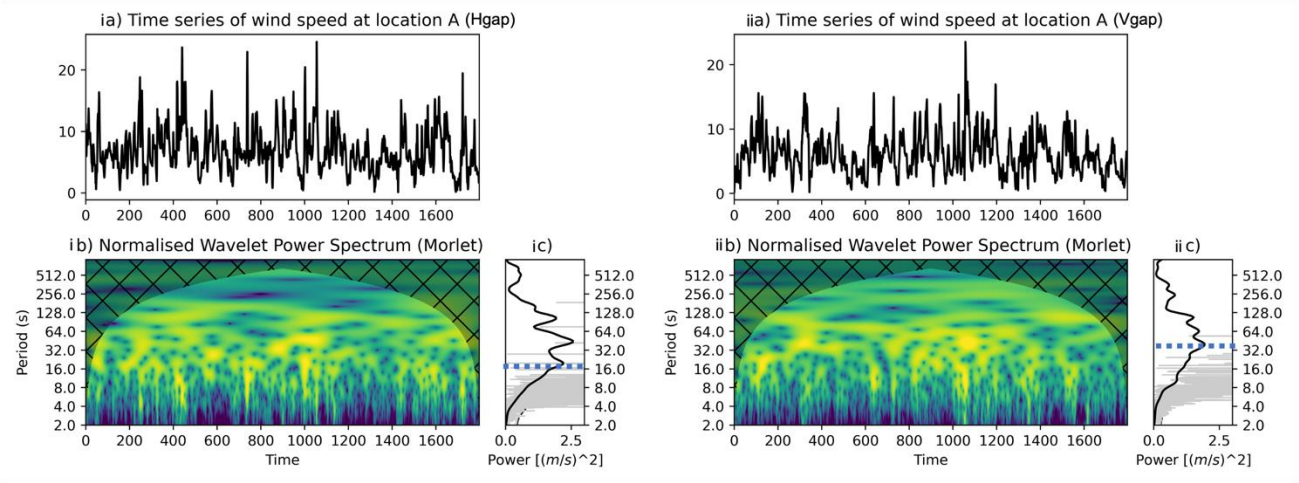

Figure 10- Wavelet analysis of the wind speed (1Hz) taken at the same location (star marker in Figure 8) for Hgap (left) and Vgap (right) simulations. ia) and iia) are the time series, ib) and iib) show the wavelet power spectrum using Morlet mother wavelet function, ic) and iic) show the global wavelet spectrum (black line, dashed blue line shows the first power peak) and Fourier power spectrum (grey line).

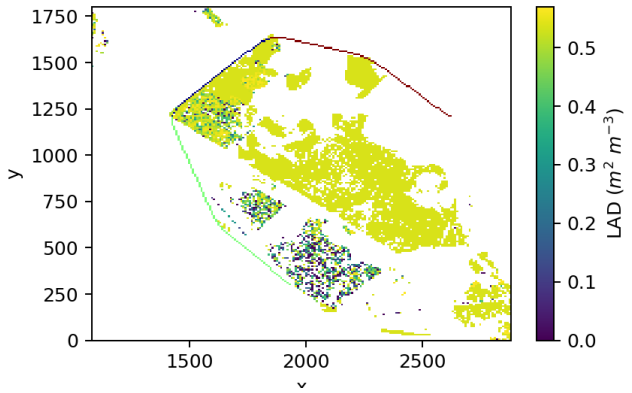

Figure 11- The passive tracer release location map. Green, blue and red curved lines indicate three different tracer groups that will be released at different sides of the vegetation canopy around the village. The rest of the image shows the leaf area density (LAD) at 7.5m AGL to indicate the relative location of the tracers to the vegetation canopy.

5. Conclusion

Preliminary results show that the vegetation canopy surrounding Lake Ōhau village can modulate wind gusts within and around the village. Removal of surrounding trees can alter the spatial wind gust distribution in different ways. In our case study simulations, the total removal of forest vegetation around the village resulted in increasing the average wind gusts of about 4m/s and higher in almost all areas within the village. On the other hand, forest gaps created through partial removal of the trees resulted in varying changes to the wind gusts in the village, depending on the direction of the gaps. Comparisons of the spatial distribution of wind gusts over the lake adjacent to the village also show that the influence of the vegetation canopy changes can extend far beyond the village area. Our current results suggest that the alignment of the forest gap might impact the dominant inflow component which might then impact the fire spread through changing wind speed and wind gust intensities, Further spatial and temporal analysis of the wind field and passive tracer distribution will help further verify these hypothesis.

Vegetation management; post-fire damage; CFD modelling; Wildland-Urban Interface

Abstract

In most Wildland-Urban Interface (WUI) fires, damage to building can result from poor vegetation management, comprising a lack of mandatory brush-clearing around building or an unwise location of trees (e.g. too close to building or overhanging the roof). It was interesting to check if post fire damage can be predicted by CFD fire modelling in different scenarios of vegetation management (treated vs untreated) according to different past-fire events. Ultimately, this work will help to assess if the fuel treatment regulation in the framework of fire prevention is efficient and to pinpoint possible limitations.

Different scenarios of vegetation treatments were tested on four study cases of dwellings surrounded by gardens juxtaposed to wildland vegetation (therefore submitted to the regulation on fuel management in WUI) that were affected by the Rognac fire in 2016 (SE France). In each case, comparisons of modelled and observed fire behaviour and impacts on buildings were performed using the Fire Dynamic Simulator model (FDS) and very accurate georeferenced ornamental vegetation mapping, especially around buildings.

Despite problems to adapt FDS modelling to the high fuel moisture content (FMC) of some species, results showed that overall brush-clearing mitigated fire intensity and propagation and therefore damage to building and ornamental vegetation, sometimes highlighting that this fuel management measure could be softened (decreasing the radius treated) or, on the contrary, strengthened according to the topography and wind. The fuel biomass treatment involving vegetation residues left on site was also found as deleterious as the lack of treatment.

Overall, the modelling using FDS, at the WUI scale and taking into account a very refined vegetation distribution, was mostly successfully validated by post-fire damage recorded during the past-fire events, which was rarely attempted in the complex environment of forest fires in the French Mediterranean area. The current scientific limitations of the model did not allowed obtaining realistic results in terms of heat flux received by the building, even if they were coherent in global intensity comparing treated and untreated vegetation, and have to be addressed in future improvements of the model.

1. Introduction

In some Mediterranean countries, the culture of fire risk has declined slowly with the decreasing trend of fire occurrence and burned area over the past decades (Fox et al. 2015). However, peaks of large fire occurrence still occur during extreme weather events (e.g. 2003, 2016 in SE France), often resulting in catastrophic fires difficult to suppress (Maditinos & Vassiliadis 2011; Jones et al. 2016). As a prevention measure in SE France, implementing the regulations on fuel reduction around housing (i.e. mandatory brush-clearing) at the wildland-Urban Interfaces (WUI) is of the upmost importance to mitigate the fire effects on buildings and to keep safer people and firefighters during a fire. However, these regulations are difficult to control and little respected, even if experience feedbacks also showed that the environment surrounding the housing (e.g. location of hedges, no fuel areas, etc.) can play an important role during WUI fires, especially on the resulting damage (Syphard et al. 2019).

In order to improve the fire prevention at WUI along identifying the different environmental factors surrounding the housing that can contribute to increase or decrease its vulnerability (usually, vegetation types, slope, and

wind), it is also necessary to verify if the regulations in terms of fuel reduction are still efficient in critical scenarios of wind and slope or if they can be softened or strengthened in some cases.

Previous studies revealed that WUI fire issue is mostly due to the building susceptibility to fire rather than a difficulty to control the fire (Cohen 2000, Cohen 2008). Fire behaviour modelling is a useful alternative tool, when properly calibrated and validated, to forecast the fire intensity and propagation as well as the fire impact on building in different scenarios of vegetation, terrain, and weather conditions. Despite several fire behaviour models (Sullivan, 2009) applied to forest fires, few are used for simulation at WUI, for instance, because WUI vegetation differs from that of wildland (more heterogeneous in terms of species composition and spatial distribution; Ganteaume 2018). Only complex CFD physics-based models (e.g. the wildland-urban fire dynamics simulator WFDS, Mell et al., 2007) or raster-based models (e.g. SWIFFT, De Gennaro et al. 2017; Fernandez et al. 2018), for instance, have achieved this goal. HRR and heat fluxes received have been validated on isolated dry tree experiment (Mell et al, 2009) at the laboratory scale but there is a gap on the validation at meso scale (i.e. the scale of the garden). The current study is therefore an attempt to validate simulation results using post-fire damage.

This work aimed at comparing post-fire damage recorded during past-fires to results of CFD modelling run on different scenarios of vegetation management (brush-clearing *vs* no brush-clearing) to validate the modelling results and assess the role of the regulation on fuel reduction on the fire mitigation at WUI.

2. Material & Methods

2.1. Study cases

Three study cases of housing, located at WUI and differently affected (from partial damage to total destruction) by a large past fire event in SE France (Rognac fire that occurred in 2016 ; Fig. 1) was considered in this work. Regarding this fire, three areas have been selected: « Griffons » (community of Vitrolles) as well as « Barnouins » and « Château » (community of Les Pennes-Mirabeau). Damage recorded during post-fire surveys were used as a validation of the modelled fire behaviour and impact on buildings. According to the French regulation, buildings located at WUI were theoretically subjected to fuel reduction within a 50 m-radius. Depending on the case, this regulation was implemented, sometimes partially, or not at all. Some cases presented, around the building, an area corresponding to a garden, with ornamental lawn, trees and shrubs, others presented a home ignition zone (HIZ) composed of natural vegetation, brush-cleared or not, similar to the neighbouring natural vegetation (Table 1).

2.2. Modelling

So far, the models FDS (version 6.7.5) (Vanella et al., 2021) and WFDS developed by NIST (McGrattan et al. 2013) regarding wildfires have been validated by laboratory experiments (e.g. Mell et al. 2009, Perez-Ramirez et al. 2017 ; Morandini et al. 2019) or grass fires (Mell et al. 2007).

In this work, the inputs used for the simulations (see table 1) were :

(i) topographical data (EU-DEM-v1.1 COPERNICUS program, available with a resolution of 25m) ;

(ii) vegetation data : Vegetation was recorded with as much as precision as possible (in the field during the post-fire survey and using aerial or satellite images available before the fire), given its strong heterogeneity, according to three strata (litter and grass, understorey, and overstorey). The WUI vegetation can be composed, according to the study case, of exotic species and/or native species similar to the wildland vegetation and was managed or not according to the regulation;

(iii) wind data : the wind direction was taken from the fire-fighter reports of the events. The wind speed considered is 11 m s^{-1} on average over 5 min. The intermittent wind is modelled by a simple alternation every 15s of 2 m s^{-1} and 20 m s^{-1} (typical of the dominant wind, Mistral, in the study area).

The outputs of the modelling are the flame front position and vegetation mass loss variation at different times of simulation, and the temporal variation of the total power and of heat fluxes (located at different heights on buildings) during the simulation.

The modelling was run for each study case on the two vegetation management scenarios (with or without brush-clearing), except in the study case « Château » which was divided into three different scenarios (one of them comparing the ignition by firebrands and by flame propagation from a hedge) given the extended area damaged by the fire (Fig. 2).

3. Results and discussion

Post-fire surveys carried out in the four study cases showed a large range of damage from scorched vegetation to building destruction (Fig. 3).

Overall, the results of the modelling run on brush-cleared vegetation showed a fire behaviour less intense than when the fuel treatment was not implemented (Fig. 4), however, with a fire heat release similar during the first 10 to 20s (up to 40s in the case Château C2) according to the study case.

3.1. Griffon

Post-fire damage assessment : Only the windward house was severely burned and it sheltered the neighbouring house, which was undamaged (Fig. 3). The facade exposed to the fire was the most damaged (window with broken glass allowing the fire to impact the inside) mostly because the close by ornamental hedge acted as a vector for fire propagation. The southern hedge was burned by a surface fire fueled by the brush-clearing residues and spread the flame to the neighbouring ornamental shrubs located in the garden.

Modelling : During the first part, flames propagated further in the modality brush-cleared because the lower tree density (Fig. 5) and possibly because of the tilt angle between the flame and the slope located between the forest and the garden. Beyond 20s of simulation, the HIZ (and thus the ornamental vegetation) seems to be unaffected by the fire in this modality in contrast to the other scenario.

This study case allowed highlighting the importance of cleaning the residues after treatment. Indeed, the modality with brush-clearing, without vegetation residues, showed that the fire intensity would have been decreased avoiding the damage to the building.

3.2. Barnouins

Post-fire damage assessment : The fire propagated uphill in the brush-cleared garrigue towards the house (slope of ~50%), the damage was mostly due to a windward window that had been left open, allowing the firebands generated by the pine stand downhill to enter the building and set it on fire. A large part of the windward ornamental vegetation (located on the left of the house) was also impacted in contrast of the leeward side of the house (Fig. 3).

Modelling : Regarding the fire spread (Fig. 6), after the first 15s of simulation, the flames were more scattered in the modality with brush-clearing, especially at T0+50s and T0+65s and the tree canopy burned (higher tree mass loss), probably because of the low simulated FMC. Flux sensors located at different heights on the house windward facage, in both modalities, were quickly reached by the flames and intensities higher than 80kW m^{-2} were recorded, showing that the contribution of the vegetation, even brush cleared in this case, was significant (Fig. 7).

The heat sensor positioned the highest (13m) was strongly affected by the wind gusts. It is then possible that, even if the window had been closed, the combination between the steep slope and the strong wind could have provoked intensity to break the window pane allowing the fire propagation into the house and its destruction. With this combination of two important factors (terrain and wind), the limitation of the mandatory brush-clearing is reached, showing that the area treated should have been extended beyond the mandatory 50m.

3.3. Château

Post-fire damage assessment C1 : In this case, the fire propagated from the NNW to the SSE, first in an untreated wildland vegetation (pine stand) and reached the tall northern cypress hedge located to the South of the south-werstern building that completely burned.

Modelling : In the modality with brush-clearing, the fire propagated less intensely, limiting the spread on the flanks, therefore avoiding the cypress hedge and the other trees around the building (Fig. 8). This was due to

two main factors : i) a lower intensity in all of the vegetation strata in the modelling and ii) a stronger wind in the HIZ in the modality with brush-clearing because of the lower tree density. In contrast, in the modality without brush-clearing the hedge partially burned.

In this case, the scenario without brush-clearing underestimated the fire effects on the hedge which did not totally burned, despite the simulated low FMC, unless the ignition be provoked or enhanced by the firebrand shower generated by the burning pine stand (highly likely synergy). In contrast, in the modality with brush-clearing, the fire impact on the ornamental vegetation located East of the building was low, highlighting the importance of the mandatory fuel treatment.

Post-fire damage assessment C2 : In this case, the fire behaviour was assessed when the flame front reached the northern building. The tall pine (11m) located close to the building (overhanging the roof) completely burned participating to the building destruction.

Modelling : Beyond the first 40s of simulation in the modality with brush-clearing, the fire spread in the pine stand and in the brush-cleared area but with decreasing intensity when approaching the buildings. After 45s, the tall pine was reached by the fire in both modalities but more intensively (totally burned) in the modality without brush-clearing (Fig. 9) according to the post-fire damage assessment.

In this case, the impact of the fire on the pine was moderate highlighting once more the effect of the vegetation treatment, especially in the area submitted to the dominant wind, therefore to the fire.

Post-fire damage assessment C3 : In this case, three tall trees, a cedar, a palm tree, and a linden tree, located close to the southernmost building (and partially overhanging the roof) have been impacted by the fire (the two formers having mostly or totally burned while the latter was heavily scorched), participating to the building destruction.

Modelling : The simulation presenting the fire propagation due to firebrands showed that the fire could ignite the tree canopy and spread progressively towards the ground (Fig. 10), igniting then the lower branches and the vegetation close by. This was possible thanks to local wind currents of different directions generated by neighbouring obstacles (buildings, trees, etc.) during wind gusts (i.e. 11.7 m s^{-1}). This result was not observed in the post-fire survey, especially for the linden, possibly because the higher FMC than in the modelling.

The simulation presenting the fire propagation involving the cypress hedge located to the North (Fig. 11) showed that the tall cedar burned. The fire then reach the side of the building where the linden tree was located, but without succeeding in its ignition while, at 100s, the fire ignited the southern cypress hedge. According to the post fire damage recorded, the linden tree was less impacted than the cedar, even with a lower simulated FMC. However, the synergy with the firebrand shower is also probable.

4. Conclusions

This work consisted in implementing the CFD model FDS on three different study cases impacted by a past fire event and comparing the results to the post-fire damage recorded in the field for validation. For each case, two scenarios of vegetation management were tested (brush-clearing *vs* no brush-clearing). Simulations results could mostly be validated by the post-fire survey and underlined once more the relevance of the fuel reduction measures in terms of fire mitigation. In some cases, they highlighted the necessity to strengthen this regulation. This work also proved the functional capacities of the model used to assess the fire behaviour at the WUI scale despite the bias inherent to the model, mainly regarding the simulated FMC, which was lower than in the field. This hypothesis is common to all of the calculation codes (e.g. Swifft, WFDS, etc.) and cannot be by-passed in the current state of knowledge

Abstract

Wildfires in Portugal are increasingly putting the population and existing assets at risk. In the aftermath of the fires of 2017, there was a renovated concern to increase the protection of settlements and the self-protection abilities of the population; as such, several initiatives were developed with the aim of increasing the resilience and safety of communities. This study analyzes the implementation of the "Safe Village and Safe People" program, created by the National Emergency and Civil Protection Authority, in the municipalities of the Algarve region, taking into account its spatial distribution and the relationship with hazard levels in the immediate surroundings of settlements (100 m). It also aims to analyze whether this program can be combined with other ongoing initiatives associated with fuel management and landscape transformation in the area surrounding the settlements. For this, a database was created with the location of the Safe Villages already implemented in the Algarve region, with the geographic coordinates defined by a point that intersects the village. This point was then spatially joined with the polygon of the matching built-up area, retrieved from the cartography of Built-up Areas of Portugal, to obtain the boundaries of the villages and delimit the 100 m buffer around. Then, the total hazardous area (of high and very high wildfire hazard) in the 100 m buffer around each Safe Village was retrieved. Finally, the hazardous area around the Safe Villages was analysed in relation to the total hazardous area around all the settlements of the region, to assess the adequacy of "Safe Villages" location with regard to hazard levels for the whole region. Results show that 135 Safe Villages are implemented in 9 municipalities of Algarve. Around 6.6% of the 100 m area surrounding all the settlements in the region presents high and very high hazard. The municipalities of Monchique and Aljezur have the largest hazardous area in the surrounding 100m of all their settlements (61.96% and 20.86%, respectively). When analyzing the implementation of Safe Villages program, the ones implemented in the municipality of Alcoutim cover a greater percentage of surrounding hazardous area (58.08%) in relation to the total. The efficiency of this program and, therefore, the protection of local communities, can be improved by selecting the villages with higher hazardous area around and by combining its implementation with different programs that focus on fuel management that promotes hazard reduction, such as the "Condominium of Villages", created by the Directorate General of the Territory.

1. Introduction

In the last decades, wildfires in Portugal have been increasing significantly, either by the high extent of burned area or by the high material damage and human losses they have caused (Bergonse et al., 2021; Gonçalves et al., 2021; Nunes et al., 2016; Oliveira et al., 2020; Vilar et al., 2016). These events put at risk local rural communities as well as urban areas, which increasingly expand into the wildland-urban interface (Tonini et al., 2018). Since the 1980s, these problems have been rising, essentially due to the rural exodus and farmland abandonment, with the subsequent accumulation of fuels in the areas surrounding settlements (areas that were once occupied by agriculture will now be covered by shrubland and/or forest) and the aging population that remains in rural communities (Ferreira-Leite et al., 2013; Nunes et al., 2016). All these factors increase the susceptibility to wildfires in these areas and increase the exposure of people, assets and natural areas (Ager et al., 2013; Gallardo et al., 2016; Vieira et al., 2009). The year 2017 was the most devastating to date in Portugal, with the largest recorded burned area (~ 500 000 ha) and more than hundred fatalities in the June and October fires (Comissão Técnica Independente, 2018; Instituto da Conservação da Natureza e das Florestas, 2017). These events renovated the need to improve the protection of human communities and to increase the coping capacity of the population (Alcasena et al., 2019; Costafreda-Aumedes et al., 2017; Gonçalves et al., 2021;

O'Connor et al., 2016; Oliveira et al., 2020; Palaiologou et al., 2019). Since then, several initiatives have been developed in Portugal to deal with these challenges; one such measure is the Safe Village Safe People program, initiated in 2018 and coordinated by the National Emergency and Civil Protection Authority (ANEPC). This program aims at creating structural measures for the protection of people and assets located in rural villages or in the wildland-urban interface, through the implementation of strategic infrastructures, the identification of critical points and places of shelter and refuge or the creation of evacuation routes. For a settlement to be classified as a "safe village", it must have implemented several measures, among which:

a) prevention of risky behaviour, by developing awareness actions to reduce the number of ignitions caused by anthropogenic actions;

b) awareness of the population about wildfire risk levels and self-protection practices they should adopt, by organizing fire drills in coordination with local authorities;

c) creating evacuation plans for when a fire is approaching the village;

d) creation of shelter and places of refuge able to protect the population during the passage of the fire, in cases where it is the most viable option (Autoridade Nacional de Proteção Civil, 2018).

By implementing these strategies at the local level, it is intended to increase the self-protection capacity of the population and mitigate the consequences of large wildfires. This is especially important in a context of climate change, where fires will be more frequent and severe (Ager et al., 2014; Birkmann et al., 2013; Dupuy et al., 2020; Marques et al., 2011; Moreira et al., 2010). The objective of this study was to analyze the implementation of the "Safe Village Safe People" program, considering the spatial distribution and the relationship with the level of wildfire hazard in the surrounding area, specifically in the 100m protection area around settlements (defined by Decree Law No. 82/2021, October 13). With this analysis, it is also possible to analyse whether the "Safe Village Safe People" program can be aligned with other initiatives, associated with fuel management and landscape transformation in the surrounding area of villages, such as the " Condominium of Villages" program, coordinated by the Directorate General of Territory (DGT). The implementation of several programs in an integrated manner, which concur to the same objective of wildfire mitigation and communities' protection, can promote a more efficient management of resources and increase the effectiveness of the implemented strategies.

2. Methods

2.1. Study area

The analysis of Safe Villages was carried out for the municipalities of the Algarve region (NUTS III) (figure 1). The Algarve region has an area of 4 996 km^2 and is composed of 16 municipalities. Regarding land use and occupation, 63.02% of the Algarve region corresponds to forest and shrubland and 23.31% to agriculture and pasture. In terms of hazard, 30.65% of the region is at high and very high hazard of fire. According to the provisional results of the 2021 Census, the Algarve has 467,475 inhabitants, showing a positive variation of 3.7% compared to 2011. Monchique is the municipality with the most significant hazard level as 90.74% of its area falls into high or very high hazard while Lagoa records the lowest percentage (1.27%). The municipality of Monchique with the highest percentage of forest and shrubland (91.96%) and the one with the lowest percentage is Faro (17.79%). Over the last decade, Vila do Bispo recorded the highest population growth (+8.7%) while Alcoutim recorded a significant population loss in the same period (-13.5%).

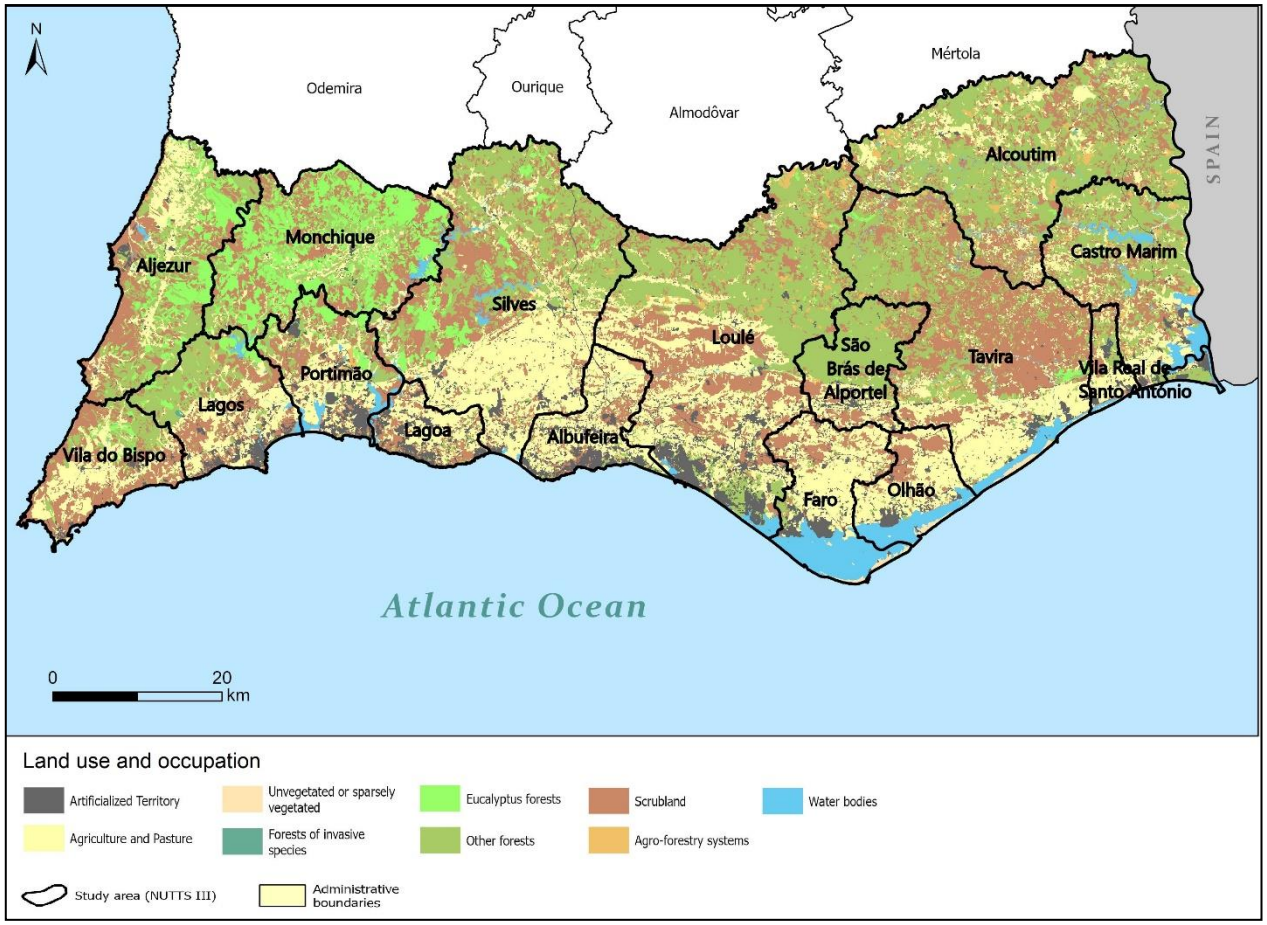

Figura 1 - Geographical setting and hazard level of the study area (Source: ICNF, 2020)

2.2. Data collection and processing

For this analysis, a database was first built with the location of the safe villages already implemented in the Algarve region. For this task, the geographic coordinates of a point that intersects the settlements designated as safe villages were retrieved from the website of the program "Safe Villages"[6] . To obtain the boundaries of the settlements, the built areas made available by the DGT were taken, mapped from the artificialized classes of the 2018 Land Use and Occupation (COS2018) combined with the geographic base of classic residential buildings of the National Statistics Institute (INE) (2011). Although a settlement is generally defined as a group of 10 or more residential buildings (Instituto Nacional de Estatística, 2001), this database of built-up areas includes several typologies: type 1 concentrated settlement (settlements with 10 or more residential buildings); type 2 dispersed settlement (isolated houses or places with less than 10 residential buildings); type 3 non-residential areas. For this analysis, all non-residential areas (type 3) and all isolated houses defined as type 2 were excluded, keeping the dispersed settlement that corresponds to at least 2 residential buildings. This option is connected to the application of fuel management areas (FGC) of 100 m around a settlement, since in the cases of isolated houses the FGC defined by law are of 50m. The definition of the FGC for the protection of settlements around built areas was accomplished by creating a 100 m buffer in the surroundings, using *ArcGIS tools*. Then, the area of high and very high hazard existing in these surrounding buffers was calculated, being considered the most critical or priority area. The hazard layer corresponds to the structural assessment of wildfire hazard levels for 2020-2030, based on probability from historical burned area and susceptibility resulting from landcover and topography (Oliveira et al., 2020) and it was obtained from the Institute for Nature Conservation and Forests (ICNF). The following step was to calculate the proportion of critical area (high and very high hazard) in the

[6] https://aldeiasseguras.pt/aldeias-seguras/)

buffer zones around the safe villages, in relation to the critical area within all buffer zones in the settlements of the municipality.

3. Results and Discussion

In Algarve the high and very high hazard levels cover 6.6% of the 100 m buffers around the built-up areas of the region, which are composed of 8060 individual polygons. In these polygons, 25% have high or very high hazard area in the surrounding 100 m buffer. In these settlements with hazardous surrounding area, 22% have more than 50% of critical area in their buffer.

Up to 2021, 135 safe villages were implemented (figure 2), in 9 municipalities (table 1). These villages (SV), cover 6.7% of the critical area around the settlements where hazardous levels are found.

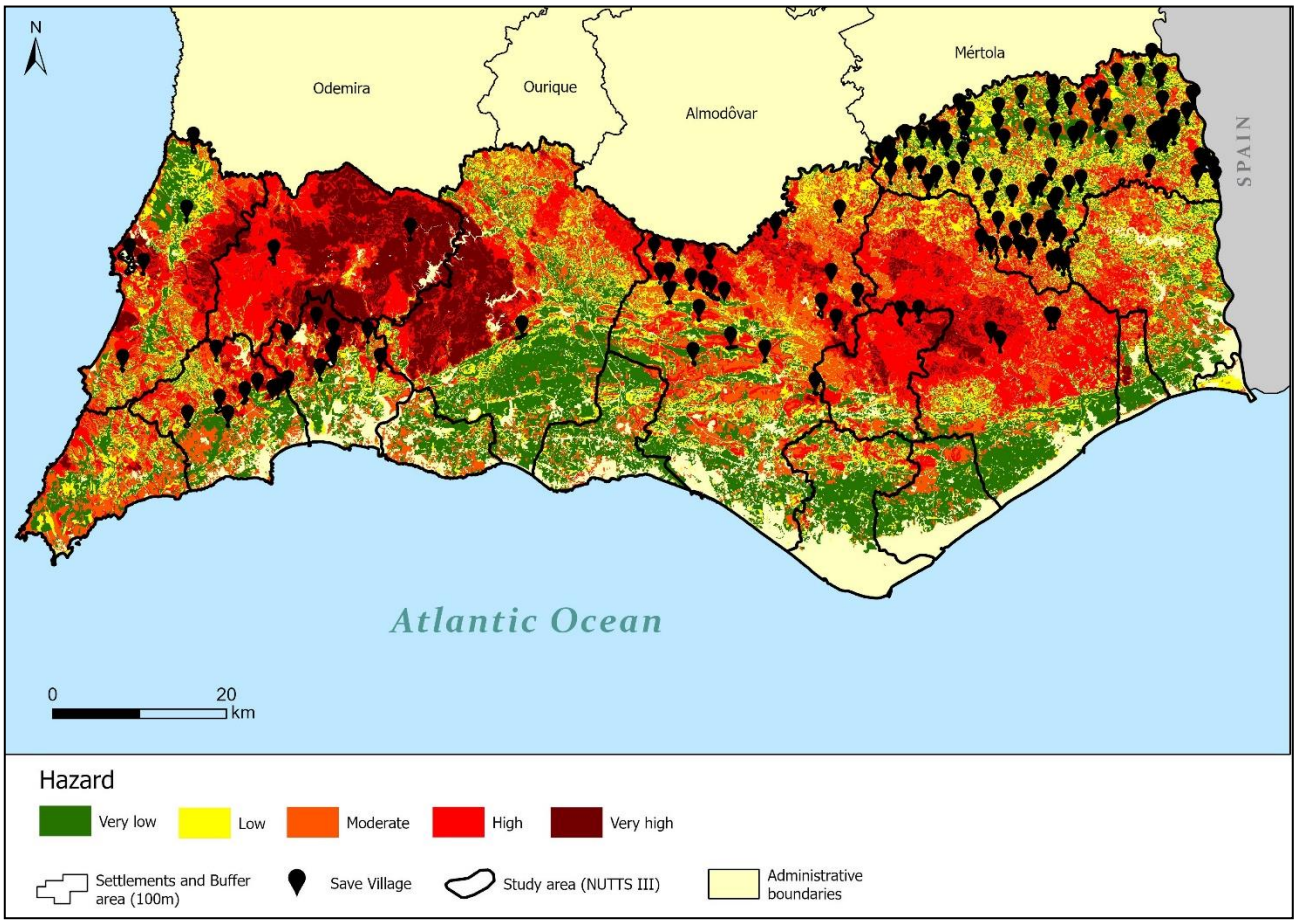

Figure 2 - Location of Safe Villages and wildfire hazard levels in the Algarve region

Overall, Monchique has the highest percentage of critical area in the surrounding 100m of its settlements (61.9%), followed by far by Aljezur (20.9%) (figure 3). However, the municipality of Alcoutim and Aljezur (figure 3a) are the ones where the SV implemented cover a higher percentage of critical area around (58.1% and 32.7%, respectively). The SV in Monchique cover 2.2% of the hazardous area around its settlements. These results suggest that the implementation of SV is done in view of conditions other than the hazard levels around the settlements. Alcoutim, for example, shows a low amount of critical area surrounding the settlements (<1%), but it is the municipality with more SV, whose implementation has covered nearly 60% of the critical area. It should also be noted that the 100m buffer here considered may not suffice to protect a settlement in case of large fires, nor match the size of the wildland-urban interface that should be considered in wildfire management strategies (Sirca et al., 2017).

Table 1 - Percentage of critical areas in implemented Safe Villages

Municipalities	% high and very high hazard in the FGC of SV (with total FGC of settlements)	% high and very high hazard in total FGC of settlements	Number of Safe Villages	% of Safe Villages
Albufeira	0	1.98	0	0
Alcoutim	58.08	0.86	84	62.22
Aljezur	32.69	20.86	5	3.70
Castro Marim	0	2.21	0	0
Faro	0	4.18	0	0
Lagoa	0	1.50	0	0
Lagos	4.16	3.59	7	5.19
Loulé	12	4.12	20	14.81
Monchique	2.28	61.96	2	1.48
Olhão	0	0.52	0	0
Portimão	3.29	5.47	8	5.93
São Brás de Alportel	11.32	13.57	2	1.48
Silves	5	3.28	1	0.74
Tavira	2.09	13.27	6	4.44
Vila do Bispo	0	6.92	0	0
Vila Real de Santo António	0	1.17	0	0

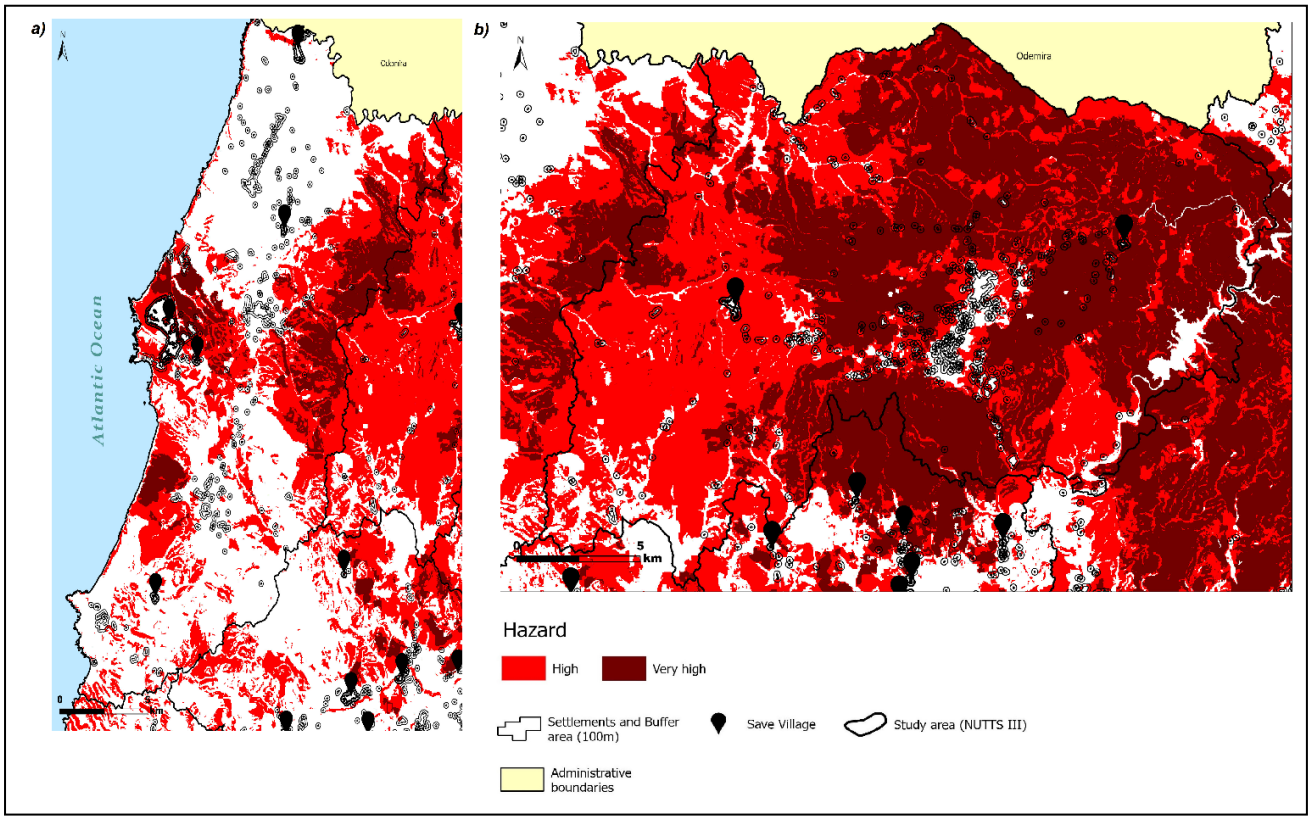

Figura 3 - Safe Villages and critical areas in the municipality of Aljezur (a) and Monchique (b)

To accelerate the implementation of protection measures around human settlements, the connection and integrated application of different but complementary initiatives can be helpful. One example is the

"Condominium of Villages", a program created by the DGT in 2020 that is directed towards fuel management around settlements. Its main purpose is to support actions aimed at changing landcover-landuse and promoting fuel management around built areas, to improve the resilience of vulnerable villages, particularly those located in parishes with at least 40% of critical area in their territory.

The articulation of measures will enable a better definition of priorities, namely in the the location of safe villages, but also a better implementation of fuel management around the village. Although this interconnection is important, at this moment the implementation of the "safe village" program does not depend only on the physical factors of the territory, but also on the involvement of the resident population, namely the existence of a volunteer to be a Safety Officer in the settlement. This officer must also have knowledge of the geographic and social context and of existing structures at the local level. If we consider demographic aging and rural exodus, especially in the inner part of the country, it is challenging to designate a Security Officer, since many villages only have elderly residents, who do not have the required profile to assume this role.

4. Conclusions

In the ideal scenario, all settlements should be Safe Villages. The creation of different initiatives in Portugal should increasingly allow an interconnection in the implementation of measures that contribute to the protection of people and assets. That said, a main objective must be a better articulation between entities and local communities, for the application of this type of programs. This becomes even more pertinent in a context of climate change, which can increase the frequency and magnitude of wildfire events, but also in a context of sociodemographic changes that increase the vulnerability of territories, thus making it necessary to have a better definition of mitigation and prevention strategies for wildfires.

Fire spread, Flame pulsations, Flame residence, Ignition, Flame leaping

Abstract

Detailed physical understanding of fire spread is important in the face of the increasing frequency of wildland fires around the globe. Historically, fire spread across porous vegetative media has been considered a continuous phenomenon. Most studies neglect the influence of flame pulsations on the ignition of fuel particles ahead of the fire front, hence approximating the fire spread to a steady and continuous process. This research explores the dynamic nature of fire propagation by experimentally examining the instantaneous flame pulsations and their impact on the ignition of virgin fuel particles. Fire spread experiments were conducted over a longleaf pine needle (Pinus Palustris) testbed under varying crossflow conditions. In addition to introducing a flame tilt, the presence of crossflow strongly enhances the pulsating nature of a free-burning fire. The flame region of influence ahead of the fireline was augmented by the flame tilt and flame pulsations thereby leading to point ignitions at a distance. If sustained, these point or flash ignitions merge with the fireline, leading to flame spread in the form of leaps. Fire behavior was evaluated by conducting detailed image analysis of videos acquired by placing various cameras around the testbed. Additionally, local temperature and flow velocity were measured by placing a series of thermocouple trees and bi-directional probes within the fuel bed. A curved flame profile was observed under wind-aided conditions, and the curvature was seen to increase with the increasing velocity. Alternatively, a flat temperature profile was observed for no wind conditions. Under forced flow conditions, the bi-directional probes within the testbed measured the flow blocking effect (drag forces) and the presence of flame greatly enhanced the local flow velocity.

1. Introduction

Rapid changes in the global climate (Ellis et al. 2021) and years of inefficient land management techniques (Hann and Bunnell 2001) are the major reasons behind the increased frequency of high-intensity wildland fires. The future global average temperature is expected to follow an increasing trend (Arnell et al. 2009), which will further reduce the fuel moisture content (Keeley and Syphard 2016) and thereby increase the frequency and intensity of large wildland fires. Proximity of the human population to the forested regions and increase in the wildland urban interface (WUI) (Radeloff et al. 2018) adds urgency to this problem. Reliable fire spread models require a thorough physical understanding of the fire spread phenomenon under varying atmospheric conditions. A significant portion of wildland fire literature focuses on understanding flame spread across vegetative fuel, which has further been utilized to build and validate various fire spread models.

The pulsating nature of free-burning fires under the influence of crossflow has been studied using burners (Tang et al. 2019), pool fires (Lin et al. 2021), cribs (McAllister and Finney 2016), engineered cardboard (Finney et al. 2015), and most importantly vegetative fuel (Simpson et al. 2014). Non-spreading flames are helpful in evaluating the fire behavior under changing external conditions but with limited conclusions that may or may not be applicable to the flame spread problem. This work draws an understanding from the pulsating nature of non-spreading flames and furthers it to evaluate the influence of flame pulsations on particle ignition and flame spread behavior. Flame spread is mostly considered as a continuous movement of fire through spontaneous ignitions ahead of the fire front. However, the non-continuous nature of flame spread has been recently studied (Viegas et al. 2021) through various experimental studies. This research focuses on the non-continuous and dynamic motion of the fire front through a pine needle testbed. The multi-scale interaction between wind, fire,

and topography makes the fire spread a dynamic phenomenon, that can influence the development of a fire. Hence, the quantification of this dynamic fire behavior is important for accurate fire prediction.

Flame pulsations during flame spread was first explored in the context of the *trench effect* (Atkinson et al. 1995, Smith 1992, Drysdale et al. 1992) where pressure pulsations were measured by placing probes along the flame spread direction. The controlling physical mechanism generating these pressure variations was observed to change with the trench orientation. Frequency and magnitude of these pulsations were inversely related (Atkinson et al. 1995). Recent work by Finney et al. (2015) examined the flame intermittencies and described the importance of convective heating for fire propagation. Delayed ignition due to intermittent particle heating was also analyzed and continuous flame presence was shown to be necessary for particle ignition and hence fire spread. In the current research, flame pulsations and their impact on particle ignition and fire spread are explored using image analysis and video observations. Delayed fire movement is also examined using temperature measurements while local flow measurements show flow blocking and air entrainment.

2. Experimental details

Fire spread experiments were conducted under various crossflow conditions using a well-characterized wind tunnel, shown as a schematic in Fig. 1(a). These experiments used a *Pinus Palustris* testbed (1650mm by 600mm) placed inside the tunnel with an ignitor embedded in the sand at the leading edge. Sand was used as the pine needles' base to emulate a natural setting. Baked insulation board was used to make the ignitor wick of width 600mm and length 15mm which was soaked with ~20ml of liquid methanol. The ignitor flame was initiated using a heated Nichrome wire placed across the width of the wick top surface. Since methanol generates a clean fast-burning flame, fire spread independent of the ignitor was observed within the first 400mm of the testbed. Fire spread behavior was qualitatively and quantitatively analyzed for five different flow conditions, namely 0, 0.23, 0.28, 0.42, and 0.75m/s. The fuel loading was kept constant at 0.5kg/m^2 and the fuel moisture content (FMC) varied between 5 and 7% on a dry basis.

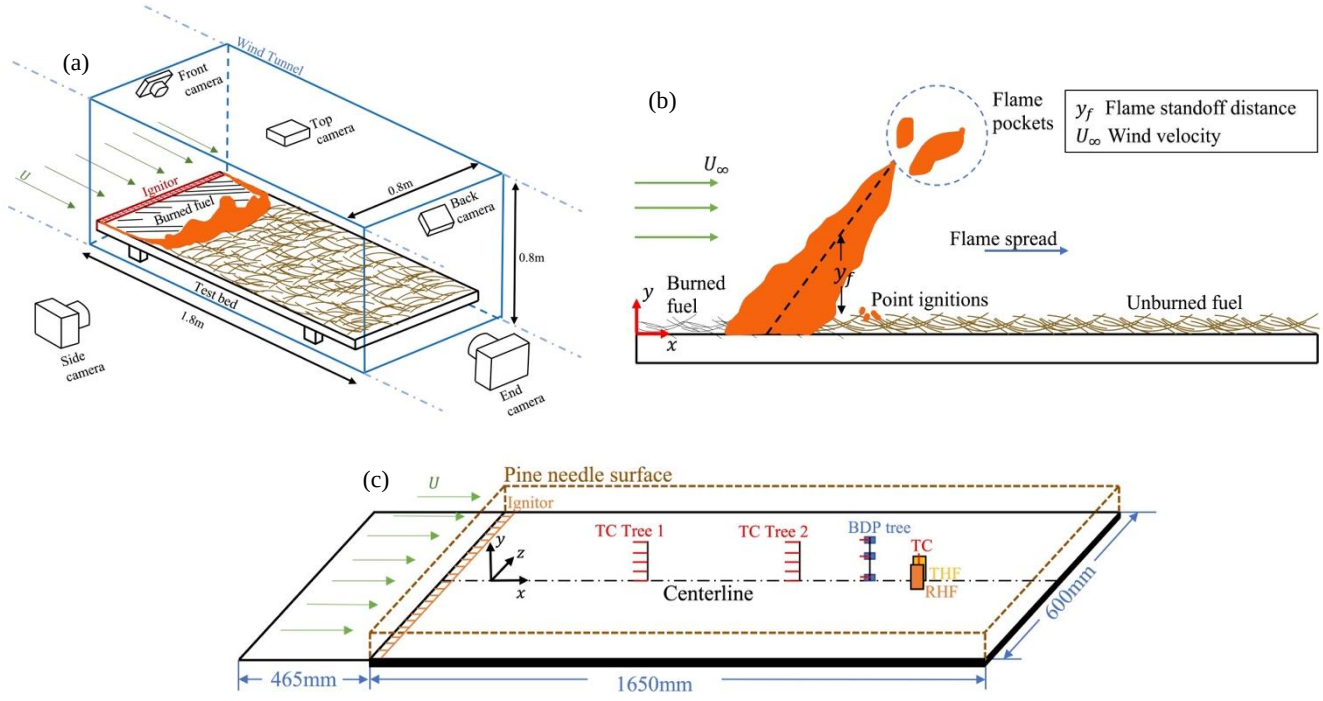

Figure 1 - (a) Schematic of the testbed placed inside the wind tunnel along with the cameras. (b) Fire spread behavior through a pine needle testbed (c) Testbed with the sensor setup.

A schematic of the sensor layout within the testbed is shown in Fig. 1(c). The testbed consisted of two thermocouple trees composed of five K-type thermocouples of 150µm wire-diameter each placed at x = 540mm and x = 1040mm from the leading edge. Five thermocouples were placed in each tree at five different heights with equal increments of 23mm starting from the bottom of the bed (z = 0, 23.3, 46.6, 70, and 93.2mm). Three 10mm diameter bi-directional probes (BDPs) were also placed in a tree-like arrangement (z = 0, 70 and

93.2mm) at x = 1250mm from the leading edge. A K-type thermocouple was attached to each BDP for density correction and flame location. Heat flux measurements were conducted by placing a radiometer and total heat flux gauge at x = 1400mm along with a K-type thermocouple to assess the flame location. Temperature and heat flux measurements were carried out at a sampling rate of 75Hz while pressure was measured at a frequency of 220Hz. Five cameras were placed above and around the testbed to observe the fire behavior as the flame front moved along the testbed.

A detailed image analysis algorithm was developed using the previously established technique (Singh and Singh 2021) of generating flame probability contour profile for non-spreading flames by assuming negligible fire front movement within 0.5s. Side-view cameras acquired the videos at 120 frames per second and every 60 frames (0.5s) were binarized and averaged to build an instantaneous contour profile, which was used to extract the mean and intermittent flames. Additionally, the videos were qualitatively analyzed to observe the flame pulsations and their influence on particle ignition and fire spread.

3. Results and discussions

A detailed qualitative analysis is presented in this section by conducting visual observations using various videos acquired from cameras placed around the testbed. This qualitative analysis is verified by comparison with the temperature and velocity measurements. To understand fuel particle ignition and fire front movements, flame pulsations in the form of mean and intermittent flame are evaluated. The increased region of influence of the fire front is seen to cause point ignitions leading to flame leaping, which is observed from the side, top and back cameras.

3.1. Flame pulsations – Mean and intermittent flame

Buoyancy-induced instabilities and air entrainment lead to flame pulsations generating a mean and intermittent flame. This intermittent flame appears in the form of flame pockets separating from the mean fire front along the direction of flame orientation. A robust image analysis technique was used to evaluate the mean and intermittent flame regions (Singh and Singh 2021, Sun et al. 2021) using the videos acquired from the side-view camera. It is observed from Fig. 2 that for the same wind velocity, the flame region of influence increased due to the presence of the intermittent flame and the area of intermittent flame increased with increasing crossflow momentum. Furthermore, the flame tilt generated under the influence of crossflow decreased the *flame standoff distance* (see Fig. 1(b)), leading to an increased preheating of the unburnt fuel particles ahead of the fire front.

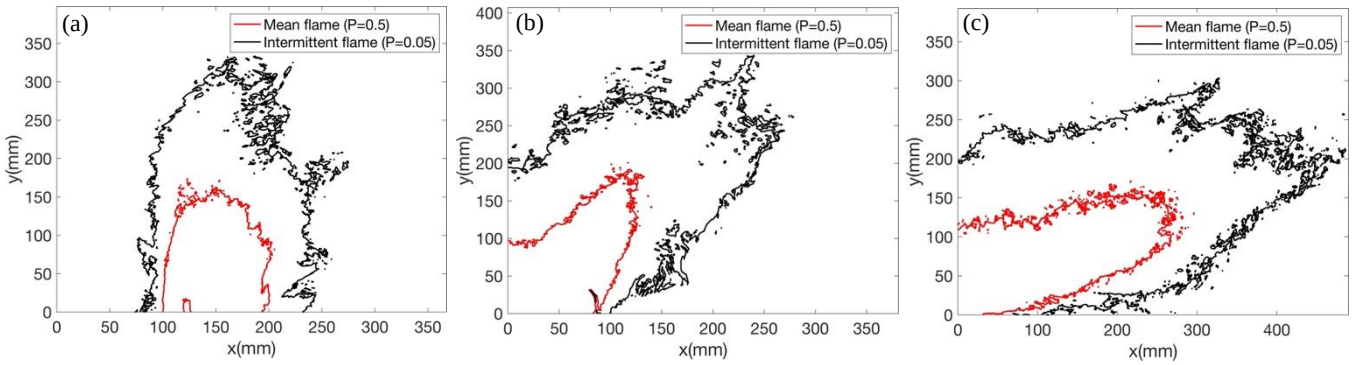

Figure 2 – Mean and intermittent flame contour profiles evaluated using 60 frames (0.5s) for (a) 0m/s, (b) 0.23m/s, and (c) 0.75m/s flow.

3.2. Ignition and fire line movement

Fire front acts as an obstacle for the flow, which intermittently breaks through this barrier, pushing the hot gases towards the unburnt fuel (Finney et al. 2015). This increases the flame region of influence and causes intermittent point ignitions ahead of the flame. This phenomenon is presented in Fig. 3 using the back view for 0.42m/s case with time t = 0s taken as the first frame. Point ignitions, represented by the dotted blue line, have dynamic nature, and depend upon the instantaneous heating conditions. Under low heating conditions, these point ignitions are seen to extinguish and then re-ignite, as observed between t = 0.099s and t = 0.132s. The fire front stagnates at a given *x*-location until the point ignitions merge with the fire front, leading to *flame leaping*

over the top surface (at t = 0.198s). This behavior is seen to continue throughout the testbed and under varying wind velocities.

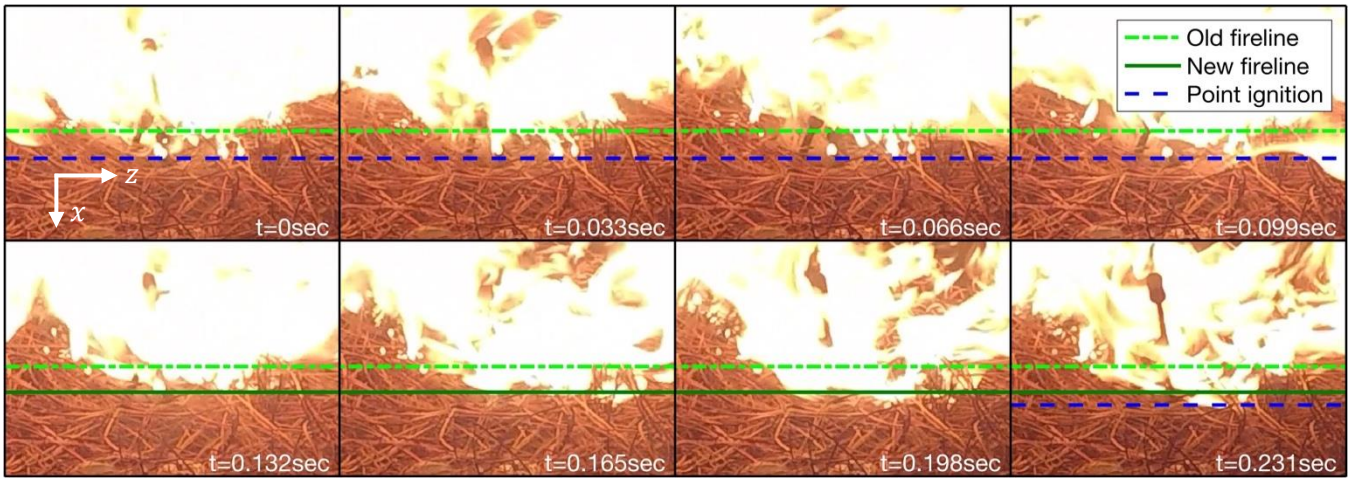

Figure 3 – Intermittent point ignitions and flame spread in the form of leaps for a wind velocity of 0.42m/s. The frames are extracted from the video captured using the back camera.

3.3. Local temperature and flow variations

Two thermocouple trees were placed along the testbed centerline to evaluate the flame behavior during fire front stagnation. Flame presence at a location was acquired using a threshold temperature of 300°C (Mueller et al. 2018). Figure 4 contains the flame profile measured by both the thermocouple trees for wind velocity of 0m/s, 0.28m/s and 0.75m/s. Fire spread under no-flow condition shows a flat flame profile, while this flatness was lost with the introduction of cross wind. For wind-aided fire spread, the flame skimmed over the top surface of the fuel bed, while a delayed movement was observed through the bed, leading to a curved flame profile throughout the bed.

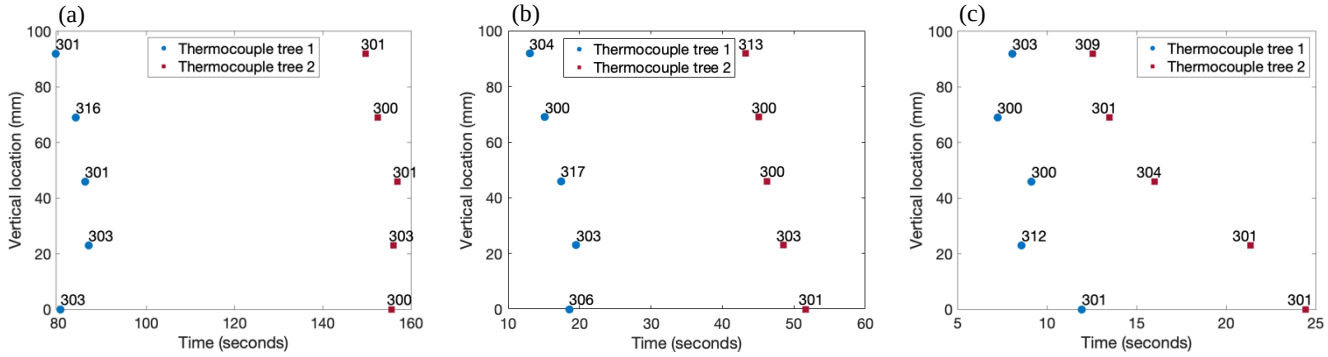

Figure 4 – Flame profile measured using two thermocouple trees consisting of five thermocouples at various vertical locations for wind velocities of (a) 0m/s, (b) 0.28m/s, and (c) 0.75m/s.

The flow velocity measured at the fuel bed surface (=70mm) using a bi-directional probe is presented in Fig. 5 for crossflows of 0m/s, 0.28m/s and 0.75m/s. Temperature measurements at the same location are also presented in the same graph. Near-zero velocity fluctuations were initially observed for all the crossflow wind speeds, representing the flow blockage effect by the porous vegetation. This flow blockage delays the fire movement through the fuel bed, thereby causing the flame to skim over the top surface. For no-flow and low-wind conditions, a significant reduction in the velocity, leading to negative or reverse flow can be seen. This reverse flow represents cold-air entrainment that leads to convective cooling and possible extinction of the point-ignitions ahead of the fire front. No reverse flow is observed for a wind velocity of 0.75m/s because the forced momentum dominates over the induced air entrainment near the fire front.

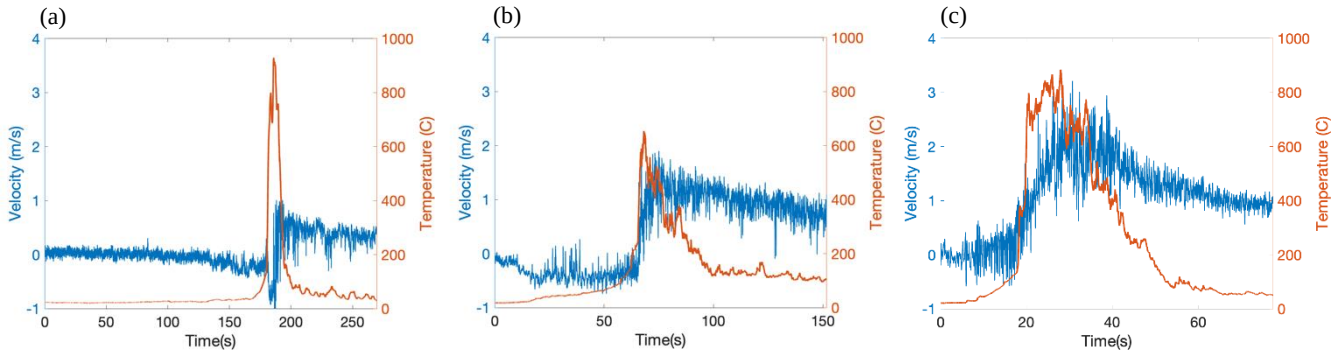

Figure 5 – Local flow velocity and corresponding temperature measured along the top surface of the testbed for wind velocities of (a) 0m/s, (b) 0.28m/s, and (c) 0.75m/s.

4. Conclusions

This work experimentally investigated the dynamic nature of flame spread over a pine needle testbed under varying crossflow conditions. Buoyancy-induced flame pulsations and their interaction with wind was seen to increase the flame region of influence. The flame standoff distance was also seen to decrease with the crossflow momentum, thereby enhancing fuel preheating. The increased flame influence leads to point ignitions in the unburnt fuel ahead of the fire front. These point ignitions can grow under suitable conditions and eventually merge with the fire front leading to flame spread in the form of leaps. Fire front is observed to halt before leaping to a new downstream location. During this flame front pause, it was seen that the fuel bed top surface experiences the flame while flow blockage within the fuel bed delays the fire spread through the bed. Furthermore, the cold air entrainment ahead of the fire front causes convective cooling of point ignitions, leading to extinction and re-ignition. On re-ignition, these point sources grow and merge with the fire front, leading to flame spread. Quantification of the observed point ignitions and leaping phenomenon will be conducted in the future work alongside building a theoretical understanding for intermittent fireline movement.

Abstract

The most well-known type of large outdoor fires are wildland fires that spread into developed, urban areas, known as wildland-urban interface (WUI) fires. More than a decade ago, the state of California in the USA identified the need to develop an approach to harden communities to WUI fires exposure. The term harden simply indicates to make infrastructure in communities more ignition resistant. The premise has its roots in the development of standards and codes developed to mitigate urban fire disasters that were observed in the USA, such as the 1871 Great Chicago Fire or 1904 Baltimore Fire. The urban fire codes and standards provide the basis for fire resistant construction in many countries throughout the world. In the USA, the concept of WUI fire building codes and standards is far newer, due to the more recent WUI fire problem in this country. It is important to note that the exposure conditions used in these test methods are best guess estimates of what exposure conditions would be in a WUI fire and were developed with the best available information at that time. For these reasons, it is not surprising WUI communities will continue to be lost in the future. The lack of physical understanding is a major barrier to developing computational methods to be able to predict and understand how WUI fires spread well as develop sorely needed scientifically-based building codes and standards need to ensure resilience to these threats. There has been little in the way of quantification of firebrand production from vegetative fuel sources. Three ignition sources were utilized. The first considered a custom propane burner, the second made use of firebrand showers using a custom firebrand generator, and the third utilized one tree to ignite another tree. In this short paper, some results are presented using the firebrand generator igntion method for one conifer tree species, Douglas-fir.

1. Introduction

The large outdoor fire problem is a global issue that shows no signs of stopping in the future. The most well-known type of large outdoor fires are wildland fires that spread into developed, urban areas, known as wildland-urban interface (WUI) fires. In the USA, the size of areas burned in 2020 is simply staggering. In California, the August Complex fire itself consumed more than 1 million acres. WUI fires continue to occur throughout the Americas, Australia, Europe, and in Asia. Studies have linked climate change to increased wildland fire hazards [Abatzoglou, and Williams, 2016]. Significant WUI fires were observed in South Korea in 2019 [Lee and Lee, 2020**]** and in Australia in 2019 and 2020 [Deb et al., 2020]. It is important to distinguish WUI fires from wildland fires [Mell et al., 2010]; WUI fires include the combustion of both vegetative fuels and entire communities whereas wildland fires include the combustion of vegetative fuels and occur in uninhabited areas. Estimates place at least 70,000 communities, nearly 46 million structures at risk from WUI fires, which amounts to nearly 120 million people in the USA [Manzello *et al*., 2018].

More than a decade ago, the state of California in the USA identified the need to develop an approach to harden communities to WUI fires exposure. The term harden simply indicates to make infrastructure in communities more ignition resistant. The premise has its roots in the development of standards and codes developed to mitigate urban fire disasters that were observed in the USA, such as the 1871 Great Chicago Fire or 1904 Baltimore Fire. The urban fire codes and standards provide the basis for fire resistant construction in many countries throughout the world. In the USA, the concept of WUI fire building codes and standards is far newer, due to the more recent WUI fire problem in this country. Developing test standards for outdoor fire exposures presents significant challenges. Based on post-fire studies of ignition vulnerabilities in WUI fires, standard test methods were devised by the office of the State Fire Marshal (SFM) in California to address ignition vulnerabilities to exterior walls, exterior windows, horizontal projections such as eaves, decking assemblies,

and the use of ignition resistant materials. It is important to note that the exposure conditions used in these test methods are best guess estimates of what exposure conditions would be in a WUI fire and were developed with the best available information at that time. For these reasons, it is not surprising WUI communities will continue to be lost in the future. To put in it lightly, the science is not there and is dangerous to even reside in many places in California or other areas prone to WUI fires. The international standards organization (ISO) has just begun to address the large outdoor fire problem, as WUI fires are occurring all over the globe [Manzello, 2020].

An important missing piece to better grasp WUI fire spread processes are firebrands. Firebrands are new far smaller combustible fragments from the original fire source. Firebrands signifies any hot object in flight that are capable to ignite other fuel types. Firebrands are produced or generated from the combustion of vegetative and structural fuels. Firebrand processes include generation, transport, deposition, and ignition of various fuel types, leading to fire spread processes at distances far removed from the original fire source. There has been little in the way of quantification of firebrand production from vegetative fuel sources [Manzello *et al*., 2020]. The lack of physical understanding is a major barrier to developing computational methods to be able to predict and understand how WUI fires spread well as develop sorely needed scientifically-based building codes and standards need to ensure resilience to these threats. In this study, discrete fuel packages, manifested as conifer trees, were spaced apart, and the flame spread processes through these fuel packages were observed under an applied wind field. The experiments were conducted using wind facilities at the National Research Institute of Fire and Disaster (NRIFD) in Japan. Three ignition sources were utilized. The first considered a custom propane burner, the second made use of firebrand showers using a custom firebrand generator, and the third utilized one tree to ignite another tree. In this short conference paper, some results are presented using the firebrand generator igntion method for one conifer tree species.

2. Experimental Description

There was interest to see if firebrand showers alone could result in tree ignition and combustion. For these experiments, the reduced-scale firebrand generator was used to generate firebrand showers (see **Figure 1**). The firebrand generator has the ability to produce continuous firebrand showers. In this experimental series, Japanese cypress chips were used to produce firebrands. For a detailed description of the firebrand generator technology and procedures, please see Suzuki and Manzello (2017). A brief description is provided here.

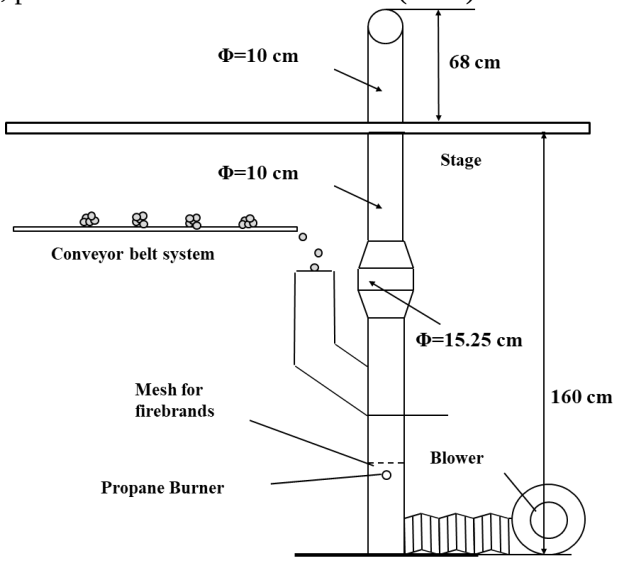

Figure 1- Reduced Scale Firebrand Generator

The reduced-scale continuous-feed firebrand generator consisted of two parts; the main body and continuous feeding component. The capability of a smaller-sized firebrand generator to develop continuous firebrand showers has been described [Suzuki and Manzello 2011]. Japanese Cypress wood chips, which represent firebrands generated from *structures*, and Douglas-fir wood pieces, which represent firebrands generated from *vegetation*, were used to produce firebrands. The Japanese Cypress wood chips had dimensions of 28 mm ±7.5 mm (L) by 18 mm ± 6.3 mm (W) by 3 mm ± 0.8 mm (H) (average ± standard deviation), respectively, before combustion. These were provided from a supplier and filtered to remove really small wood chips by using a 1

cm mesh. Douglas-fir wood pieces were machined to dimensions of 7.9 mm (H) by 7.9 mm (W) by 12.7 mm (L). Similar to the authors' prior full-scale studies, firebrands made from Japanese Cypress wood chips have approximately double the projected areas at a certain mass, compared to firebrands generated from Douglas-fir wood pieces as also seen in [Suzuki and Manzello, 2017]. The difference of wind speeds on characteristics was not observed. In this case, a tree was placed at Δx = 500 mm, from the exit of firebrand generator, similar to prior work that exposed structural fuels to firebrand showers **[**Suzuki and Manzello 2017].
In this short paper, the confier tree species used was Douglas-fir. These trees were collected a tree farm in Japan. The trees were not being grown for inside use. Nearly all the previous confier tree research in laboratory settings used conifers that were collected from Christmas Tree farms in order to have a full, uniform tree for easy comparison. Rather, in these experiments, it was of interest to determine if a tree growing in a more natural state may be ignited by wind-driven firebrand showers.

3. Results and Discussion

Figure 2 displays the results for the interaction of firebrand showers and a Douglas-fire tree of 1.5 m in height. In this experiment, the applied wind speed was 4 m/s. The firebrand generator was fed with Japanese Cypress wood chips to simulate an attack from a near-by adjacent structure. It is interesting to observe that even conifer trees with an open shape may be ignited from firebrand showers. As will be presented at the conference, the authors have recently investigated conifer tree ignition processes under and applied wind field for Nobel-fir conifers [Manzello and Suzuki 2021]. For both species, ignition was possible from firebrand showers. Perhaps the most striking feature is that combustion dynamics are vastly different under an applied wind.

Figure 2- Douglas-fir tree ignited by the firebrand generator under a 4 m/s wind

4. Summary

An important missing piece to better grasp WUI fire spread processes are firebrands. Firebrands are new far smaller combustible fragments from the original fire source. There has been little in the way of quantification of firebrand production from vegetative fuel sources. In this study, discrete fuel packages, manifested as conifer trees, were spaced apart, and the flame spread processes through these fuel packages were observed under an applied wind field. The experiments were conducted using wind facilities at the National Research Institute of Fire and Disaster (NRIFD) in Japan. Three ignition sources were utilized. The first considered a custom propane burner, the second made use of firebrand showers using a custom firebrand generator, and the third utilized one tree to ignite another tree. In this short paper, some results were presented using the firebrand generator igntion method for one conifer tree species, Douglas-fir. Results indicated that it was possible to ignite Douglas-fir trees using wind-driven firebrand showers. Once ignited, the combustion dynamics of a real-scale tree combusting under wind were markedly different than all the studies performed under no-wind conditions.

Wildfire, Firebrands, Fire spread

Abstract

Firebrands are one of the leading mechanisms of spread during wildfire and WUI fires, where hot firebrands can be transported several kilometers ahead of the fire front, potentially creating new fires. Thus, a better understanding of the parameters affecting firebrand generation and characteristics is mandatory to develop better simulation models and predict the "firebrand potential" of different species. The goal of this study is to create a test procedure to characterize the firebrand generation efficiently and to analyze the reproducibility and relevance of the results. The experiments were conducted inside an 11m-long wind tunnel with two variable speed fans. Trunks and branches from Douglas-Fir (*Pseudotsuga menziesii*) samples were dried and tested separately using a 30cm-by-30cm propane burner under wind velocities that ranged from 0.4 m/s to 2.0 m/s. For each experiment, the firebrands generated were collected using water-filled pans with fine meshes inside. The mass distribution of the firebrands over the test section was measured using a load cell. It was observed that the heaviest firebrands only reach the pans next to the tree. Moreover, these pans contained most firebrands produced during the experiments. Thus, at low wind velocity (0.4 m/s), the wind is not strong enough to propagate the firebrands on a large area.

1. Introduction

Firebrands are primarily generated from burning wildland fuels (trees, shrubs, branches) and wooden structures (roofs, structural members). They are produced when the burning fuel thermally decomposes, loses structural integrity, and breaks down into smaller burning portions (Cohen & Deeming, 1985). These smaller portions will eventually separate from the main structure due to the drag forces generated by the airflow surrounding the burning element. Then, they will be lofted in the air by the fire-induced buoyant plume in a flaming or smoldering state (Sánchez Tarifa et al., 1965).

Several parameters have an impact on the geometric characteristics of the firebrands such as the fire behavior, the characteristics of the fuel and the environmental conditions (Bahrani, 2020). Furthermore, the ignition-by-firebrand potential depends on the number of firebrands landing in the same area, the thermal properties of the recipient fuel (moisture content, thermal inertia, density) and the properties of the firebrands (temperature, area, mass) (Cohen & Deeming, 1985).

This work presents the preliminary results of a series of experiments focused on studying the generation of firebrands from 1 m tall Douglas-fir (Pseudotsuga menziesii) samples as a function of wind velocity and for a set fire exposure in the controlled setting of a large-scale wind tunnel. First, a description of the experimental design will be given. Then, the different test parameters and the test matrix will be presented. Finally, the results of the preliminary experiments, including the mass distribution and the characterization of the firebrands, will be presented.

2. Experimental design

2.1. Experimental setup

The wind tunnel used in these experiments comprises a conditioning section, a test section, and a discharge section. The structure of the wind tunnel is shown in Fig. 1.

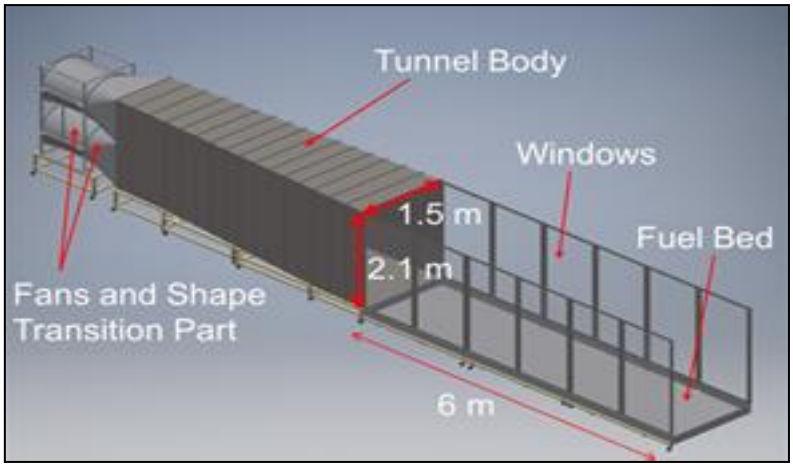

Fig.1: Schematic of the wind tunnel

In the conditioning section, two variable speed fans, along with the diffuser and straighteners, provide a stable and well-characterized inflow at the inlet of the test section.

The 6 m long test section is attached to the exit of the conditioning section and has a cross-sectional area of 1.5 m (width) by 2 m (height). It is equipped with tempered windows for flow and flame diagnostics. Within the test section, a 1.5 m width by 6 m long test bed is placed.

At the beginning of the test bed, a 30cm-by-30cm propane burner was installed. The heat release rate (HRR) of the burner is set by a mass flow controller regulating the volumetric flow of propane being delivered. The size of the burner was selected based on the maximum diameter of the samples used to ensure complete flame engulfment and avoid edge effects over the sample, as shown in Fig. 2a.

Downstream from the burner, the vegetation sample is mounted over a 60cm-by-45cm platform and held in place with a steel bracket, as shown in Fig. 2b. A 0.2 g sensitivity scale sampling at 1 Hz is placed below the platform to record the mass loss of the sample during testing.

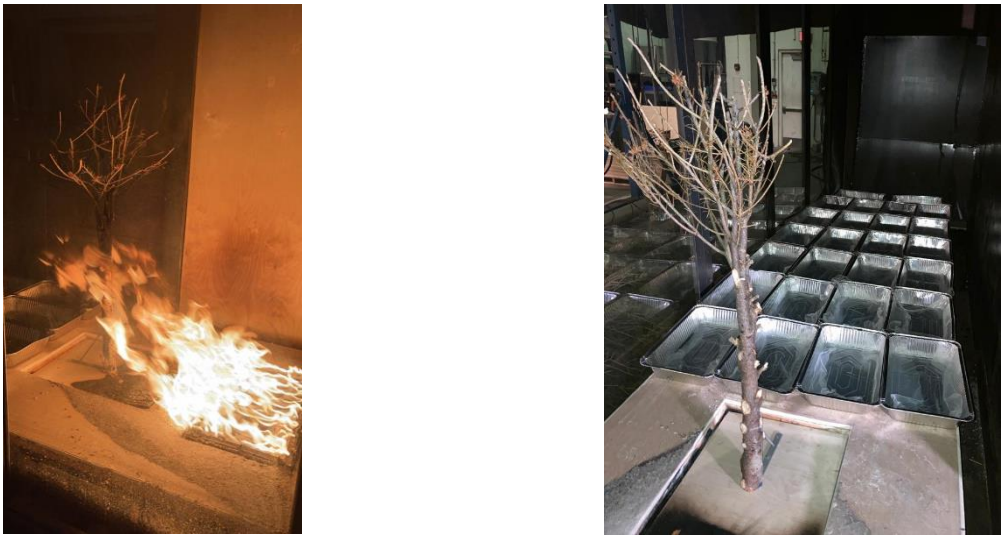
To collect the firebrands, a layout of aluminum pans of 53cm-by-33cm was placed on the test section downstream from the sample (Fig. 2b). These pans were filled with water to extinguish the firebrands when they landed. A fine mesh (0.6mm-by-0.6mm grid size) was placed below the water level to collect the firebrands inside the pan after each experiment.

At the discharge section, a deflector is placed to prevent the firebrands from escaping the confined test environment.

Two cameras were used to record the experiments and to track the firebrands:

- A high-speed camera on the side of the tunnel facing the glass panels was used to track the firebrands throughout the test section. The data collected from this camera allowed for estimating firebrand velocities during flight.
- A GoPro camera placed close to the fuel sample, behind the glass panels, was used to record its ignition at the beginning of the experiments

After each experiment, the firebrands were collected, dried, and weighted using a 0.01g-accurate load cell to determine the mass distribution.



(a) (b)

Fig. 2: Testbed. (a) Propane burner. (b) Mounting platform and aluminum pan array used to collect the firebrands generated

2.2. Fuel selection

For the current study, Douglas-Fir (*Pseudotsuga menziesii*) samples were used. The species was selected due to its geographical accessibility and the availability of data and results from the literature (Manzello et al., 2006; Baker, 2011; Manzello et al., 2008).

The moisture content inside vegetative fuels significantly impacts the fire behavior and the firebrand generation. A quantitative analysis of the effect of the different moisture content of vegetative fuels is given in (Manzello et al., 2008). Three different levels can be found (mass basis); With a moisture content of 70% or above, no sustained burning after the ignition will be observed, and thus no firebrand generation. When the moisture content is between 30% and 70%, a transition regime occurs where the tree will be partially burned after the ignition. For moisture content below 30%, the tree will be entirely consumed after the ignition and firebrand generation will occur. Moreover, Douglas-Fir will not produce firebrands if its moisture content exceeds 30% (mass basis) (Baker, 2011).

Thus, a fuel conditioning chamber was built to reduce the moisture content of the vegetative fuels used for the experiments. This chamber will also allow us to dry the wet firebrands after the experiments to then characterize and analyze them. An operational temperature of 61°C was achieved inside the chamber.

The samples were prepared from locally sourced two-meter-tall live trees as follows:

First, the branches were separated from the trunks and stacked in different packages. Then, the trunks were cut in half to fit inside the test section, labeled, and placed in the drying chamber. The moisture content and the weight of each trunk were checked every day to follow the evolution of the drying procedure.

Before testing, the moisture content was determined using a wood moisture meter able to measure the moisture content (volume basis) between 1.5% and 50 % with a +/- 2% accuracy. Through the drying procedure described above, the samples achieved a moisture content of 15% before testing.

2.3. Experimental matrix

Preliminary experiments were conducted to determine the most suitable HRR and wind velocities inside the tunnel. The different wind velocities selected are shown in Table 1. A HRR of 300 kW/m^2 was selected as it was the minimum HRR to achieve sufficient flame engulfment given the characteristics of the burner and the rest of the experimental setup.

The branches and the trunks were tested separately to see the difference in terms of firebrand production with the same parameters.

Table 1: Experimental matrix.

Fuel Type	Wind velocity (m/s)	HRR (kW/m^2)	Repetitions
Trunk	0.4	300	3
	1.0		3
	2.0		3
Branches	0.4	300	3
	1.0		3
	2.0		3

3. Results

In the following section, the preliminary results of some experiments conducted using tree trunk samples are presented to illustrate the approach in practice. These experiments were conducted at a 0.4 m/s wind velocity and 300 kW/m^2 HRR.

3.1. Weight distribution

The primary trend observed in the mass distribution is that the heaviest firebrands only reach the first row of pans. Figure 3 shows the weight distribution of the firebrands under a 0.4 m/s wind velocity. Because of the low velocity, none of the firebrands generated reached the pans furthest from the fuel sample. Further experiments using higher wind velocities are required to determine the impact of the wind on the distance traveled and the mass distribution of the firebrands.

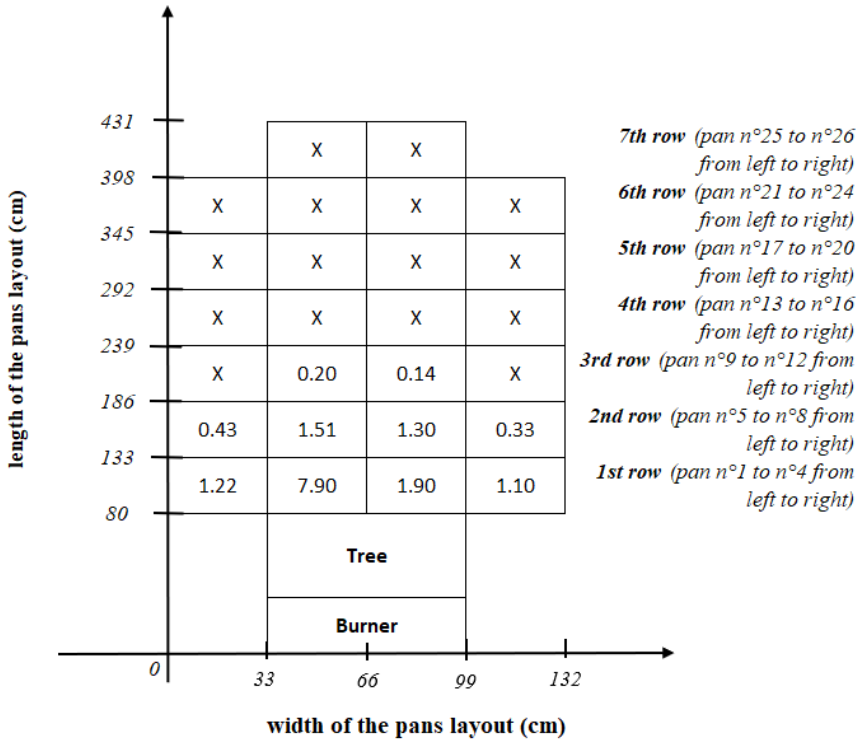


Fig. 3: Weight distribution of the firebrands for a preliminary test

3.2. Characterization of the firebrands generated

After each experiment, the meshes containing the firebrands were removed from the pans and dried for two hours. Pictures from two different pans are shown in Fig. 4a and Fig. 4b.

The primary trend observed during the preliminary experiments is that the number of firebrands per pan and their size decreases when the distance from the tree increases. Moreover, for the same row, the pans placed on the sides of the test section will receive fewer and smaller firebrands than the pans placed in the middle.

(a) (b)

Fig. 4: Firebrands collected at different locations during preliminary experiments with a 0.4 m/s wind velocity. (a) Firebrands collected in the first row (pan n°2). (b) Firebrands collected in the second row (pan n°5).

3.3. Firebrand velocity

From Figure 5, it can be seen that the absolute velocity of the firebrands correlates well with the imposed wind velocity. The variation in the range of velocities measured is attributed to the variation in mass and geometry of the firebrands collected. Both parameters will alter the contribution of buoyancy and aerodynamic drag over the firebrands. As mentioned earlier, further experiments are required to analyze the influence of wind velocity over the absolute velocity of the firebrands generated.

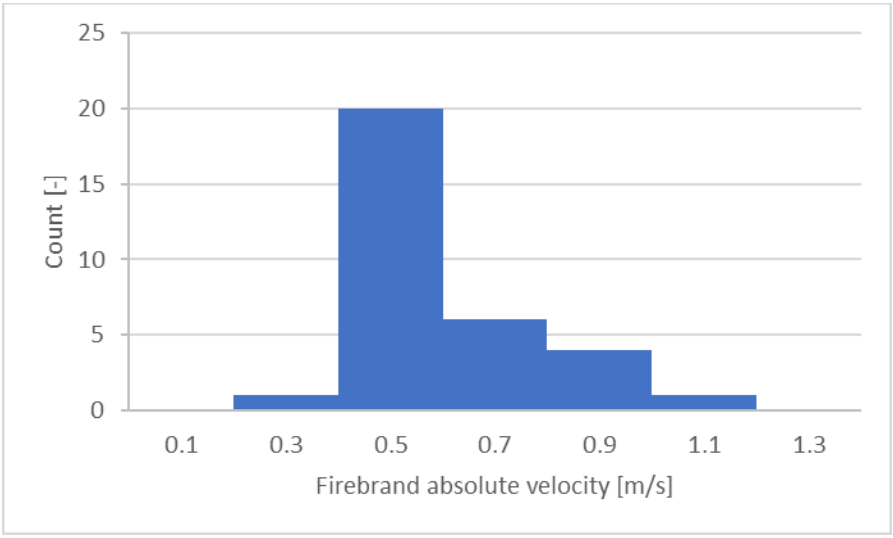

Figure 5: Aggregated firebrand velocity distribution for an experiment conducted using a flow velocity of 0.4 m/s.

4. Conclusion

A series of experiments were conducted using Douglas-fir under different wind conditions to analyze the firebrands' characteristics and mass distribution as a function of fuel type and crossflow velocity.

The preliminary results presented here demonstrate the methodology under which the study is conducted. The complete version of the study will showcase a detailed analysis of the results obtained for the complete experimental matrix proposed.

Fuel Management, Fuel Management Areas, Firebreaks, Fuelbreaks, Legal Regulation; Integrated Rural Fire Management System (Portugal)

Abstract

Fuel management areas (FMA) can be classified depending on their different objectives, as primary, secondary and tertiary, and can be made up of firebreaks when fuels are totally removed, fuelbreaks and shaded fuelbreaks when land remains covered by vegetation, but fuels are reduced in volume and flammability. Given the recognized importance of these areas (as defensible spaces), but also their variety, they may be found in several legislations but regulated in quite different modes. In general terms, however, it is possible to observe that there are common features which are considered in the legal regulation of fuel management, mostly at the wildland-urban interface: the location of the land; its wildfire hazardousness and the type of activity and vegetation present on the property and its surroundings. Portuguese legislation distinguishes between primary, secondary and tertiary fuel management areas, but adopts a very simplified approach to secondary FMA, considering only the type of activity at hand and the type of land (forest or agricultural) in the surroundings, and no other relevant factors as topography, climate and concrete vegetation. This contribution focuses on secondary areas and defines their main traits, from the point of view of legal regulation, and also the difficulties in their operationalisation. This article is an output of the project House Refuge (PCIF/AGT/0109/2018), funded by the Portuguese Foundation for Science and Technology.

1. Introductory remarks

Fuel management plays a crucial role in preventing forest fires and especially mega-fires and their consequential damages to lives, environment and property (ANDERSON/ANDERSON, 2012).

However, because they involve actions with long term results, highly complex and technical, and because the technical precepts that fuel management involves are very hard to translate into law, they ended up receiving little attention for many years within the legal field, when the focus on forest fire policies was placed on actions of suppression of forest fires, which have more immediate result, especially in countries affected by large fires, such as Portugal (BENTO-GONÇALVES, 2021) and USA (BUSENBERG, 2004; ANDERSON/ANDERSON, 2012; STEPHENS, 2016). Yet the increase in the incidence and size of fires has highlighted the importance of adequate regulation of fuel management and investment in this sector.

Fuel management areas (FMA) can be classified depending on their different objectives, as primary, secondary and tertiary. Also, they can be made up of firebreaks when fuels are totally removed or extremely reduced in usually linear areas, in order to diminish the intensity of a fire and allow for an easier access to fire related departments and forces; fuelbreaks, when fuels are greatly reduced in volume and flammability and shaded fuelbreaks that include vegetation but at a low density, in order to break up the continuity of fuel and limit the fire progression (ASCOLI et.al., 2020).

Given the recognized importance of these areas as *defensible spaces*, but also the various factors that influence fire behaviour and therefore the technical requirements for fuel management, they may be found in several legislations but regulated in quite different modes, as the particularities of the place where management is carried out must be taken into consideration (VIEGAS, 2005).

The purpose of this contribution is to give a broad framework of the international regulation models of fuel management in particular at the wildland-urban interface (WUI) and also to analyse in more detail the legal solutions in Portugal.

2. Regulation types of fuel management areas

Although the legal regulation of FMA in WUI in different countries is not uniform, common features can be found regarding fuel management conditions, the size of fuel management strips and those responsible for rule-making, implementation and, eventually, enforcement.

In the table below we highlight some examples of foreign regulation of fuel management in what regards fuelbreaks, such as the state of Victoria in Australia, the state of California in the USA and France. Note that in the first two countries, the regulation of the fuel management rule is left to the states, while France establishes a general rule that can be altered by regulations drawn up by fire-prone regions (Code Forestier, Article L131-14).

Country	**Rules of fuel management**	**Responsible entity**
Australia (State of Victoria)	10/50 and 10/30 rules of fire management: building a firebreak area within 10 meters of the house, with the removal of all the vegetation in this area, and one fuelbreak area within 30 or 50 meters – depending on the hazardousness of the area	Owners or those with administration powers
USA (State of California)	Three different zones of fuelbreaks: 1st: area up to five feet around the house in which the responsible person has to build a fuelbreak area removing the flammable vegetation. 2nd: 5 to 30 feet zone, requires management actions such as the creation of fuel breaks with driveways and decks, spacing trees and the removal of the fuel under them. The 3rd zone (30 to 100 feet) only takes place if the administration considers that the other areas are not sufficient due to accentuated risks (NFPA, 2022).	Id.
France	Around buildings: General rule to reduce the vegetable fuel within a 50 m area surrounding the buildings on lands located up to 200 meters from forests.	Id. The owners can request the municipalities to carry out fuel management and its maintenance, but they remain responsible for the costs of these operations (Code Forestier, article L131-14).

In general terms, it is possible to observe that there are common features which are considered in the legal regulation of fuel management in those countries and that influence the different dimensions and practices of fuel management: the location of the land; its wildfire hazardousness; the presence of homes in the surroundings; the type of the activity undertaken and the kind of the vegetation present on the property and vicinities.

There has been some consensus on the main factors that lead to a wildfire, on the need to take action to reduce hazardous fuel levels and safeguard wildland-urban interface communities, and on the range of conditions that should be considered when delimiting FMA's. Naturally, since many firebreaks are located in private areas, legislations place legal duties on owners or administrators of the property to prepare and maintain them. Therefore, it is necessary to translate technical requirements into law so that those demands are complied with, and, in case of failure to comply, so that legal consequences are applied (for instance administrative or criminal sanctions or civil responsibility claims).

For law to be effective it is necessary that rules are consistent and understandable and also that their scope (which rules apply to whom, when and where) is clearly defined, so that their addressees know what is expected from them at any point in time and space. This means that in the wildland-urban interface, unless specific

planning instruments are adopted that detail rules based on susceptibility of wildfires in concrete defined areas, it is difficult to include a wide range of variables when defining which legal rules to apply.

This is particularly apparent when considering the situation of homes or other human activities near slopes. Despite the fact that this is the most dangerous location for such uses (https://www.portugalwildfires.com/wildfires-on-slopes/), it is quite challenging to define a general rule on firebreaks (for a whole country, a state, a department or even a municipality) that complies with the legal demands of certainty and predictability. The wildfire hazardousness of an area could and should indeed take into consideration this factor (if the area of reference is mainly slopy or not); however, this is an approximate exercise that might not lead to the best definition of the concrete conditions under which firebreaks should be established.

Nonetheless, this need not be an unsurmountable task. Law is not a straitjacket (KEITER, 2006) and allows for moments of flexibility, as long as applicable legal solutions are duly framed into specific instruments (for instance territorial or land management plans) made known to the public. In addition, law is a tool for engagement and change and can, therefore, play an important role in addressing relevant societal challenges, such as wildfires. This implies the involvement of all actors, public and private, and the adoption of balanced solutions that are technically adequate, but also legally sound.

3. Portuguese regulation of fuel management areas

After this bird veil on existing types of regulation across several countries and the importance of an adequate legal regulation, a more precise look should be directed to the Portuguese Legal System. Let's start without delay, observing firstly that Portugal is undergoing a period of normative change. Decree Law no. 124/2006, 28 June, established the National Defense of Forest against Fires System (SNDFCI), and regulated, among many other instruments, FMA of primary, secondary and tertiary nature (Articles 13 to 15). Despite the fact that Article 15 of Decree Law no. 124/2006, that regulates secondary FMA is still in force in many Municipalities, according to article 79(4) of Decree-Law no. 82/2021, 13 October, this new piece of legislation is, from the 1st of January 2002 onwards, the basic framework of the Integrated Rural Fire Management System (SIGFR).

According to SGIFR, fuel management is defined as the creation and maintenance of horizontal or vertical discontinuity of the fuel load, through modification or partial or total removal of the plant biomass and the composition of plants, using the most recommended techniques with the intensity and frequency appropriate to meet the objectives of the intervened spaces [Article 3(1)(g)]. FMA functions are referred to in Article 47(2).

Three FMA are established. Primary FMAs correspond to linear strips in rural areas that have a standard width of 126 m and compartmentalize areas that should preferably have between 500 and 10,000 ha. These areas are managed and executed by the Portuguese State and defined in Regional Action Programs (Article 49). On the other side of the spectrum tertiary FMAs are of local interest and are to be defined in more concrete forest management instruments (Article 51).

As for secondary FMAs, they are established in Article 49 and can be summarized in the following table:

Type of activity	**General rule of fuel management**	**Responsible entity**
Road network	10 m outside the limits of the carriageway	Entities (public/private) responsible for the infrastructures
Railway network in operation	10 m from the outer rails	Id.
Very high voltage and high voltage electric power transport and distribution lines	Strip corresponding to the vertical projection of the outer conductor cables + a strip 10 m wide on each side	Id.
Medium voltage electric power distribution lines	Strip corresponding to the vertical projection of the outer conductor cables + a strip 7 m wide on each side	Id.

Low voltage electrical power distribution lines, with conductor cables without electrical insulation	Strip not less than 3 m wide on either side of the vertical projection of the conductor cable	Id.
Gas and oil products transportation network	7 m from the duct axis to each side	Id.
SIRESP (communication system for emergency and security) support infrastructures	Surrounding strip with a width of 7 m	Id.
Camping and caravan parks, hotels, hazardous activities that may lead to grave accidents, industrial establishments and entrepreneurial areas, fuel stations, logistics platforms, electricity or gas production and storage facilities and sanitary landfills	Surrounding strip with a standard width of 100 m	Owners, lessees, usufructuaries or entities that, in any title, administer the land within the strip
Surroundings of built-up areas, when bordering forest land	Surrounding strip with a standard width of 100 m from the interface of built-up areas	Id.
Buildings that are being used for housing or economic activities, if the 50 m band covers forest land	Standard width of 50 m, measured from the outer masonry of the building	Id.
Buildings that are being used for housing or economic activities, if the band covers agricultural land	Standard width of 10 m, measured from the outer masonry of the building	Id.

These rules are applicable to all areas except for built-up areas where fuel management is carried out in accordance with municipal regulations [Article 49(9) and Article 3(1)(b)], regardless of their wildfire hazardousness or location in fire prone areas. Also, the size of the FAM is "watertight" and does not take into account the specific conditions of the terrain, being too large in some cases and insufficient in others (i.e. properties located in slopes, for instance).

The legal regulation in Portugal is therefore oversimplified, taking only in consideration the type of activity at hand and the type of land (forest or agricultural) in the surroundings, and no other relevant factors as topography, climate and concrete vegetation, and, therefore, not being sufficiently multidisciplinary and multifunctional in its scope (VIEGAS et al., 2020).

The SGIFR tends nonetheless to introduce some plasticity to this general legal framework in two different ways:

a) the admissibility of *compatible uses* in the FMA, seen as the occupation of land in a manner different from that foreseen in the fuel management standards, as long as it is compatible with the objective of fuel management, reducing its availability for the ignition and progression of fire, and generates value for the owners or communities [Article 3(1)(k)];

b) and the *flexibility* of the FMA width, in duly justified cases, and depending on the hazard and wildfire fire risk, up to 50 /prct. greater or less than that established in these paragraphs 4 to 7 may be adopted [Article 49(2)].

These possibilities need to the included into the newly introduced (and not yet in adopted) subregional programs (Article 34). Hence, so far, the terms of such compatibility and flexibility possibilities are indeterminate.

4. Conclusive remarks

Translating technique into law is not an easy task. The demands of a dynamic and flexible framework that prevents wildfires and reduces the devastation of their effects, needs to be compatibilized with the logic of law, that aims at fair, but also, stable rules and results (LOPES, . The legal regulation of secondary fire management

areas tends to such a balance, at the price of, in some cases, excessively reducing the technical complexity of fire management techniques, as can be seen in the Portuguese case.

Extreme events, wildfires, lessons learned, resilience

Abstract

Managing extreme wildfires requires a more holistic approach where proactive governance, citizens, and local communities play a central role.

Two recent devastating wildfires in Greece, the one in July 2018 in Mati/Attica and the other in August 2021 in North Euboea, demonstrated to a large extent the weaknesses and gaps in the Civil Protection mechanism as well as the inadequate preparedness of the local population to deal with such fires. In addition, both fires had a high societal and political impact and raised a lot of criticism and opposition.

Both fires burned under extreme weather conditions (i.e., extreme winds in Mati and prolonged heatwave in Euboea) and in parallel with other major fires in the country. However, they were characterized by quite different fire regimes, ecosystem and landscape features, and the local community type they affected.

This paper studies and analyses the combined response of the civil protection authorities and the local communities during these significant fire events.

Focused surveys, questionnaires, interviews, onsite discussions, and round tables with local authorities, citizens, first responders, and representatives of the touched communities were organized to collect information on problems, challenges, and risks, as well as response practices that proved to be effective during the response phase.

This work aims to identify lessons learned for suggesting a revision of current practices and policies to bridge the gap among the actors involved in wildfire management and to facilitate the development of local adaptation plans to increase the resilience of the local communities to wildfire risk.

1. Introduction

The new context of extreme wildfires requires implementing a more holistic fire management approach. Environmental management, climate adaptation, safety concerns, and cultural and socio-economic opportunities need to be coupled with proactive governance to mitigate disastrous situations in the near future. Furthermore, revision of forest management practices and large-scale and community-based actions are necessary for reducing the risk, increasing awareness, and improving preparedness. In this puzzle, citizens, local communities, the forestry, and bio-economy sectors have to play a significant role. (Cordis-European Commission, 2021)

Furthermore, the intermix of settlements with natural ecosystems and the fires occurring between wildlands and rural and peri-urban settlements cause severe wildfire challenges that often become the subject of intense political debate and confrontation.

Wildfires that break out the recent years under severe weather conditions, exacerbated by the ongoing climate change, can rapidly grow across the intermingled structures and vegetation, and firefighters can hardly control their propagation. Such fires can potentially burn large wooded and rural areas and destroy houses, properties, infrastructures, and livestock, while they may also result in severe injuries or even fatalities.

Recent major wildfire disasters in Greece and other EU countries have proved that the government organizations, the public authorities, and the citizens are not sufficiently prepared to handle the worsening of fire regimes. Therefore, the communities need to adapt landscape management to prevent and reduce the risk of wildfires, defend the rural communities and the natural resources, and protect human lives against the adverse direct and indirect impacts and consequences of wildfires. (Goldammer et al., 2013, Dimitrakopoulos, 2019)

Becoming a fire-resilient community that can cope with the wildfire challenges is linked to a continuous, iterative process of adaptation to the landscape and the socioeconomic factors in these areas. Unfortunately, the way the threatened communities may pursue adaptation remains entirely unclear. There is also inconsistency in how citizens perceive risk and how the civil protection authorities do so. This fact contributes to a risk perception-action gap (Wachinger et al., 2012; Margolis, 1996) that often sub-optimizes both efforts.

Fire disasters offer lessons on organizational weaknesses and allow to identify good and bad practices. Moreover, there is a specific "window of opportunity" following the disastrous event to integrate the outcome of such lessons into local government policy changes. (Mockrin, 2018)

This paper studies and analyzes the combined response of the civil protection authorities and the local communities during two recent major wildfires in Greece. The purpose is to identify lessons learned to suggest a revision of current practices and policies and bridge the gap among the efforts of the actors involved in wildfire events. In addition, organizational and societal adaptation to the risk of large wildfires must be considered to increase the local communities' resilience and protect the natural ecosystems in fire-prone areas.

Focused surveys, questionnaires, interviews, and round tables with local people, first responders, and representatives of the touched communities were organized to collect information on identified problems and practices that proved effective during the response phase. The aim is to use this material to develop a proper local adaptation plan to increase the resilience of the local communities to wildfire risk.

1.1. Fire events

The fires under consideration are characterized as "extreme events" and had a very high impact on society and at a political level. However, they had pretty different features regarding the fire regime, the ecosystem environment, landscape patterns, and the local communities' attributes that they affected.

Both occurred in parallel with other important fires in the country, which had started earlier and occupied most suppression forces; the authorities initially underestimated or overlooked their severity. Thus, the initial attack effort was inadequate.

1.1.1.Mati fire – July 2018

On the 23rd of July 2018, at 16.30', a fire ignited north of Athens in the settlement of Daou-Penteli, which belongs to the municipality of Penteli. Due to very strong and gusting winds in the area, blowing from an unusual direction, the fire spread quickly as a crown fire and headed east towards the sea. It propagated across the wildland-urban interface causing significant damages and losses in the settlements Neos Voutzas, Mati, and Kokkino Limanaki, which are sited north of Rafina port.

Due to the extremely fast fire spread in a built forested area with thousands of houses mixed with forest vegetation and narrow streets, several people were blocked in their homes or trapped in their cars trying to flee from the area. In addition, several people were caught by the fire as they attempted to reach the sea to be safe. In a fire that lasted less than six hours, hundred two (102) people lost their lives, several were injured or inhaled toxic smoke, while many houses suffered partial damage or total collapse. The fire propagation stopped when it reached the sea after a few hours and burned only 1400 ha.

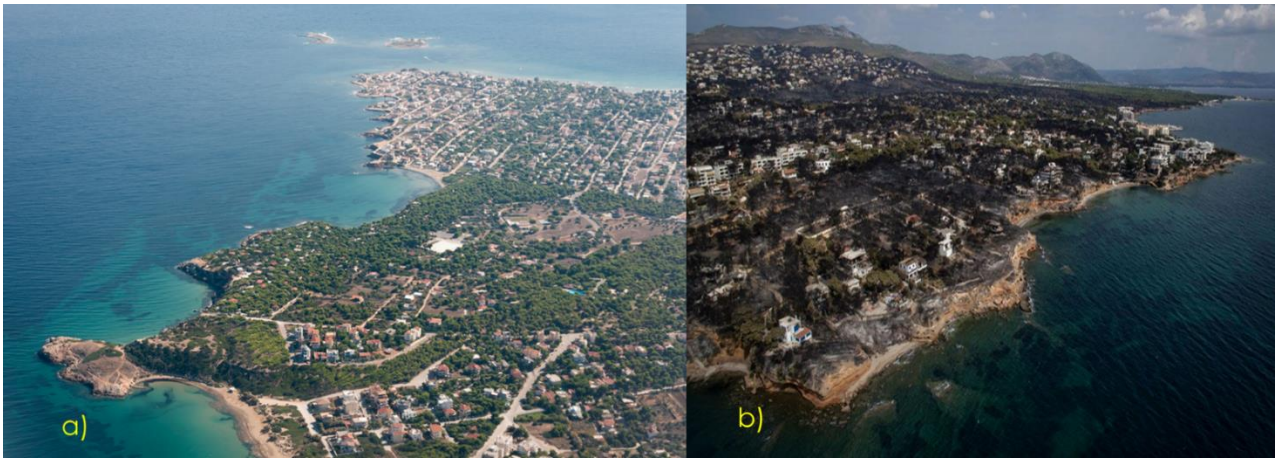

Figure 1.View of Mati area a) before[7] the fire and b) after[8] the fire

1.1.2.*N. Euboea fire – August 2021*

The fire ignited on 03/08/2021 at 15:30 and was finally contained and secured on the 17th of August. The total burned area was 51245 ha and affected two municipalities of the Northern part of the Euboea island, namely Istiaia-Aidipsos & Mantoudi-Limni-Agia Anna.

Figure 2. Burned area of N.Euboea mega-fire (2021)

Figure 3. Burned area of Mati-Neos Voutzas fire (2018)

The fire weather conditions were characterized by the extreme heatwave affecting Greece, Turkey, and the southern Balkan peninsula, lasting from the last days of July until the first ten days of August. The heatwave was the most intense of the past 30 years. It was a high-intensity surface & crown fire, especially in places of dense pine stands, with a low rate of spread due to low wind speed during combustion, in combination with a considerable accumulation of fuel, due to inadequate forest management for fire prevention through fuel treatment actions.

Figure 4. The fire threatened the town of Limni in N.Euboea[9]

Figure 5. Several losses in Mati were due to the trap of cars in the narrow streets of the settlement

2. Methodology

To identify diverse approaches and understand the role, the practices, and the interaction among local actors during the fires, targeted surveys/interviews and dialogue meetings were applied with Local Civil Protection Authorities, first responders, and representatives of local communities.

Two workshops were also organized in the areas of interest, with thirty-two (32) and forty-six (46) participants, in Mati/Attika and North Euboea, respectively, in which round-table discussions took place and provided a lot of information input for the local response, community and volunteers involvement, the impact of the fire and the activities after the fire events. The topics discussed during the interviews and dialogue meetings and the round table discussions during the workshops concerned:

a) general aspects of the operation of local civil protection authorities and community groups, such as existing resources and operational framework and knowledge and training background, perception of resilience

b) Relationship and interaction with other authorities, community groups, and also citizens during a forest fire emergency

c) Response actions during the specific fire events

d) Evaluation of actions and suggestions for improvement after the fire

The information extracted was analyzed, and shared elements were grouped to identify common aspects of local fire management and response during fire events, and to understand problems, discrepancies, strengths, and potential for development through lessons learned.

3. Results & Discussion

According to the results of this study, regional and predominantly local authorities are in direct communication with various community groups, organized volunteers, and active citizens who are active in their area. Typically, there is good collaboration with these groups, and they perform jointly several actions related to the fire management phases, including the response.

As many interviewees stated, the authorities tend to be more rational and objective in their perception of risk and try to be guided by circumstances and statistics. In contrast, the population tends to react more emotionally. (Varela et al.,2022)

The authorities highlighted the opinion that citizens do not understand the risks they face and that they need to become more self-reliant.

[9] https://www.ekathimerini.com/news/1165654/six-villages-evacuated-in-evia-as-fire-burns-through-forest/

However, it is expected that local voluntary groups often specialize in forest fires in their area, especially in the rural and forested areas, and have a good perception of the fire risk. Therefore, voluntary groups, which were self-organized, played an essential role during the mega-fire in Euboea.

Technological systems (the 112-emergency line) and social media communicate the fire emergency with the community. However, the challenge is to disseminate information to vulnerable groups, the elderly and children, who do not have access to the Internet. The civil protection plans provide specific provisions and practices for vulnerable groups of citizens.

Despite the overall cooperation, a problem commonly mentioned is the lack of an interoperable Operational Centre. All the local, regional and national authorities can use such an organizational structure to have a complete operational picture of the event, facilitate the coordination suppression effort, and provide specific instructions to the volunteer firefighters and the citizens.

It is worth mentioning that according to most local authorities, a fire disaster provides opportunities for improvement. Nevertheless, many interviewees commented on the weaknesses of their organization due to limited resources or coordination problems and the insufficient actions for risk management and communication. However, after evaluating and criticizing the management's actions during the fire events, they provided ideas and suggestions for the future. For example, in the region of Mati, after the fire in July 2018, gathering places were created, signs marking routes to the sea were erected, and special spatial plans (SPPs) began to be drafted.

Some of the actions at a national and local level after the catastrophic fire in Mati/Attica are the following:

- 112 Emergency Service was activated

- the responsibility of evacuation was transferred from the first and second levels of local government to the central authority in the Ministry of Climate Crisis and Civil Protection.

- local government officials are trained in Civil Protection by institutions such as the Centre for Training and Lifelong Learning and the National University of Athens.

- Independent Civil Protection Offices have been established both at the first & second level of local government and at the Central Authority

- Updated natural disaster plans were created.

- The Municipality is funded by the relevant Ministry of Climate Change and Planning in addition to the low funding it received until recently from the Central Government

- G-Polis web application was organized as a means tool to inform the residents of the Municipality directly on their mobile phones about any dangerous - alarming event that takes place and "guide" the residents for its evolution.

Nevertheless, the excessive use of evacuation orders and the misleading instructions during the fire in North Evia led to non-compliance with state recommendations and relative loss of trust. This fact was confirmed by the majority of local authorities and residents interviewed, demonstrating the need to reorganize and update the plans and procedures and the doctrine for evacuating areas during wildfires, considering the fire situation, landscape conditions, and the capabilities of the local population. The possibility of partial evacuation should be given case-by-case (evacuation of children, elderly and vulnerable groups to a safe place). This approach will allow the competent/healthy people from the area to support the response mechanism since the local population knows the site better than the firefighters, who are often sent as reinforcements from services that arrive from distant municipalities or regions. The above presupposes that the volunteers know how to protect themselves, i.e., that they have received training, are adequately equipped, and are collaborating with the firefighters in an organized manner.

The study of local response to extreme fire events that occurred in two geographic areas that significantly differ in landscape and socioeconomic aspects allows the broader analysis of the applied practices at the local level. It can also be used to understand the deficiencies and weaknesses of the response actions comprehensively. There are a need to integrate, monitor, and coordinate fire management activities from the local to the central level in the context of the civil protection organization. However, to improve the effectiveness and efficiency

of protection, it seems necessary to strengthen the involvement and preparedness of the local actors during significant wildfire events.

Properly designed adaptation plans aiming to increase the resilience of the local communities to wildfire risk can benefit from the results and the analysis envisaged in this paper.

Abstract

Controlled grazing is a useful tool to manage and control fuel in the bush and reduce the risk of forest fires. In Castilla-La Mancha, an eminently agrarian region with a vast forest area, forest management of fuels has traditionally been carried out by crushing or burning waste in piles. Recently, this work is beginning to be carried out through prescribed burning. In recent years, experimental efforts have also been made to reintroduce controlled grazing to eliminate forest fuels through continuous browsing of forest vegetation in fire defense areas, previously carried out through preventive forestry work, avoiding or delaying the maintenance of these areas, assuming significant economic savings. Effectively reducing fuel, using local cattle ranches as a resource for fixing the population in the territory and recovering some autochthonous breeds of cattle contributes to the rural development of these regions of emptied Spain and helps to mitigate climate change. The present work analyzes the results of using cattle for the maintenance of the defense areas of Castilla-La Mancha with the results in the province of Cuenca, in approximately 1,100 annual hectares of management through managed grazing.

1. Introduction & antecedents

Extensive livestock farming can be considered a strategic sector, since as it is less dependent on external factors (fuel prices, fluctuation in feed prices, etc.) it can become essential as a method of exploitation dependent on its own resources.

The objective is to increase the periods in which a defense infrastructure against forest fires requires maintenance by means of mechanical tools. With this, the cost of maintaining the infrastructure is achieved in order to continue fulfilling the purpose for which it was designed. In this way, the creation and maintenance of a silvopastoral system was achieved, combining fire defense actions and the sustainable use of livestock, thus achieving the elimination and control of forest fuels and the maintenance of the defense areas of Castilla - La Mancha.

2. Objectives, methods

The feasibility of applying managed grazing in an area must be evaluated taking into account the area, the type of vegetation cover, accessibility, the presence of nearby cattle herds, as well as available infrastructure (sheepfolds, corrals, etc.) and possibility of having water. The economic justification is obtained by comparing the costs of treatment or maintenance through mechanical or manual clearing (which is the most common treatment) of a typical defense area in which, due to the plant formation and the quality of the site, it would have to be repeat the treatment in cycles of 5 years, with the maintenance costs of that same area through intensive controlled grazing.

The province of Cuenca has a long tradition of transhumance livestock related to ranches in the west of the community, Valle de Alcudia (Ciudad Real) and the north of Sierra Morena in the province of Córdoba and Sierra de Cazorla in Jaén. Extensive grazing has been carried out in a traditional way since ancient times (Figure 1) and participation in this program tries to give value and recognition to this activity.

Figure 1- Example of the effects of previous continuous grazing and observed in 2016 before the start of the program on mount 1097 in the municipality of Vega del Codorno (Cuenca).

The GENERAL OBJECTIVE is to maintain the defense infrastructures against forest fires or defense areas (AACC or AAEE) that make up the RAD in optimal conditions for the use for which they were made, reducing maintenance costs. To achieve this objective, it has been essential to have the coordinated work between shepherds and shepherds with their respective farms, the environmental agents Corps and forest engineers of the Ministry of Sustainable Development of the *Junta de Comunidades de Castilla - La Mancha* and *GEACAM*.

3. Results, conclusion

The line of work with controlled grazing was received differently depending on the provinces of Castilla-La Mancha, but in all of them actions were carried out on more or less surface. The provinces that best received this incentive were Cuenca and Guadalajara, executing 80% of the total area of the community in them. In this section we will focus on the results obtained in the province of Cuenca.

The year 2018 was the beginning of the journey with 7 contracts and 115 hectares grazed in the municipalities of Cuenca and Vega del Codorno. In 2019, the number of assigned hectares was increased and 873.57 hectares could be worked on, including the initial area of 2018 to add others in various municipal terms. In 2020, the last year of the program, the expansion was even greater and the 2018 and 2019 areas were joined by some more of them until reaching 1011.95 hectares.

The herds were homogeneous, for the most part, finding sheep, goats and cattle as the main species. Some farms were mixed, especially in the case of sheep with some goats. The breeds of each herd were varied.

The result of browsing was similar between flocks of sheep or mixed flocks of sheep and goats in equal plant formations. Better yields were obtained with herds of pure goats, mainly due to the increase in browsing on the shrubby species and the regrowth of Quercus. Cattle farms also showed good results in terms of vegetation control, since these animals uproot grasses and legumes, which means longer regeneration times, in addition to the effect of trampling in those areas where the presence of weeds is intensified cattle, also delaying the growth of vegetation.

One of the strengths of the program has been the involvement and perseverance of the work team, especially the shepherds, which has made it possible to obtain an optimal result on maintaining the infrastructures that have been worked on.

At the same time, the links between shepherds and the regional government were strengthened and it was shown that by carrying out this work it was possible to be more efficient in preventing forest fires.

The economic interest has made it possible to involve and motivate existing shepherds in the area who have actively participated by contributing with their experience and knowledge.

Abstract

Wildfires cause several damages to flora, fauna, soil, atmospheric air and human health. The places where there is a concentration of forest fuels in contact or very close to the homes represent a great risk, because the human presence can contribute to the start of fires and can also be drastically affected in the event of a fire. These environments are called wildland-urban interface, represented by places where human beings and anthropic structures meet or mix with vegetation. There are different methodologies for the classification of the wildland-urban interface, aiming to serve as a subsidy for preventive and vegetation fire-fighting policies. In Brazil, discussions about the theme are incipient. Campina Grande do Sul and Quatro Barras are two Brazilian municipalities with an extensive vegetative area with social interaction (areas of wildland-urban interface) and, in addition, suffer from the presence of wildfires. From 2011 to 2020, a total of 797 occurrences were registered in this area. The objective of the present study was to delimit the wildland-urban interface for Campina Grande do Sul and Quatro Barras municipalities, located in the state of Paraná, Brazil, relating to the occurrence of wildfires. To achieve the proposed objective, it was necessary to use a methodology for classifying wildland-urban interface areas, already established globally, based on the density of households and forest cover, dividing into intermix and interface zones. Two methodologies from the Brazilian Institute of Geography and Statistics were used to obtain the density of households (statistical grid and census sectors). The statistical grid presents fixed cells of 0.04 km² for urban areas and 1 km² for rural areas, while the census sectors have variable areas. The results showed that when using the statistical grid, Campina Grande do Sul and Quatro Barras had coverage of 12.5 and 15.2% of the municipal areas classified as wildland-urban interface, respectively. In the use of census sectors, Campina Grande do Sul presented 25.7% and Quatro Barras 13.6% of the areas as a wildland-urban interface. This discrepancy observed when using the census sector may be related to an overestimation of household densities due to the variable size of the census sectors. When distributing the 314 geolocation of fires that occurred in the municipalities from 2011 to 2016, it was observed that when using the statistical grid, 15.3% of these were present in areas of wildland-urban interface and using the census sectors, 17.2 % of occurrences located in these areas. Based on the results obtained, it can be concluded that the delimitation of the wildland-urban interface using the method of household information contained in the statistical grid presented greater detail than use of the census sectors. However, it is necessary to evaluate the methodology used to quantify coverage forestry. The presence of fires in areas with a wildland-urban interface demonstrates the need for preventive policies to be applied to the habitants of these places. Finally, it is recommended to continue studies, as well as to create or adapt methodologies for classifying the wildland-urban interface based on local characteristics.

1. Introduction

Forest fires are directly and indirectly responsible for numerous environmental, economic and social damages. Its occurrences are increasingly affecting the daily lives of communities present in areas adjacent to vegetation cover, especially in areas classified as wildland-urban interface.

Wildland-urban interface (WUI) zones can be generically conceptualized as areas where urban and vegetational aspects merge. This promotes human influence both in the generation of combustible residue and in the burning of different materials. Also, when preventive measures are not adopted, the presence of buildings close to vegetated areas may present susceptibility to damage in the event of a fire in vegetation.

Until part of the 20th century, the distinction between forest, farm and city was generally well defined (CHANDLER, 1983), but the advance of urban areas and the population increase from urban centers towards peripheral areas has mixed these different zonings, creating zones of wildland-urban interface (VÉLEZ, 2009). The different classification methodologies of wildland-urban interface, differ in classification methods, but converge in presenting buildings, population and vegetation as the main variables used.

In Brazil, there is no explicit definition of the wildland-urban interface areas for purposes related to the fuels involved in the wildfire occurrences. According to Prudente (2014) and Sakakibara (2019) the distinctions between urban and rural areas are not clear. According to Caballero (2019), this situation can bring about possible harm in the elaboration of preventive policies and actions to minimize the occurrence of fires

The cities of Campina Grande do Sul and Quatro Barras are located in the metropolitan region of Curitiba, capital of Paraná, Brazil, and have an extensive vegetative area with social interaction (presence of buildings). In addition, these municipalities suffer from the occurrence of wildfires, with a total of 797 records from 2011 to 2020.

The application of methodologies consolidated in other countries for wildland-urban interface characterization can be a first step towards future adaptations and elaboration of specific classification methodologies for the reality of Paraná, contributing to science and society. Thus, the present study aims to delimit the wildland-urban interface of the municipalities of Campina Grande do Sul and Quatro Barras, relating it to the occurrence of wildfires.

2. Material and methods

2.1. Study area

The study area is the municipalities of Campina Grande do Sul and Quatro Barras, located in the state of Paraná, belonging to the south region of Brazil (Figure 1). The Campina Grande do Sul city hall presents the coordinates UTM fuse 22S N 7.199.737 and E 695.805 e and the Quatro Barras city hall presents the coordinates UTM fuse 22S N 7.193.123 e E 693.494 (*INSTITUTO BRASILEIRO DE GEOGRAFIA E ESTATÍSTICA* - IBGE, 2011).

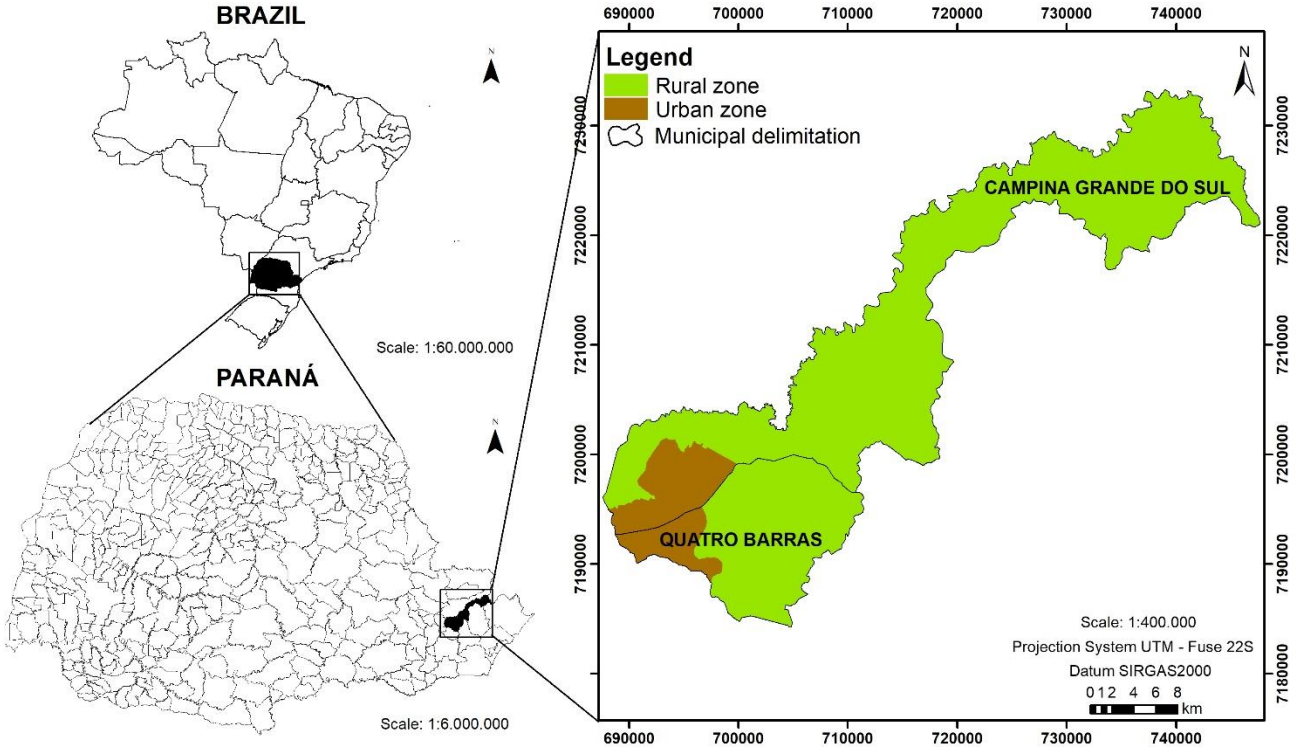

Figure 1- Localization map

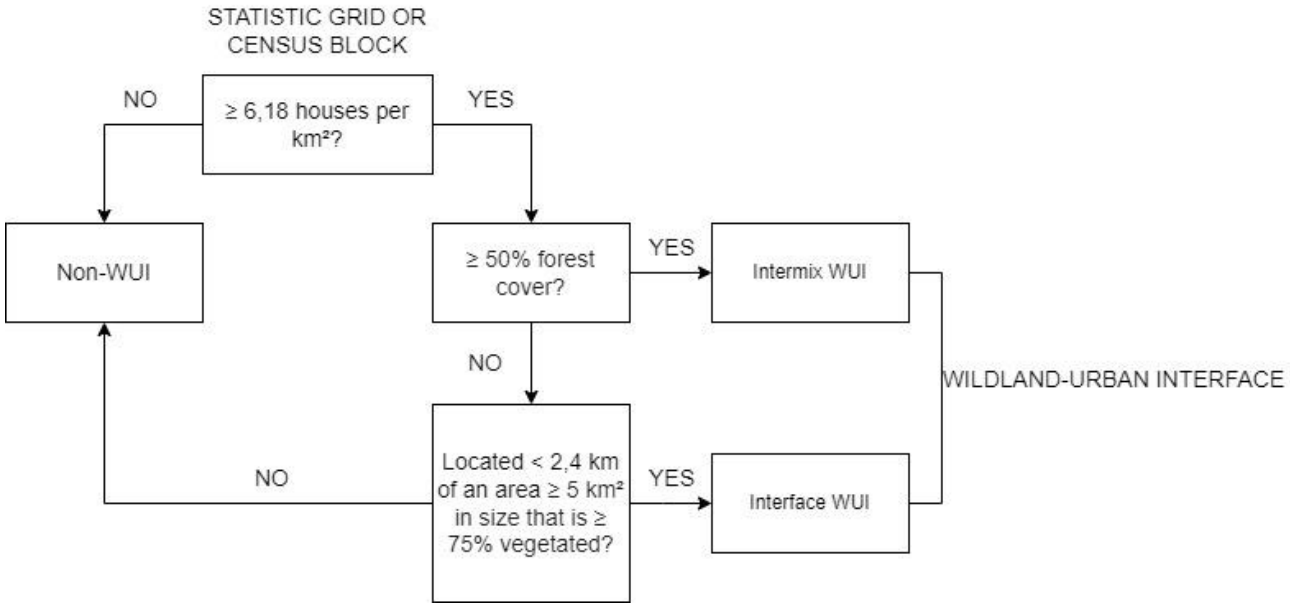
The municipality of Campina Grande do Sul has an area of 539.25 km² and Quatro Barras 180.47 km² (IBGE, 2019). According to the 2010 demographic census (IBGE, 2011), they have a population of 38,769 and 19,851,

respectively. Campina Grande do Sul has 9.6% of its area considered as urban and Quatro Barras 15.6% (IBGE, 2011).

According to data obtained by Alvares *et al.* (2013), the study area is located in a climate type Cfb and Cfa region according to the Köppen classification. The study area is inserted in the Atlantic Forest biome, presenting the phytogeographic domains: araucaria moist forests, dense rainforest and natural grasslands (*INSTITUTO DE TERRAS, CARTOGRAFIA E GEOGRAFIA DO PARANÁ* - ITCG, 2009).

2.2. Data collection and analysis

An adaptation of the methodology proposed by Radeloff *et al.* (2005) was carried out. These authors are supported on USDA and USDI (2001) definitions, which show the division into intermix WUI and interface WUI. Figure 2 presents the decision flowchart for classifying the wildland-urban interface.



SOURCE: MARTINUZZI *et al.* (2015), adapted by the authors.

Figure 2 – Decision flowchart for wildland-urban interface classification

The results of the 2010 IBGE demographic census (IBGE, 2011) were used to obtain data on the number of households per square kilometer. The data are arranged by statistical grid and by census sectors, with limits defined by the institute. The IBGE divides the statistical grid into cells of 1 km² (1 x 1 km) for areas considered rural and 0.04 km² (200 x 200 m) for areas considered urban. Census sectors are defined using IBGE's own methodology and have variable areas. Thus, it was necessary to calculate their area and then proceed with the division of the total number of households per square kilometer.

Land cover and use was obtained through the 2019 year 5.0 collection of the *Projeto de Mapeamento Anual de Cobertura e Uso de Solo do Brasil* (MAPBIOMAS, 2020). In order to obtain exclusive forest cover, the polygons classified as "forest formation" and "planted forest" were extracted.

"Planted forests" were considered in the present study, because in addition to the lack of information on their silvicultural management (providing greater or lesser probability of fires), planted forests are relevant in the quantification of forest fuels, which may affect households close to cultivation.

By superimposing the statistical grid and the census sectors with the forest formations and planted forests, it was possible to obtain the percentage of forest cover for each polygon, classifying them with coverage equal to or greater than 50% or with coverage less than 50%.

Also, based on forest cover, polygons with areas greater than 5 km² and with at least 75% of forest cover were grouped. A 2.4 km buffer was subsequently applied to verify the centroids of the statistical grid and census sectors present in the area of operation of these polygons, enabling interface zone classification when applicable.

The geolocation of wildfire data was obtained through the database obtained by Ferreira (2021) when analysing the occurrences of wildfires in the metropolitan region of Curitiba, from 2011 to 2016.

Subsequently, was verified the number of fires that occurred in the wildland-urban interface classification zones obtained by the two census methods.

Data were manipulated using ArcGis (version 10.5), QGIS (version 3.10) and Excel (version 2016).

3. Results and discussion

3.1. Wildland-urban interface delimitation

Figures 3a and 3b present the results obtained through the application of the methodology for classifying wildland-urban interface areas, based on the IBGE's statistical grid and census sectors.

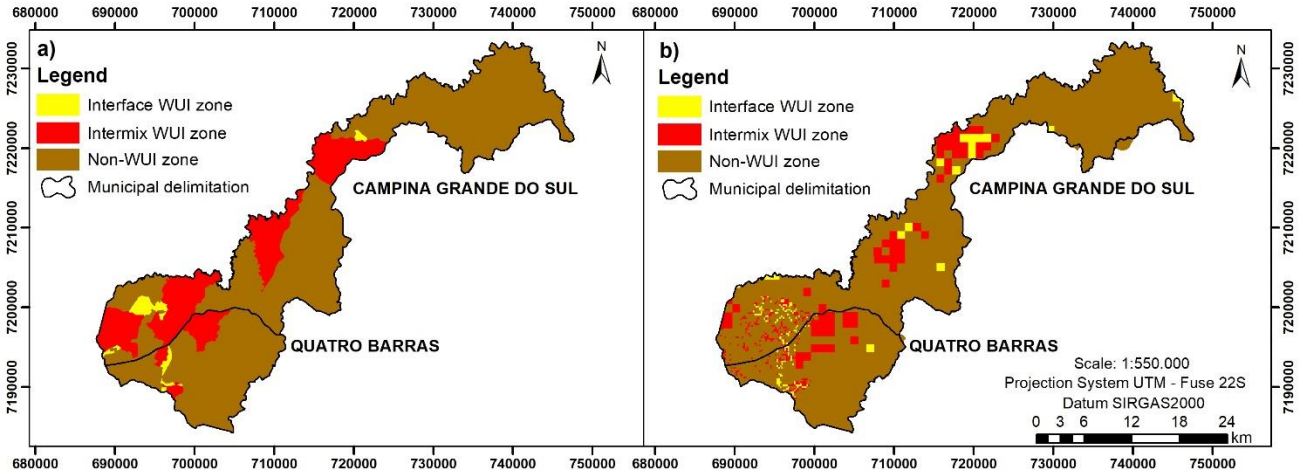


Figure 3 – Classification of wildland-urban interface areas according to: a) census sectors e b) statistical grid

It is observed that the fragmentation performed by the statistical grid (Figure 3b) presents greater detail than the use of census sectors (Figure 3a), mainly in areas classified as urban areas by the IBGE, located to the west of both municipalities.

The statistical grid presented in urban areas classified separately as intermix zones without the presence of interface zones, which may have as a possible reason the influence of "urban forest" in the study area. According to Biondi (2015), urban forest represents all vegetation cover located in the urban perimeter. Thus, vegetation cover equal to or greater than 50% of the cell area, regardless of the size of the forest fragment, combined with household density, allows the classification of the cell as intermix, even if it is present in zoning classified by the IBGE as urban.

When using the census sectors, a less refined classification was generally found, extrapolating mainly the intermix zones to areas not considered as such by the statistical grid.

In the city of Campina Grande do Sul, the intermix zone presented a total area of 129.17 km² through the census sector methodology, and when comparing with the statistical grid methodology (49.41 km²), an overestimation of 160.9% is observed. n the city of Quatro Barras, the census sector showed 21.51 km² and the statistical grid 23.27 km² for that zone.

Regarding the interface zones, the statistical grid presented higher values for both municipalities, especially Campina Grande do Sul, which obtained a total area of 17.87 km², representing 83.3% more coverage when compared to the method of census sector (9.55 km²). This value may be related to the greater distribution of cells in the statistical grid, providing greater territorial coverage and, consequently, greater possibility of fitting the parameters necessary for its classification as an interface zone.

Analysing all the wildland-urban interface, it is observed that in the city of Quatro Barras the total area occupied was very similar between both methods used, with values of 27.5 km² for the statistical grid and 24.62 km² for the census sector. In Campina Grande do Sul, the census sector, with an area of 138.73 km², was 106.2% higher than the area obtained by the statistical grid, which presented an area of 67.28 km².

The reason that may be associated with this discrepancy in value observed in Campina Grande do Sul is the high density of households in small areas of the census sectors. The census sectors may present a high concentration of households in part of the polygon and be considered as a wildland-urban interface, even if only a small portion of the polygon has households.

The observed refinement of the statistical grid allows for a better classification and segmentation than the census sectors, which, in turn, can classify the zones in a rough way, presenting the possibility of the occurrence of overestimates in certain areas and failures in non-classification of others. However, as the presence of intermix zones in urbanized areas is observed, it is necessary to evaluate the methodology used when considering the percentage of forest cover present in cells of 0.04 km², located in areas considered urban by the IBGE.

3.2. Wildfire distribution in the wildland-urban interface

Based on the results obtained by Ferreira (2021), in the period from 2011 to 2016 there were 460 wildfires in both municipalities (282 in Campina Grande do Sul and 178 in Quatro Barras), but only 314 occurrences were geolocated (68.3%).

It is observed that using the statistical grid, 15.3% (48 occurrences) were present in wildland-urban interface areas and using the census sectors, 17.2% (54 occurrences) were located in these areas.

When using the statistical grid, 19 occurrences (6.1%) were present in the intermix zone and 29 occurrences (9.2%) in the interface zone. When using the census sector methodology, 25 occurrences (8.0%) were present in the intermix zone and 29 occurrences (9.2%) in the interface zone.

As the geolocation of occurrences is dependent on addresses with registered streets, 146 occurrences (31.7%) that were unable to obtain geolocation may be related to these areas.

With the increase in population, the tendency is to have an expansion of households from urban areas towards rural areas. This can increase the tension between human occupations and vegetation, consequently increasing fire records.

The results obtained demonstrate that in the study area there is part of the wildfires at the wildland-urban interface, regardless of the methodology used to obtain the density of households. This demonstrates the need to develop prevention and combat policies focused on these areas. The peculiar characteristics of these places and the increase in anthropic pressure can cause future damage to life.

4. Conclusion

Based on the results obtained, we concluded that:

• The delimitation of the wildland-urban interface using the method of household information contained in the statistical grid presented greater detail than the use of census sectors. However, it is necessary to assess whether the cells present in the zoning outlined as urban by the IBGE should be considered, since there was an influence of the urban forest on the forest coverage percentage of the cells.

• The geolocation of the wildfire occurrences recorded in the years 2011 to 2016 showed a low presence in areas classified as wildland-urban interface. As 31.7% of the occurrences were not geolocated, there is a possibility that the presence in these areas has been larger. Regardless of the quantification, occurrences were observed in these places, thus demonstrating the need for prevention and combat policies focused on the inherent characteristics of the wildland-urban interface.

• It is recommended the continuity of studies related to the wildland-urban interface, as well as the creation or adaptation of methodologies for classification based on local characteristics.

Wildfire, Wildland urban interface, Settlement fire, Risk perception

Abstract

Few studies have the opportunity to empirically investigate changing risk perception before and after a fire event. Here, we study the impact a fire within a settlement fire has on the risk perception of residents in a high wildfire risk informal settlement in South Africa. We measured risk perception concerning wildfires and settlement fires. Findings from our questionnaire indicate a fire event raises the perception of wildfire and settlement fire risk. Residents respond differently whether they are directly impacted by the fire or not, with unaffected residents more concerned about personal risk than community risk. While other studies found that a fire event raises the likelihood of residents enacting risk reduction efforts, our results dispute this, with residents indicating they are less likely to commit to personal risk reduction efforts. Finally, a fire event appears to lower the likelihood of residents leaving a settlement due to the perception of wildfire or settlement fire risk.

1. Introduction

Wildfire risk management at the wildland-urban interface (WUI) relies on institutions, politicians and residents who are often at opposing ends with policies and other risk reduction efforts cooperating (Christ et al. 2022). Risk perception is key for understanding how humans respond to interventions to reduce risk and, therefore, successful implementation (Arvai et al., 2006; McGee et al., 2009). Furthermore, experiencing disaster events changes perceptions of the specific disaster and other disasters (ibid). Thus, understanding how fire events change risk perception can improve making tailor-made interventions.

Recently, Dupey & Smith (2019) found that a wildfire can trigger residents to participate in risk mitigation behaviours. Flores Quiroz et al. (2021) disputed this claim after they investigated fire risk perception in Imizamo Yethu (IY) but focused on what the elements residents believe cause fire in IY, not how they perceive the hazard of fire itself. Few studies have empirical data collected on residents' fire perception before and directly after a fire event. Here, we define wildfires as fires that start in the wildland and potentially move into the settlement, whereas settlement fires are those that start in the settlement and may move into wildland.

We investigated IY, an informal settlement, to evaluate what impact a recent settlement fire had on residents' perceptions of wildfires and settlement fires in relation to:

- Perceived fire risk
- Vulnerability to fire and the consequences of fire
- Perceived coping capacity
- Implementation of risk reduction efforts
- Residents' intentions to remain in the area

2. Study Area

IY (0.57 km^2) is an informal settlement in the City of Cape Town, bordering the Table Mountain National Park (TMNP), South Africa (Figure 1) (Kahanji et al., 2019). TMNP forms part of the fire-prone and fire-dependent fynbos biome. Over the years, IY has experienced multiple fires, including threats from wildfires in 2009, 2015 and 2022 (African News Agency, 2015; Engel, 2022; Eyewitness News, 2009). Access to IY is difficult due to

the steep incline and the narrow and informal structure of the roads (Gibson et al., 2019). Settlement fires in IY are likely to run up the mountain if wind conditions are favourable (Gibson et al., 2019; Kahanji et al., 2019).

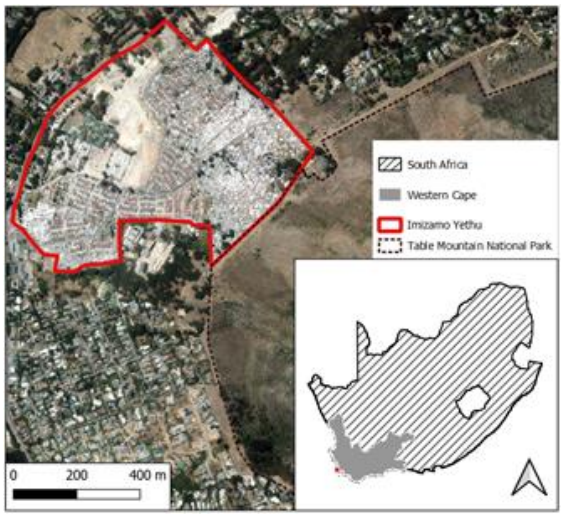

Figure 1- Imizamo Yethu in South Africa

The two most recent fires were on 6 September 2020, 9 months before our first survey and 15 August 2021, 1 month before our second survey (Ntseku, 2021; Stent, 2020).

3. Methods

We developed a questionnaire based on the works of authors who focussed on fire risk perception, housing decision making and fire management (Brenkert-Smith et al., 2012; CapeNature, n.d.; Dupey & Smith, 2019; Ghasemi et al., 2020; Martin et al., 2007; Pharoah, 2012; Statistics South Africa, 2020; Turner, 1968). A fieldwork team surveyed residents using Epicollect (https://five.epicollect.net/). First with a battery of 106 questions, using non-probability sampling to capture specific areas for another study. Data collection occurred between 21 June and 08 August 2021 (244 respondents.

To measure changes in perception, we modified the second questionnaire (127 questions) to include factors such as whether a respondent was directly affected by the fire on August 15 or not. Data was collected between 21 September and 3 October 2021. With limited funding, we captured 109 responses (56 directly impacted, 53 not directly impacted).

For this report, we focussed on a selection of 18 questions that address the research objectives. We measured perceptions on a Likert scale 1-7, with 1 representing completely disagree and 7 completely agree. To evaluate if the differences between the groups of residents were statistically significant we used the non-parametric Mann-Whitney U test in SPSS (28.0.1.0) (McKnight & Najab, 2010).

4. Results and discussion

4.1. Basic description

Respondents had a mean age of over 34, and over 11 years in IY (Table 1). Most were employed and about half were owners, indicating potential means for implementing risk reduction efforts if deemed important and effective enough.

Table 1- Basic statistics of groups

	Before fire %	After fire – direct impact %	After fire – no direct impact %
Mean Age	34	44	38
Mean Time in IY	11	15	14
Housing status			
Living rent-free	18	2	25
Owner	55	50	66
Tenant	27	48	9
Employment status			
Full time employed	19	80	68
Part-time employed	37	11	17
Self-employed	17	2	6
Unemployed	26	7	9

*Percentages may not total 100 due to rounding

4.2. Fire risk perception

All residents felt their property was more at risk after the fire, with those that experienced direct impact more aware of the risk of settlement fire (Figure 2). Those experiencing a direct impact considered the community at a higher level of risk of wildfire and settlement fire than before. Those without a direct impact, however, perceived both risks lower than before the fire. These findings agree with what McGee et al. (2009) found comparing residents who lost their homes in a wildfire and those that were at home during the fire but had no losses.

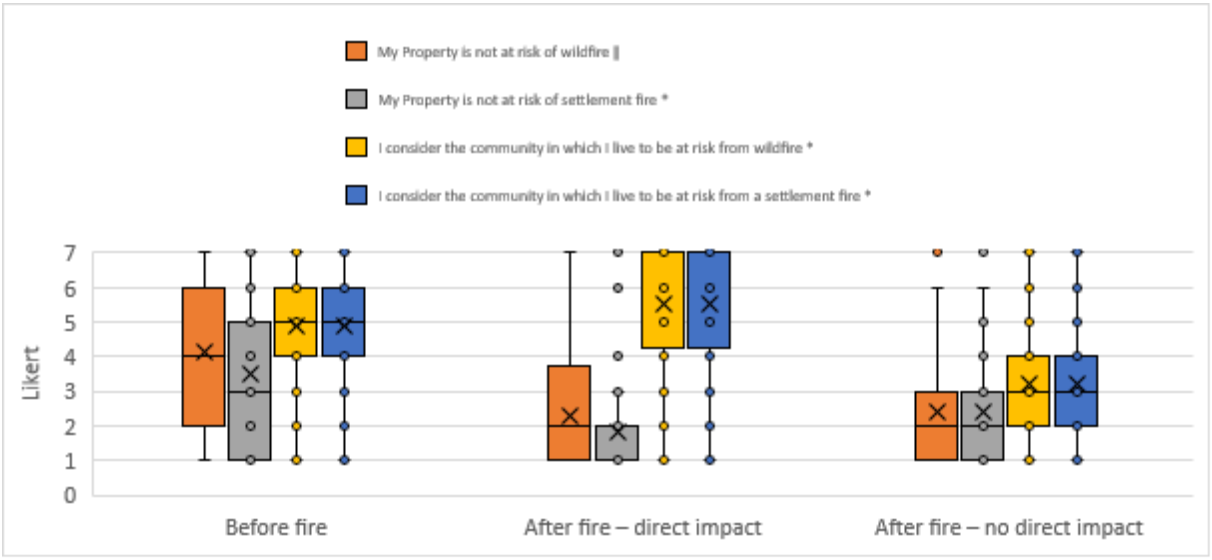

Figure 2- Property and community risk (X represents the mean, * $p \leq 0.05$ between all groups, ‖ $p \leq 0.05$ between before fire and direct impact as well as between before fire and no direct impact only)

Although all residents perceived a raised property risk perception of both wildfire and settlement fire, those that experienced the fire have a more acute sense of settlement fire than of wildfire. Those that did not experience the fire considered both risks equal.

4.3. Vulnerability and consequences

Respondents have always felt vulnerable to fires, with a slightly higher vulnerability to settlement fires (Figure 3). After the fire, those who were directly affected had an increased sense of vulnerability to both fires. They, however, felt the severity will be lower for where they live, indicating they feel it had a direct impact on them, but not so great an impact on their neighbours who may not have been affected. Interestingly, those who were not directly affected by the fire felt less vulnerable than before the fire as well as the impact less severe. It could be that residents now have a tangible idea of what a fire event looks like and believe that they are not as

vulnerable and could recover post-fire as Wachinger et al. (2013) indicated can be the case with people who only witness a disaster but do not experience losses.

Figure 3- Vulnerability (X represents the mean, * p ≤ 0.05 between all groups)

4.4. Perceived coping capacity

Before the fire, most residents believed that they could defend their properties. This, however, reduced post-fire, with respondents believing they are not able to defend their homes against either type of fire (Figure 4).

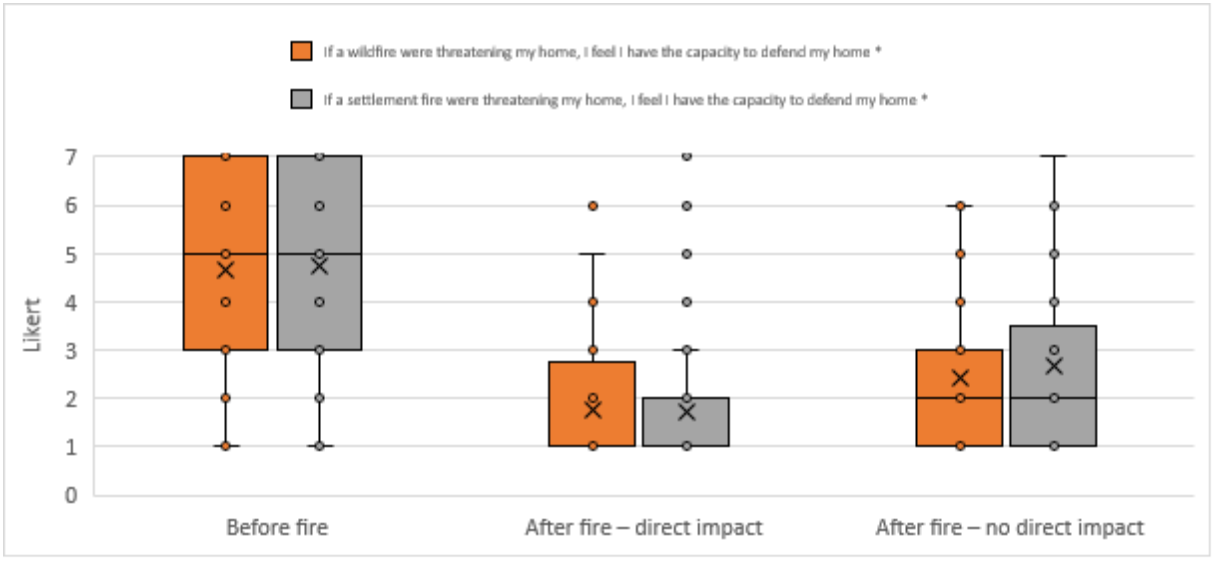

Figure 4- Coping capacity (X represents the mean, * p ≤ 0.05 between all groups)

4.5. Implementation of risk reduction

Respondents that experienced the fire were less likely to implement risk mitigation efforts (Figure 5). This contrasts with Dupey & Smith, (2019), who found residents more likely to participate in mitigation efforts after a near-miss fire event. However, our finding is in agreement with McGee et al. (2009) who found that those who lost their homes felt it was not possible to mitigate against wildfires. Those with no direct fire impact were still more likely to implement mitigation efforts than those who experienced the fire. This may be as they still believe it to be effective and thus more likely to partake in it (Bubeck et al., 2012). Most respondents were still

willing to implement the low-cost action of keeping their plots free from garbage and vegetation, but the likelihood was reduced and more spread between individuals.

Figure 5- (X represents the mean, * p ≤ 0.05 between all groups, ‖ p ≤ 0.05 between before fire and direct impact as well as between before fire and no direct impact only)

The reduction of the intention to keep roads clear of cars can be interpreted as keeping a vehicle close by as a means of escape in case of a fire, but also as a way to protect the asset in high-crime areas such as South Africa (Cheteni et al., 2018). This is illustrated in South Africa through residents fortifying homes for safety from crime but making it difficult to escape in emergencies (Zweig et al., 2018).

South African informal settlers perceive open fire cooking and settlement density as the greatest hazard for fire ignitions and irresponsible drinking in IY (Flores Quiroz et al., 2021; Zweig et al., 2018). However, implementing electrical cooking and settlement density reduction requires a multi-stakeholder approach.

These findings confirm “windows of opportunity” for different mitigation actions that have been theorised by Wachinger et al. (2013) to close even faster for those who did not directly experience the disaster.

4.6. Intention to stay in IY

Residents who experienced the fire directly were more likely to stay in IY even with the fire hazards (Figure 6). The self-selection bias that they are the ones who returned and, thus, are less likely to leave has to be acknowledged. Unaffected residents were more likely to leave due to the fire hazards than residents before the fire. Those that experienced the fire, however, were as likely as before to move to a safer location within IY due to wildfire, but less likely for settlement fires. Indicating that residents are aware of the spatial element of wildfire, and the random nature of settlement fires. Leaving IY due to settlement fire and wildfire, however, agreed with those that experienced fire and those that did not with their intention to leave.

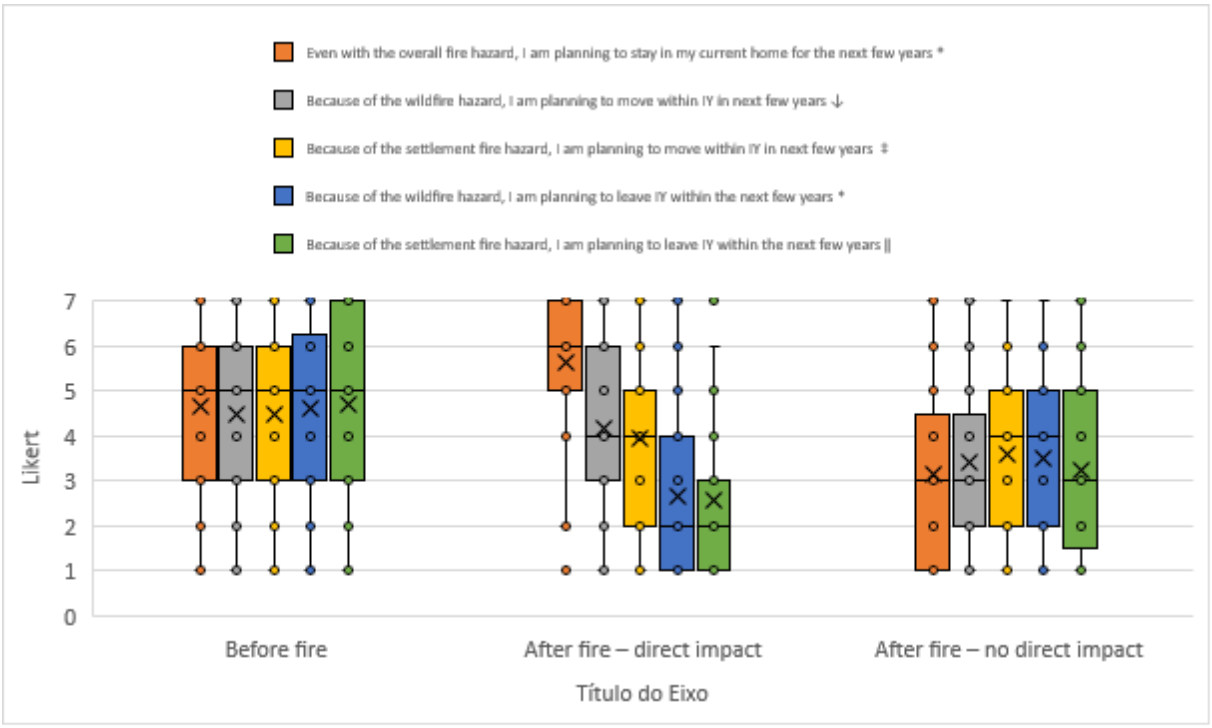

Figure 6- Intention to remain in IY (X represents the mean, * $p \leq 0.05$ between all groups, ‡ $p \leq 0.05$ only between direct impact and no direct impact, ‖ $p \leq 0.05$ between before fire and direct impact as well as between before fire and no direct impact only, ↓ $p \leq 0.05$ between before fire and no direct impact as well as between direct impact and no direct impact only)

5. Conclusions

We highlighted that any fire event affects the perceptions of residents. The level of impact on community risk perception depends on whether a resident was directly impacted. All residents, however, perceived increased fire risk after a fire occurred in the settlement. Those directly affected feel more vulnerable to fires whereas factors such as seeing the recovery may reduce the feelings of vulnerability of other residents. In IY, fires appear to make residents less likely to implement mitigation measures.

Those that experienced the fire and returned are not likely to leave, yet are also less likely to implement risk mitigation efforts and feel the most vulnerable to fire events. Importantly, these perceptions peak briefly after a fire event but are likely to regress towards the pre-fire level as early as nine months after the fire. Interventions relying on residents' perception of self-efficacy are best addressed when residents' perception of their coping capacity improves. Whereas interventions relying on external education and group action could best be implemented while residents feel they are powerless to help themselves individually.
